Porges described a syndrome in 1922 for which he subsequently (1932) gave the term 'coma hypochloræmicum' in which he found diminution of the chloride content of the blood with rise in the nitrogen of the blood. Since the publication of Porges, the condition has drawn the attention of workers all over the world and has come to be recognized universally. The French school under Blum and von Rathery studied this condition clinically and applied the term *azotémie per manque de sel*. These workers have been corroborated by others of the French school.

The American workers, Brown *et al.* (1923), studying the problem from a clinical point of view, and Haden and Orr (1923a), Whipple, Cook, and Stearns (1917), studying it experimentally, have confirmed the findings of Porges (*loc. cit.*).

A study of these papers shows that the hypochloræmic condition may appear in the following five groups of instances:—

1. Hypochloræmia appearing in conditions following persistent removal of the gastric contents by vomiting or loss of chloride by severe diarrhoea.
2. Hypochloræmia by transport and retention of chloride in the tissues.
3. Hypochloræmia due to deficient intake of NaCl.
4. Hypochloræmia due to removal of a big quantity of fluid with high NaCl content, e.g., ascites, burns, etc.
5. Hypochloræmia in suprarenal insufficiency.

Of these five groups of conditions causing hypochloræmia the first group falls under the subject of our present study. Our present study

(Continued from previous column)

determined. From the results of preliminary experiments it is suggested that desiccated vaccines sealed *in vacuo* retain their antigenic properties longer and that this method of preparation is readily applicable and offers many advantages over the usual method of preparation and distribution of cholera vaccines.

REFERENCE

PASRICHA, C. L., CHAT- Indian Med. Gaz., 73, 463.
TERJEE, D. N., and PAUL, B. M. (1938).

goes a step further, as in cholera we find a combination of both the conditions comprising the first group, i.e., a combination of persistent removal of NaCl of the gastric content by vomiting and loss of NaCl by severe diarrhoea.

In cases of excessive vomiting the removal of a large quantity of chlorides which are normally secreted into the stomach leads to a diminution in the level of the plasma chloride. This condition has been repeatedly observed in cases of vomiting due to gastric irritation, pylorospasm, pyloric obstruction, toxic states, e.g., uræmia, toxæmia of pregnancy, etc. This is also true in cholera.

That it is not due to retention of chlorides is shown by the fact that the degree of hypochloræmia is dependent upon the quantity of chloride secreted into the stomach. This is exemplified in cases of carcinoma of the stomach or in achylia of pernicious anaemia, where excessive vomiting is associated with little or no hypochloræmia, as there is a condition of true achlorhydria existing in these conditions. It appears thus that the hypochloræmia in cholera is due to elimination of the chloride through vomiting and purging and not due to retention of chloride in the tissues. Our own observation shows a great loss of chlorides through vomiting in cholera.

TABLE I

Showing the amount of vomitus during 24 hours and the sodium chloride content per 100 c.cm. of the vomitus

Case number	Total volume of vomitus in c.cm.	NaCl content mg. per 100 c.cm. of the substance
1	3,500	221
2	2,500	262
3	4,800	455
4	2,500	233

This shows an average of 3,325 c.cm. of vomitus containing 293 mg. of NaCl per 100 c.cm. of the substance. Thus the total excretion of NaCl through vomiting during 24 hours had been more than 9.7 grammes in an average case of cholera. Thus, it is seen that a great loss of chloride from the stomach takes place through vomiting.

Normally, most of the chloride secreted into the gastro-intestinal tract is re-absorbed from the intestines into the circulation. Our material shows that in every case of cholera with large quantity of fluid evacuations a considerable amount of chloride is lost through this channel.

From this we find, in cases of ordinary severity, the maximum figure of 865 mg. per 100 c.cm. of stools. The total quantity of stools was 4,000 c.cm., that means, there had been a loss of 34.6 grammes of chloride during 24 hours by the bowel.

A study of the literature shows that in 1849 Parkes (Rogers, 1911) found in cholera stools $\frac{1}{2}$ to 1 per cent of salts and in 1850 Schmidt (Peters and Van Slyke, 1931) pointed out the extreme dehydration and loss of chloride in cholera. Rogers (1911, 1921) found an average of 0.53 per cent of chlorides, i.e., loss of half an ounce of chloride in every 100 oz. of stools. He is of the opinion that in most severe cases over two-thirds of the salts of the blood may have been lost from the circulation and presumably almost as great a proportion from the whole system.

Rôle of hypochloræmia in the production of azotæmia

Banerjee (1931) has pointed out that there is great retention of nitrogenous waste products in the blood in almost every case of cholera. This azotæmia often becomes extreme but it shows lowering as soon as the urine flow is re-established. Banerjee and Datta (1935) have further called attention to the fact that a high non-protein nitrogen, or urea retention, does not necessarily mean a bad prognosis. This shows that the azotæmia in cholera is of extrarenal origin. It shows further that there exists a close relation between hæmoconcentration and hypochloræmia, and nitrogenous retention. There has been a great deal of controversy regarding which factor, hæmoconcentration or the hypochloræmia, is of more importance in the production of azotæmia. Banerjee (1939) has shown that hypochloræmia is of more importance as introduction of a fairly big quantity of fluid in the form of glucose produces little change in azotæmia, while a small quantity of hypertonic NaCl solution improves both hypochloræmia and azotæmia.

Factors for the production of hypochloræmia

It is the general opinion that the fall of blood chlorides in cases of vomiting is mainly due to loss of chlorides from the stomach. This has been observed repeatedly by animal experiments. In animals, e.g., rabbits, which are unable to vomit, Gamble and McIver (1925) found in the stomach sufficient salt, hydrochloric acid and water to account for the loss of blood chloride. These animals generally recover if the obstruction is relieved within 15 hours, but not so if the stomach contents are previously removed and replaced by water, before relieving the obstruction. Further, other workers, notably Foster and Hausler (1925), Foster (1928), and Gatch, Trusler and Ayers (1927) have shown that death never takes place of toxæmia or hypochloræmia, but of inanition if sufficient NaCl is administered parenterally. That toxæmia can be a factor in the fall of blood chloride is shown by the experiments on monkeys by Haden and Orr (1925) when they observed that there had been no vomiting in the animals with experimental intestinal obstruction, which

The loss of considerable quantities of NaCl through vomiting and purging leads to a condition of hypochloræmia and as a result the elimination of chloride in the urine is also greatly diminished. Table II shows the amount of chloride in the blood observed from day to day. It must be noted in this connection that these cases received a fair quantity of fluids containing on an average about 25 grammes of NaCl in the form of intravenous and subcutaneous injections daily during the first 2 or 3 days. It is seen that in spite of this considerable quantity of NaCl administered intravenously or subcutaneously the blood chloride never rose above 495 mg. per 100 c.c.m. of blood. In quite a large number of cases it remained at 350 mg. to 450 mg. level. The samples of blood taken before intravenous injections of saline gave a much lower figure. This shows that, in cholera, hypochloræmia is invariably present in all cases.

As a 'threshold substance', NaCl with a threshold value of 560 mg. to 570 mg. per 100 c.c.m. of blood is re-absorbed through the tubules back to the circulation in order to maintain its equilibrium in the blood. In cholera, as the plasma chloride concentration is lowered to the limit of the threshold value, a decrease in the urinary chloride occurs and this may sometimes be very low or totally lacking. The diminution in the plasma chloride concentration produces a great alteration in the distribution of electrolytes and in the acid-base balance. This constitutes one of the most significant metabolic features in conditions producing hypochloræmia, and particularly in cholera.

showed the characteristic fall of blood chloride. All animals showed the marked rise in non-protein nitrogen. Coincident with the change in chlorides there had been a rise in the CO_2 combining power. Haden and Orr (1923a) believe that a fall in chlorides is the first and seemingly most significant change to take place in the blood after pyloric and intestinal obstruction. The chloride is apparently utilized by the body as a protective measure against the primary toxic substance. This is shown by the fact that the life of the animals is prolonged when NaCl is given subcutaneously daily, while a like amount of distilled water, or 25 per cent glucose showed the changes typical of untreated animals. They have found that solutions of NaCl have a marked effect in preventing and controlling the toxæmia of pyloric and intestinal obstruction as shown in clinical symptoms and in chemical changes in the blood. Solutions of glucose have no specific value and sodium bicarbonate solution prolongs life only for a short while. They (1923b) believe that the chloride is probably bound somewhere in the process of protein destruction.

The great loss of chloride in cholera might be explained by the action of some poisoning of the vascular membrane leading to increased permeation through the capillaries or by some physiochemical change in the blood leading to the loss of NaCl directly into the tissues, or body cavities. Haden and Orr (1923) drew attention to the similarity of the blood findings in intestinal obstruction, acute lobar pneumonia, and serum disease suggesting that these widely different conditions may have a common chemical basis. It appears to us that cholera can also be included in this list.

The kidney plays a great rôle in regulating the chloride balance in the body, more particularly in cholera when the function of the kidney is greatly altered. Hypochloræmia is due to the tendency of the kidneys to excrete chloride in the urine even when the chloride concentration in the serum has fallen far below the threshold level. It appears that the function of conserving the salt supply is lost.

Hypochloræmia and acidosis

Chlorides play a great part in stabilizing the acid-base balance of the body fluids by helping the interchange of buffer effects between the richly buffered cells and the poorly buffered plasma. In cholera, the acid-base balance is greatly altered (Banerjee, 1936) and so is the quantity of the chlorides. This shows that deficiency of the chloride anions in plasma interferes with the exchange of the bicarbonate anions from cells to plasma.

A vicious cycle thus occurs in cases of cholera as a result of the intimate relations which exist between the loss of chloride and the maintenance of the acid-base balance. If the base and

chloride loss remains unrestricted, it leads to but one result and that in the form of depletion of the salt supplies of the body as a whole which is invariably followed by loss of water, dehydration, retention of nitrogenous waste products and renal failure.

From the point of view of the presence of considerable hypochloræmia in every case of cholera, an attempt has been made to increase the strength of NaCl in the fluid now used for intravenous injections. As a 10 per cent NaCl solution often causes great discomfort to the patient a 5 per cent NaCl solution is used with favourable results. As this is in an experimental stage no detail need be given now.

Summary

It is pointed out that hypochloræmia occurs in various widely different conditions, particularly in those in which vomiting and purging occurs, and more particularly in cholera.

From our own material a great loss of chlorides is found to occur in every case of cholera through vomiting and purging even after replacement of NaCl and fluids by adequate quantity of hypertonic saline.

Attention is drawn to the effect of hypochloræmia in the distribution of electrolytes and that of the acid-base balance in cholera.

The rôle of hypochloræmia in the production of azotæmia, uremia and renal failure in cholera is shown to be of great importance.

My thanks are due to Prof. C. C. Basu for his helpful interest, to the physicians in charge of the Isolation Hospital for permission to utilize the material, to the house physicians for their co-operation, and to Mr. A. K. Chakrabarty for technical assistance in the work.

ERYTHROPOIETIC FACTOR IN HUMAN MIXED SALIVA

By A. SITARAMAMURTI, M.B., B.S.
Central Institute of Physiology, Medical College,
Madras

It is an old saying that the habit of constant spitting has debilitating effects on the individual. On going through the literature on the effects of saliva, it was found that recently Tempka (1937) recorded erythropoietic effect of human saliva. He fed 20 litres of saliva to a patient with pernicious anaemia in relapse and observed a reticulocytic response and symptomatic improvement on the sixth day of the treatment; he considered that these haematological changes were not the result of spontaneous remission but were due to the beneficial effects of saliva. This investigation of mine was undertaken with the hope of throwing more light on the subject.

Method

The mixed human saliva was collected in a flask and it was detoxicated according to Duyvensz (1934) by mixing well with three times its quantity of ether. This was found to be quite unnecessary and so in the later experiments fresh human mixed saliva, soon after it was collected, was directly injected intramuscularly into pigeons without any detoxication or sterilization.

Muller (1932) was of opinion that pigeons were peculiarly sensitive to haemopoietic factor which causes striking reticulocyte response and therefore pigeons were selected as experimental animals in this investigation. All the pigeons were allowed to become stabilized as to their weight and reticulocyte percentage before the commencement of the injections of saliva. This usually occupied about a week and during this time frequent examinations of peripheral blood and bone-marrow were made.

Injections of saliva.—When the pigeons were thus stabilized they were given 3 c.cm. of fresh human mixed saliva intramuscularly twice a day for three days continuously. Microscopic examinations of the peripheral blood and bone-marrow were carried out daily. A drop of blood for this purpose was obtained by puncturing a vein in the wing and the bone-marrow by aspirating the shaft of the femur.

Staining.—The blood drop and the bone-marrow thus obtained were added separately

to 1 c.cm. of brilliant cresyl blue solution in separate test-tubes. The contents were thoroughly mixed up immediately and also at intervals of five minutes for about half an hour. The cells were allowed to settle down.

The brilliant cresyl blue solution was prepared as follows:—

(a) 1 per cent brilliant cresyl blue in 0.9 per cent saline.

(b) 1 per cent sodium oxalate in 0.9 per cent saline. Just before use, (a) and (b) solutions were mixed in the proportion of two of (a) and one of (b).

Reticulocyte counts.—Counts were made in at least a total of 500 red blood cells almost daily throughout the period of experimentation.

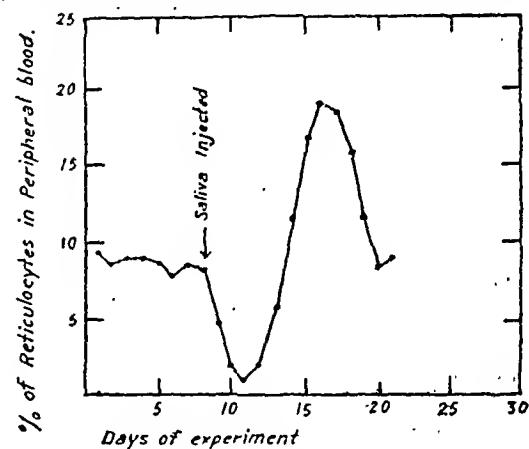

Figure showing reticulocyte response

Weight of the pigeon 274 grammes.

After the period of stabilization for one week, 3 c.cm. of fresh human mixed saliva was injected intramuscularly on the 8th, 9th and the 10th day. The fall in the reticulocyte count noticed soon after the first injection continues till about 24 hours after the last injection. This is followed by a gradual increase in the reticulocyte count day by day. The maximum count is reached by about the 6th day after the last injection.

The slides were prepared in two ways. After the cells settled down in the test-tubes, (1) films were made on clean slides by the usual technique and were lightly counterstained with Leishman's stain. These slides were then examined under the oil-immersion lens; (2) a coverslip preparation of a drop of each of the specimens was directly examined under the oil-immersion lens. By this method the reticulocytes could be more easily recognized as compared to the former method.

Results

Before the course of injections of saliva, the reticulocyte count was at about 8 to 9.5 per cent in the peripheral blood and 1 to 1.5 per cent in the bone-marrow on the average. After the injections the reticulocyte count fell to 3.5 to 4 per cent and seven to eight days after the last injection, the reticulocyte count reached a maximum of 17 to 19 per cent in the peripheral blood.

A similar rise in the reticulocyte count from 1 to 4 per cent was also observed in the bone-marrow. The pigeons apparently maintained their normal health. Further changes in the

bone-marrow smears were noted before and after the injections.

The normal bone-marrow consisted of a large number of fat vacuoles and scanty cellular element. The cells were mostly megaloblasts with few normoblasts, erythroblasts, and erythrocytes. After the course of injections, the fatty nature of the bone-marrow has almost disappeared due to the increased formation of new erythrogenetic centres. The cells were found to be mainly normoblasts with a few megaloblasts and erythrocytes.

Discussion

The results described show a fall in the reticulocyte count soon after the injections and then a gradual increase reaching its maximum by about the fifth to the sixth day. The initial fall in the count may be due to a factor in the saliva which hastens the maturation of most of the reticulocytes. The same factor or some other factor may stimulate the bone-marrow, resulting in the maximal production of reticulocytes. Castle and his co-workers demonstrated that the intrinsic factor is present only in gastric mucosa and not in saliva. The reticulocyte response and the symptomatic improvement noticed by Tempka in patients with pernicious anaemia after the oral administration of large quantities of saliva is suggestive of the presence of some haemopoietic factor in saliva. The results obtained are in close agreement with Tempka. The marked reticulocyte-count increase in the peripheral blood, the increase in the erythrogenetic centres in the bone-marrow and the greater preponderance of normoblasts over the megaloblasts after a course of injections are all

suggestive of the presence of a haemopoietic factor in human mixed saliva.

This investigation was carried out in the Central Institute of Physiology, Medical College, Madras. I am grateful to Dr. M. A. Basir for suggesting the subject and also for the guidance throughout the investigation. My grateful thanks are also due to Dr. B. T. Krishnan for his helpful suggestions and kind permission to submit this paper for publication.

Summary

- After stabilizing pigeons as to their weight and reticulocyte count, they were given a course of six injections of fresh human mixed saliva intramuscularly.

- After the injections, the reticulocyte count in the peripheral blood had increased from about 8 to 18 per cent.

- There was an increase in the haemogenetic centres in the bone-marrow of the femur after the injections.

- The great increase in the normoblasts of the bone-marrow was also noticed after the injections.

- These are suggestive of the presence of a haemopoietic factor in the human mixed saliva.

MULLER, G. L. (1932) ... *Arch. Path.*, 14, 774.
TEMPKA, D. (1937) ... *Folia Haematol.*, 57, 30.

Note.—Muller's observations on the specific response of pigeons to the haemopoietic factor have not been confirmed. The experiment reported above is entirely uncontrolled and the fact that fresh saliva was used seems to lay the experiment open to grave criticism. Nevertheless, we consider that the findings are interesting enough to be reported briefly.—Editor, *I. M. G.*

A Mirror of Hospital Practice

INDUCED MALARIA WITH HEAVY MALIGNANT TERTIAN INFECTION

By SIR R. N. CHOPRA, Kt., C.I.E., M.A., M.B.,
S.C.D. (Cantab.), F.R.C.P. (Lond.)
BREVET-COLONEL, I.M.S. (Retd.)

B. SEN, B.Sc., M.B. (Cal.)

and

J. C. GUPTA, M.B. (Cal.)

(From the School of Tropical Medicine, Calcutta)

RAM LAL, a Hindu male, 45 years old, was admitted into the Carmichael Hospital for Tropical Diseases on 27th February, 1941, for malaria therapy. His lower extremities showed signs of great weakness. Examination of blood showed a moderately positive Wassermann reaction. Physical examination revealed the following findings:—Tongue coated; lungs moist and dry sounds all over both lungs; liver slightly enlarged; spleen not palpable; heart nothing abnormal noted; bowels loaded; lower extremities, signs of great weakness in both.

Knee jerk absent on the right and somewhat brisk on the left. Pupils eccentric but react to light and accommodation; gait, tabetic; ankle jerk, absent. The patient was suffering from tabes dorsalis and malaria therapy was advised.

The patient was injected on 28th February with 10 c.c.m. of blood showing a scanty infection of benign and malignant tertian parasites, but there was no sign of fever for three weeks. On 23rd March he was given an injection of adrenalin chloride but this also failed to bring about any pyrexia. On 27th March he was re-inoculated with 10 c.c.m. of blood showing a moderate infection of *Plasmodium falciparum*. On 29th the patient first showed signs of a rise of temperature but an examination of the blood showed no malaria parasites. The temperature, however, persisted in an intermittent form and on 3rd April, examination of blood revealed the presence of scanty malignant tertian rings. This intermittent temperature persisted more or less daily and the blood also showed scanty malignant tertian rings until 9th April on which day a moderate infection was noticed in the blood (roughly one ring in alternate fields). Spleen was found to be slightly enlarged. The intensity of infection remained like this until 10th April but on 11th we found that

between 30 and 40 per cent of the red cells in a field were infected with rings.

The physical examination at this stage revealed the following:—Pulse—soft, 140 per minute; respiration—40 per minute; lungs—rough, dry and moist sounds all over, especially marked on the right side. The patient was having great difficulty in breathing. Heart sounds very feeble; abdomen slightly distended; spleen—palpable; temperature—104°F. Patient was quite conscious but very restless.

The patient was given $7\frac{1}{2}$ grains of quinine bi-hydrochloride dissolved in about 20 e.c.m. of water by the intravenous route, injection being given very slowly. One hour after the injection examination of blood smears showed only 2 or 3 rings per field, but the general condition of the patient still caused anxiety. The pulse was small and rapid and there was a considerable amount of respiratory distress. The patient, from the beginning, was put on rum, 2 drachms every two hours and glucose by mouth; injections of cardiazol, and strychnine-digitaline were also given. He was given oxygen and an injection of atropine was also given for the respiratory difficulty.

Examination of blood smears every hour showed a gradual increase in the number of parasites and five hours after the injection of quinine 4 or 5 rings were noticed per field. Quinine bi-hydrochloride ($7\frac{1}{2}$ grains) was given by the intramuscular route. The condition of the pulse appeared to improve and the temperature came down to 99.6°F., the patient perspiring profusely. Oxygen, glucose and rum were continued.

On 12th April the condition of the patient was slightly better, temperature went up to 101°F. and blood smears showed 5 or 6 rings per field. The patient was put on quinine sulphate, 5 grains three times a day by mouth. The temperature persisted throughout the whole day and night. The highest temperature on the 13th was 102.6°F., blood smears showing 2 or 3 rings per field with very scanty crescents. The condition of the lungs was much better and the respiratory distress was much less. The pulse and respiration ratio varied from 120/40 to 140/36.

On 14th April the temperature came down to 99°F. and blood was showing scanty rings and a fair number of crescents. There was considerable improvement in general condition, pulse had good volume and there was practically no respiratory distress.

On 15th April temperature came down to 98°F., pulse attained normal tension and examination of blood showed very scanty rings and a large number of crescents. The administration of quinine by mouth was stopped, the patient having had 9 doses in all (45 grains).

On 16th April the temperature was normal and the general condition was much improved. Blood smears showed rings in thick film only and a large number of crescents were observed.

On 17th April temperature was subnormal. Blood showed fair number of crescents but no rings were detected in thick and thin films. The patient's condition was quite normal.

Discussion

The senior author (Chopra, 1936) has been using artificial infection with malaria in the treatment of neuro-syphilis for many years with beneficial results. In temperate climates the method of choice is to transmit the disease by infected mosquitoes. In India, however, cases of malaria are always available and injection of infected blood is more convenient. Further in non-malarial countries *Plasmodium vivax* is always used for malaria therapy, but our experience in India is that it is not always possible to induce infection with this species, probably on account of the immunity which a large number of people have against this parasite, because of the frequency of its occurrence. The senior

author has, therefore, often used blood infected with *P. falciparum* with which infection is more readily established, the patient being kept under careful observation all the time by examination of blood once or twice daily, as soon as the infection is established.

So far no untoward results have been observed and 8 to 10 paroxysms of fever could be given without any difficulty and danger to the patient. In this patient two injections of infected blood had to be given and it is possible that the extraordinarily heavy infection which suddenly developed was due to the summation of effects of the two injections. It will be observed that after this first injection there was an appreciably long incubation period and it is likely that the second injection served the purpose of exciting the previous one, as well as producing its own effects.

The second point of interest in this case is the ready way in which infection produced by direct inoculation of blood is controlled by quinine. Here $7\frac{1}{2}$ grains of quinine intravenously brought the number of parasites from 30 to 40 per field to 2 or 3 per field in one hour. The effect of a single intravenous injection, however, lasts for a short time on account of rapid excretion of the drug. Hourly examination of the blood films in this patient showed an appreciable increase in the number of parasites per field within five hours and an intramuscular injection of seven and a half grains of quinine, and later quinine by the mouth had to be given.

The increased vulnerability of parasites given by direct inoculation of blood compared with natural infection by mosquito bites was also demonstrated in this case. Chopra and Das Gupta (1936) showed a definite increase in the number of parasites in natural infection with *P. falciparum* after an intravenous injection of quinine. In this case there was not only no increase but in one hour the parasites were reduced from 30 to 40 per field to 2 or 3 per field.

In our cases of induced malaria in the Carmichael Hospital for Tropical Diseases in case of *P. vivax* infection by direct inoculation of blood, five grains of quinine usually suffice to get the infection under control, but in *P. falciparum* much larger quantities have to be used.

The last point is the peculiar rough, moist and dry sounds which were heard in the lungs during the height of infection. Were these adventitious sounds due to accumulation of parasites in the lung capillaries, or were these severally the result of very laboured respirations? As these disappeared as the number of parasites decreased it is possible that parasites had something to do with it.

This case should serve as a warning to those using malaria therapy in this country by direct inoculation of blood. It is not uncommon to get mixed infections and in spite of all precautions *P. falciparum* may be grown with *P. vivax* and may suddenly flare up.

INTERSTITIAL KERATITIS DUE TO FOCAL SEPSIS

By E. J. SOMERSET, M.S. (Lond.), D.O.M.S.

and

F. H. R. DAVEY, L.D.S., R.C.S. (Eng.)

THE majority of cases of diffuse interstitial keratitis occur in congenital syphilis. Other but rare causes are acquired syphilis, tuberculosis, trypanosomiasis and leprosy. A unilateral post-influenza parenchymatous keratitis has been recorded by Doggart (1931). Duke-Elder (1938), in an extensive review of the literature, makes no references to focal sepsis as a primary factor in the aetiology, but the following case seems to indicate that focal sepsis may be a rare cause.

History.—Anglo-Indian, male, aged 29 years, telegraphist. According to the patient, in the winter of 1936-37, he suffered from an attack of epiphora, photophobia and dimness of vision in the left eye which responded to treatment in about two months. He states that he had no further trouble until October 1939 when one eye, and soon after the other, became inflamed, causing him an intense epiphora and photophobia. Atropine and hot bathing gave little relief and for eight months he was only able to work occasionally. His general health had otherwise been good; he had malaria two years ago for which he had been given a full course of quinine and plasmochin. No history of allergic disease in either the patient or his family could be elicited.

Examination.—The writer (E. J. S.) first saw him in May 1940 and he presented the following picture:—

Right vision 3/60. Left vision. Counts fingers at 2 feet. Photophobia was so great that he could not tolerate the light of an indoor room and kept the eyes covered with a bandage. Epiphora was intense and was one of the main features of the case, being so marked that on raising either upper lid tears actually poured out. Both cornea showed signs of inflammation, characterized by a diffuse grey haziness, denser in some areas than in others, but involving the whole of the interstitial tissue. There was no deep vascularization perceptible to examination with a loupe. The surface of the cornea appeared normal and there was no staining with fluorescein or any superficial vascularization. There were no signs of trachoma. Tension was normal. Corneal microscopy was not available but with the loupe the inflammatory process appeared to be confined to the interstitial tissue. There was no K. P. but a moderate amount of ciliary and conjunctival congestion were apparent. There was no discharge on bandaging the eyes for twenty-four hours.

On 21st May he was admitted into hospital for investigation, he was kept in bed and atropine drops and hot fomentations were given. This treatment had little effect upon the disease process. The Wassermann and Kuhn reactions were negative. Ears, nose and throat were reported normal. Physical examination revealed no other abnormality. X-ray of the chest was normal.

Dental report (F. H. R. D.) was as follows:—

'Superficially the mouth appeared to be clean. A small amount of tartar was removed from the lingual aspect of the lower incisors. 62/ and 456 were very loose and pus could be expressed from the gingival margins of these teeth. 76/ were slightly loose. X-ray

of the loose teeth showed rarefaction areas around the roots especially marked in the region of 2/. It was considered that these teeth might be subserving to the eye condition and their extraction was recommended. Extractions were completed under Evipan anaesthesia on 10th June. Sockets were everted and healing was uneventful.

Following dental operation, a dramatic change took place in the eye condition. In a few days the epiphora had almost ceased and at the end of a week the photophobia had disappeared. On 21st June the ciliary congestion was no longer present. In view of the immediate improvement following the extractions a further critical examination of the mouth condition was made. It was considered that 5/46 were very slightly loose and x-ray showed a small degree of apical absorption. These teeth were therefore extracted under nitrous oxide anaesthesia on 28th June and the patient left hospital on 2nd July with 6/15 vision in each eye.

Progress.—The cornea continued to clear and by 10th September, three months after operation, there were no corneal opacities visible to examination with the loupe and the vision was 6/6 in each eye. There has been no further trouble to date (March 1941).

Discussion.—It is just possible that the dental extractions coincided with a spontaneous remission of the disease, but in view of the long history, the lack of response to atropine and hot bathing, and the dramatic response to dental extraction, it would appear that the dental sepsis in this case was the cause of the interstitial keratitis.

Summary.—A case of interstitial keratitis due to dental sepsis is recorded. Intense epiphora was a marked feature of the case.

A RARE CASE OF DERMALGIA

By P. L. DESHMUKH, M.B., B.T.M. & H.

Honorary Assistant Physician, Sasoon Hospitals, Poona

THE following case may be of interest owing to the rarity of the condition and the dramatic improvement in the state of the patient:—

A farmer, aged 28, was admitted into the Sasoon Hospitals, Poona, on 15th February, 1941, for severe burning sensation in the feet of 2½ months' duration. He was brought to the out-patients' department on a stretcher as he would not put his feet to the ground for fear of the burning sensation that would be increased thereby. He was admitted as a case of some disturbance of the sympathetic nervous system. On admission, it was found that he had severe burning sensation in both his feet, particularly in the soles, so intense that he could not bear even contact with light clothing. The complaint started suddenly, without any obvious cause about 2½ months back, and is continuing with the same intensity. He was treated in an ayurvedic hospital without any relief, for about a month. On examination, it was found that there was no change in the colour of the skin nor in the temperature of the affected part compared with the rest of the body. His hands were cold and clammy and he wore gloves to keep them warm. There was no history of alcohol, syphilis or leprosy in the family. There was no history of any change in the environment to precipitate this trouble. He had malarial fever for about a week ½ years back. There was no objective evidence of disturbance of his nervous or other systems. Lumbar

GUPTA, B. M. (1936).

puncture was not found to be necessary. Results of the other investigations were as follows:—

Urine: nothing abnormal was detected.

Blood pressure: systolic 125 mm. Hg., and diastolic 80 mm. Hg.

Nasal smears before and after a strong dose of potassium iodide: negative for Hansen's bacillus.

Blood smear: nothing abnormal detected.

Wassermann reaction of blood: negative.

The following clinical conditions were looked for and excluded:—

Peripheral neuritis.—There was no tingling or numbness. Calves were not painful. All tendon-jerks were normal.

Diabetes mellitus.—Urine never showed any sugar. There were no symptoms of the condition. Blood sugar of a fasting sample was 80 mg. per 100 c.c.m.

Gonorrhœa.—No history, and no evidence on examination.

Leprosy.—Nasal smears were negative repeatedly for Hansen's bacillus. There was no hyperesthetic, anaesthetic or depigmented patches on the body. No thickening of nerves was noticed.

Tubes dorsalis and subacute combined degeneration.—There was lack of any evidence on examination of nervous system.

Erythromelalgia, Raynaud's disease, endarteritis obliterans.—Absence of trophic changes. No change in the colour and temperature of the skin. Pulsation of vessels was normal.

Neurasthenia.—The patient was in real distress and woke up even from deep sleep when his feet were handled.

Pellagra.—No evidence of pigmentation, dermatitis or other symptoms.

Treatment.—In the absence of any definite diagnosis, it was decided to put the patient on intensive vitamin therapy on the evidence that he showed a little congestion of his gums and some dryness of the skin. He was given a diet rich in vitamins, supplemented by adexolin, and intravenous injections of vitamins B and C. Lead lotion compresses were given to his feet which were protected by a cradle. He also required repeated and strong hypnotics in the beginning to bring on sleep, which was greatly disturbed by the burning sensation.

He was re-examined after about ten days of treatment, and though the patient complained that he had only little and temporary relief by treatment, it was observed that his trouble was definitely much less. It was noticed during examination that, though the patient felt the agony of touch by the examining hand, he did not feel anything when he was engaged in conversation or was kept busy otherwise. This observation lead to the possibility of a neurosis, or a touch-phobia appearing on the top of his original trouble. To assess the part played by neurosis in the remaining trouble, the patient was ordered to walk in spite of his complaint. On his refusing to do so, he was taken out of his bed and forced to walk along the floor for a few feet with the help of two persons. As he gained confidence, he was gradually left to himself and it was found that he could walk alone briskly in the ward and along the corridor, the same day. From that moment his symptoms greatly ameliorated, appearing only in the early morning at about 4 a.m. for an hour or two. His remaining symptoms disappeared completely on the same line of treatment during the next week and he was able to run about like a normal man before his discharge. Though we believed that his improvement was due to intensive vitamin therapy, he used to say that it was due to the 'German hikmat' (trick) of forced walking.

Discussion.—The complaint of the patient was very peculiar and no reference to such a condition could be obtained in any of the usual text- or reference books on medicine. As the patient was about to be discharged, I came across an answer to a query about a similar case in the

Journal of the American Medical Association of 28th September, 1940, page 1120, where such a condition was diagnosed as dermatalgia. I extract below a few lines for the information of readers:—

'... there is no change in the appearance of the skin during attacks, thus justifying the diagnosis of dermatalgia, a disturbance of the nerves supplying the skin of the part affected, supposedly the nerves of the vegetative system. The pain varies in different cases, burning as in the case cited, or a sensation of hot or cold water running over the skin, of stabbing, cutting, rubbing of the skin, or the sensation of an electric current. The attacks come usually at night, affect middle aged women most often and are commonly associated with hyperesthesia so that the contact of clothing or other objects adds to the distress. Hairy parts or the extremities are most often involved. . . . As possible aetiological factors, tabes dorsalis, malaria, rheumatism, diabetes mellitus, leucæmia and other members of the lymphoblastoma group and leprosy were mentioned. In addition chlorosis, hysteria and any cause of neuritis are mentioned in the literature. Exposure to cold is also mentioned, probably the reason for the mention of rheumatism. It might be well to examine for anaemia and the possibility of certain forms of avitaminosis, especially those in which elements of the vitamin B complex are concerned. . . . In the considerable proportion of the cases in which no such basis can be found, acetyl-salicylic acid, salicin, quinine and arsenic are recommended and the local use of alternating hot and cold applications, galvanic or faradic electricity or counter irritation over the nerves supplying the part. Langeron and Desplats are quoted as having suggested roentgen therapy over the sympathetic centres for the relief of the pain of dermatalgia. . . . A small dose of roentgen rays, from 40 to 80 roentgens filtered through 2 mm. of aluminum, may be effective. This can be repeated at weekly intervals. . . . The skin should be protected as far as possible from the irritation of clothing.'

It will be realized that the case had improved as a result of our investigation and treatment before we came across the reference quoted above.

The interest of the case lies in the following:—

(1) The case presents a rare condition known as dermatalgia.

(2) The disease occurred in a middle aged man, while it is believed to be more common in females.

(3) The condition was amenable to intensive vitamin therapy.

(4) The case well exemplifies the necessity of recognizing the fact that neurosis or a phobia may in the course of time supervene on a real complaint. Later, the complaint may gradually disappear and neurosis take its place, the latter requiring treating with a firm hand.

I wish to thank Dr. M. S. H. Mody, honorary physician, for helping me in the investigation of the case and Major H. S. Waters, I.M.S., for giving me permission to report it.

A CASE OF ABDOMINAL PREGNANCY AND DELIVERY PER RECTUM

By K. M. NAYAK, L.M. & S.

Medical Officer, Government Hospital, Kasaragod

A WOMAN, aged about 30 years, wife of a forester, was admitted into the Queen Alexandra Hospital for

women in Salem town in the month of September 1932. She was said to have been pregnant for 18 months and was admitted for colicky pains which were mistaken for labour pains.

On examination, the abdomen was found to be of the size of a full-term pregnant woman. It was tympanitic all over. A round globular swelling was present in the middle line of the lower abdomen and extending up to 3 inches above the umbilicus. She had no difficulty in passing urine or stools. Frequency of micturition was a very distressing symptom. She had colicky pain with passage of blood and mucus simulating dysentery. One early morning, two days after admission, while she was passing a stool a small hand appeared at the anus; this frightened her. While examining the patient I pulled out the protruding hand and the whole of the right forearm from the elbow downwards came out easily. I had the patient taken to the Headquarters Hospital and put her on the table and examined her under chloroform. On rectal examination I felt the head 3 inches from the anus and also the stump of the remaining portion of the right arm. On pulling this down by gentle traction, the whole macerated fetus aged about six months came out followed by the placenta, all in one mass. The woman was in the hospital for eight days. Her recovery was uneventful.

I met her again in February 1939 after seven years. She was hale and hearty. She had had no more pregnancies.

Evidently this was a case of tubal rupture into the peritoneum. It could not be verified as no abdominal section was done. Her history was that she had some sort of pain about a year prior to her admission in the hospital and was treated at home by a quack.

The rupture must have taken place at six months, and the fetus was extruded into the peritoneum. Nature came to her rescue. Adhesions were formed around the fetus enclosing it in a sac and it remained there for a year after rupture. Latterly, the fetus ulcerated through the wall of the rectum and came out.

A CASE OF ECLAMPSIA*

By JIWANLATA

*Medical Superintendent, Lady Butler Hospital,
Khandwa*

A HINDU FEMALE, aged 17 years, primipara, was admitted on the 4th November, 1940, with a history of fever and rigors for 3 to 4 days and fits since the morning.

Family history.—She was a pampered child of the family; her mother had hysterical fits during one of her pregnancies and eclampsia during two of her confinements.

Present history.—The patient was attending the outpatients' department, and had a trace of albumin while three months' pregnant, which cleared up completely with treatment. She was constipated and her bowels had to be moved daily with laxatives. She kept well for 4 to 5 months but subsequently she started getting shivering attacks 2 to 3 times a day. She complained of pain in the left loin about 2 days before admission.

Condition on admission.—Healthy looking woman, temperature 90°F., pulse 92 per minute, tongue red and exfoliated due to large doses of alkalis. Uterus: full term size; L. O. A.; fetal heart sounds good; head not fixed. Urine: scanty, acid, albumin, pus cells and micro-organisms present. Blood pressure was within normal limits, the systolic being 116. Fits appeared to be hysterical.

Alkalies were continued in large doses and bowels kept moved. She got no more rise of temperature or pain in the loin, and by the 15th the urine was completely free from albumin, pus cells and micro-organisms. She had no fits for 11 days and was

therefore discharged on request to come back for delivery when pain started.

On 30th November, I was called again at 10-15 a.m., and found the patient suffering from a severe type of eclampsia, fits having started at about 8 a.m. She was getting fits one after another, and was completely unconscious. She had also become cyanosed and had bitten her tongue. She was given an injection of morphine and atropine immediately; this brought the fits under control but she remained unconscious. She was removed to the hospital and given an enema which had no effect. The catheter specimen of urine was high coloured and contained a fairly large quantity of albumin. Systolic pressure 116. Patient was not in labour as there was no uterine contraction; head was above the pelvis and no show was seen. Pelvic examination was not done in view of the contemplated Caesarean section which was done at 1 p.m. A cyanosed female child was delivered. She got no more eclamptic fits after the operation and became conscious after about 7 hours. She behaved like a mental patient on the second day and got a temperature of 100°F. accompanied by shivering. The urine showed pus cells again. She was put on alkalis. Mother and baby are now both doing well.

Points of interest.—The case is of interest because the patient was kept under observation; urine was free from albumin till 8 days before the attack; bowels were kept moved and blood pressure was normal yet she developed severe eclampsia. Bowels had moved well that morning also and the patient was feeling quite well.

This is the second case under my care who developed eclampsia while the urine was kept free from albumin till a few days before the attack.

VESICAL CALCULUS IN A VAGINAL CYSTOCOELE

By R. D. MACRAE, F.R.C.S.E.

CAPTAIN, I.M.S.

Agency Surgeon, Gilgit, via Kashmir

A MOHAMMEDAN multipara was admitted in the second stage of labour. There was delay in the advance of the head through the lower canal.

Examination revealed that a normal labour was taking place, but a hard mass was felt in the anterior vaginal wall, and a cystocoele was seen to bulge below the pubic arch obstructing the progress of the head.

A no. 10 male silver catheter was passed per rectum, with the tip pointing posteriorly, and, after taking a specimen of urine, the catheter was felt to grate against a stone in the cystocoele.

The bladder was incised through the anterior vaginal wall, and a stone about the size of a walnut removed. The fistula so formed was carefully sutured in two layers, and delivery completed by forceps so as to avoid prolonged pressure on the sutured wound.

Recovery was uneventful except for some cystitis, and no fistula resulted.

CORRIGENDUM

In the paper on 'Tuberculosis of the Female Genital Tract' by M. N. Sarkar *et al.*, published in our May 1941 issue, on page 259, under the heading *Summary and Conclusions*, para (2), line 3 should read 'From the post-mortem figures the incidence was 1.1 per cent in unselected deaths in females, and where death occurred from tuberculosis the percentage was found to be 8.9'.

The mistake originated in the authors' typescript.

* Rearranged by Editor.

Indian Medical Gazette

JUNE

PLASMA TRANSFUSION

PLASMA transfusion is not such a new-comer to the field of therapeutic medicine as is generally supposed. Its use in casualty-clearing stations was advocated by Ward in 1918, and thereafter for the next eighteen years a few reports of plasma transfusion have appeared in the literature. Recently, however, a combination of factors has occurred that has raised it from an empirical to a scientific procedure. These factors are the knowledge gained by the study of wound shock, haemorrhage and burns from a physiological standpoint; the availability of large amounts of plasma from blood banks; and abundant clinical material in the form of war casualties.

Plasma is the fluid element of blood after separation of the corpuscles, as distinct from serum, which is the clear fluid which separates off when blood clots. It can be prepared either by sedimentation or by centrifugation, and plasma obtained by either of these methods can be rendered into a powder by desiccation. The technique of obtaining plasma by sedimentation is relatively simple, and consists briefly of aspirating the clear supernatant fluid from citrated blood that has been stored for not less than 24 hours at 4°C. Centrifugation is the method used by the army blood transfusion service in England, and their technique includes an efficient system of clarification and sterilization by the use of filters.

Freshly-obtained blood is kept at about 4°C. for one day and then raised to room temperature for six to eight hours. This prevents opalescence in the plasma, which is the result of separation of fat globules. The blood is then pooled and run through an Alfa-Laval centrifuge, which operates in a manner similar to the domestic cream separator. The plasma thus obtained is freed from fat by suction through filters of sterile cotton pulp, and sterilized by passage through a Seitz filter. The asbestos pads of this filter also adsorb practically all fibrinogen and prothrombin.

This process yields about 50 per cent of the original blood volume (including added anticoagulant), and four workers can prepare 150 pints in four hours. Thus prepared, plasma will keep for at least six months.

To neutralize iso-agglutinins, either the blood or the plasma can be pooled. If B blood is added to A blood in the proportion of at least 1 to 16, then the resulting plasma will contain either no agglutinins or agglutinins of so low a titre as to be negligible. Plasma from blood, freshly drawn for the purpose, is preferable to that obtained from 'banked' blood, into whose

plasma layer considerable diffusion of potassium occurs after a time.

The properties of plasma are identical with those of blood, *minus* the properties attributable to the corpuscles. It contains albumin and globulin which maintain the osmotic pressure, some fibrinogen which assists in haemostasis, and specific antibodies which remain active in stored plasma for a limited time. The value of plasma transfusion in shock from injuries and burns can be appreciated by studying the sequence of events which McDowell calls the 'death cycle'. In a case of shock, lowered blood pressure reduces the blood supply to the tissues, resulting in asphyxia of the tissues. This causes dilatation of the capillaries and increased permeability of the capillary walls. The dilated and damaged capillaries withdraw a great quantity of blood from the circulation, and permit loss of plasma into the tissues. Hæmoconcentration, a marked feature in cases of burns, and reduced venous return cause reduced cardiac filling. The resulting reduced cardiac output helps to lower the blood pressure further, and thus the vicious circle is complete.

Plasma transfusions, therefore, would seem to be the ideal measure in cases of surgical shock and burns, as they break the vicious circle by causing a permanent increase in the volume of circulating blood, and help the corpuscles to return from the capillaries into the general circulation. In addition, numerous other indications of varying importance have been given for its use, such as haemorrhagic intestinal states, peritonitis after rupture of a viscus, and oedema due to nutritional and nephrotic states.

The administration of plasma transfusions is relatively simple. The patient's blood group need not be known, and the plasma can be given in the same apparatus as is used for the transfusion of stored blood. Witts recommends the giving of plasma to any shocked patient whose percentage haemoglobin is 10 per cent above the probable previous value. If this was 100, the plasma loss can be calculated from the formula

$$\text{Hb} = \frac{5}{100 - 5 - x} \quad \text{where } x \text{ is the plasma lost in litres*}$$

If permanent improvement in the patient's condition is to be maintained, a reasonably quantitative replacement of protein must be made. In injury cases a watch on the blood pressure is the best practical guide to a patient's progress. A dangerously low blood pressure in the presence of severe injuries demands immediate transfusion. Cases whose blood pressures

*The danger of this method of calculating is obvious, unless by any chance one knows the patient's previous haemoglobin level. At a recent meeting of the Royal Society of Medicine a speaker said in this connexion that haemoglobin of 115-120 per cent meant that that patient was in extreme danger of immediate death.

In this country the average haemoglobin of well-to-do Europeans is about 130 per cent, so that we must all be dead!

decline or fail to exceed 100 mm. in spite of routine resuscitation measures should be transfused.

A rise of 10 to 20 mm. per 540 c.c.m. of plasma given should occur if no causes of loss of circulatory fluid are still operating. If it is found that the administration of more than 1,500 c.c.m. is necessary, Whitby advises that 500 c.c.m. of this should be blood.

One of the advantages of plasma transfusion is that it is a safe and adequate substitute for whole blood in cases where the addition of corpuscles to the circulation is not required. In this connexion, however, it should be remembered that plasma will perform what has been called auto-transfusion by setting free quantities of corpuscles which have become lodged in the capillaries. Its advantage over crystalloid and gum transfusions is that it causes a permanent restoration of blood volume in a physiological manner.

Dried plasma is stable, and its small bulk and portability are important advantages in certain circumstances.

The disadvantages of plasma are those met with in the technique of preparation, especially when stored blood is used. It must not be forgotten that some cases require to be given very large amounts of plasma, and if one case consumes the contributions of fifteen donors the labour and expense that this represents assume formidable proportions.

Recent work on the use of serum instead of plasma suggests that there is little to choose between them. Serum is certainly easier to dry than plasma, as it contains no fibrin, sodium chloride, sodium citrate or glucose. But at present the consensus of opinion is in favour of the use of plasma.

In England, to use Riddell's phrase, plasma has become a commodity of national importance. It is hardly likely to assume such a degree of importance in India, especially as the success of large-scale transfusion services in democratic countries depends on the willingness of the general public to come forward as donors.

TREATMENT OF FRACTURES OF THE LEG

By MAX SCHECK, M.D.
Purandhar, via Poona

ALTHOUGH he may be equipped with several textbooks on fracture treatment, the surgeon will often find no reference to his particular case. It is the task of this article to outline general rules for treatment of fractures of the tibia or of both bones of the leg. The aim of fracture treatment is complete anatomical and functional restoration. Proper alignment of the fractured ends and healing is almost always connected with good functional results. We therefore must endeavour to reduce the fracture and to keep the fragments in the proper position for as much time as is required for the healing. There are different ways of serving this end. Manipulation, extension, open reduction, with or without fixation, by means of plates or wires.

One school prefers open reduction a few days after the occurrence of the fracture. Even if the danger of infection is ignored, this method does not seem to have any advantage over other non-operative methods. It is argued by the conservative school that the removal of blood, serum and the products of necrosis from the fractured ends and the torn periosteum during operation is harmful to the healing process. In plants there is definite proof that injuries to the stem result in the production of a hormone which stimulates growth. Though the existence of such a hormone is only hypothetical in human

beings, the conservative school regards it as essential to preserve the fluids at the site of the fracture. Only fractures of the patella and the olecranon are treated by open methods.

If we choose closed reduction we have two means at our disposal of achieving alignment of the fragments, manipulation and extension. Both can bring about alignment, but the proper position must be maintained for a sufficiently long time to have a good anatomical and functional result. A plaster-of-paris cast serves this purpose only with limitations. Thus when the muscles are relaxed it will be possible to reduce a spiral fracture by manipulation. X-ray controls after a few days will however reveal considerable displacement, even if an unpadded plaster had been applied. This is due

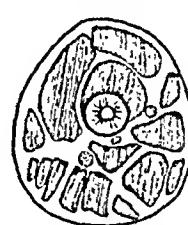

Fig. 1.—Diagram of the thigh showing the muscular tube surrounding the bone (figure 1).

The muscles have a certain tonicity which is maintained as long as they are innervated. If there is shortening of the bony skeleton, the muscles adapt themselves at once to the new length. In attempting to reduce a fracture this muscular force is such an obstacle that in many cases general anaesthesia is required to make the muscles relax, in order to align the fragments.

through our manipulations. Through muscular action the two fragments are pressed in different directions and if primary manipulation has achieved alignment of a spiral fracture and a plaster cast has been applied immediately it is still possible for the fragments to slip (figure 2). If in such a case extension is used for 2 to 3 weeks to counteract the muscles, and a plaster is applied thereafter, no slipping will occur because the fragments are already in a firmer connection.

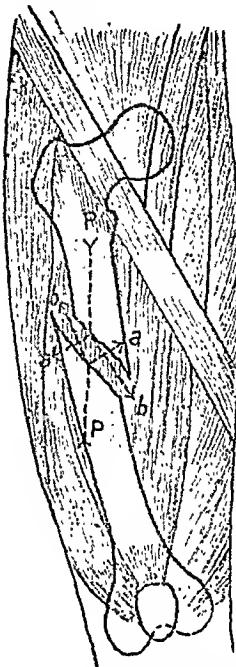

Fig. 2.—Spiral fracture of the femur. The muscular forces P are divided according to the parallelogram of forces into the two components a and b. The forces a which tend to keep the fragments together are smaller than the forces b which make them slip from each other.

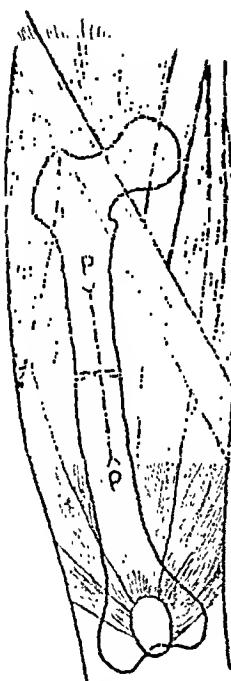

Fig. 3.—Transverse fracture of the femur. The forces P act entirely to keep the fragments together.

Fractures with transverse break lines derive only benefit from the muscular pressure, which in its full force presses the fragments together. The pressure is not only welcome for this reason, but also because, according to Roux, pressure favours the formation of bony callus (figure 3).

As the first rule we can therefore establish, that the treatment of fractures of the leg depends on the type of the fracture. We can discriminate between two principal groups—fractures with transverse lines and fractures with oblique lines. Transverse fractures can be primarily set and put in plaster. Fractures with oblique lines, as a rule, must be put under extension before a plaster can be applied.

Whether manipulation or extension shall be done will furthermore not only depend on the type of the fracture but also on the eventual complications of the case. If the type of fracture suggests pin or Kirschner wire extension on

the heel; but this is made impossible on account of a wound sustained in the same accident, some other form of treatment must be adopted. A compound transverse fracture with developing gas gangrene will not be put in plaster but extension with small weight will be applied. The leg is thus always open to inspection and every spread of infection can be watched. The method of treatment will also be decided by the particulars of the case.

The treatment of fractures with transverse lines

These very often occur through a direct kick on the leg by the opponent when playing football. Clinically, we find more-or-less swelling, pain, loss of function, and crepitus. X-ray reveals a transverse fracture without or with displacement. If there is no displacement the leg is put in a plaster slab which is U-shaped and goes from the medial side of the thigh along the inner side of the leg, round the heel like a stirrup and returns to the outer side of the thigh (figure 4). The slab is made out of two plaster bandages 4 inches broad by putting them in layers in the required length. A thin layer of cotton is put on the inner surface of the slab before it is applied. It is then tied to the leg by a moist gauze bandage, after small cuts have been made on the anterior margins at the height of the ankle joint, in order to make the slab mould to the shape. This plaster, as described by Burns, keeps the fragments fixed and has the great advantage that there is no danger to circulation, because the front and the dorsal surface of the leg are free from plaster. If the patient feels pain the gauze bandage is cut over the skin.

I would advocate this kind of plaster in every case of fracture when no x-ray is available and which has to be transferred to a hospital over a long distance. In war-time and in up-country practice this method would be very useful. The time required to apply it is a very short one, it is however more expensive than a wooden or metal splint.

To avoid rotation of the lower fragment, patella, shin and second toe must be kept in one line. The slab is kept till the swelling has diminished (5 to 8 days) and then the permanent plaster is applied. Bony prominences are covered with small pieces of cotton or lint. A slab is prepared from two plaster bandages

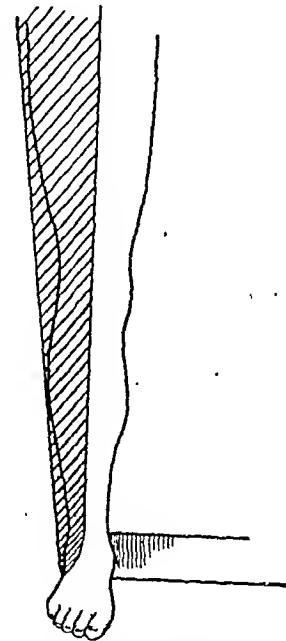

Fig. 4.—Application of the U-slab.

4 inches broad and applied dorsally on the thigh, leg, and sole. It is tied with a moist gauze bandage. Three or four plaster bandages are used for circular application. No walking-iron is used in this case because the pressure of the body-weight is beneficial to the fracture. The walking-iron serves the purpose of transmitting the pressure from the knee directly to the ground, omitting the fracture. If no walking-iron is used the pressure is transmitted through the fracture. The patient is allowed to walk when the plaster is dry and he is discharged from hospital when there is neither swelling nor pain. He is asked to return after 5 weeks when the plaster is removed and the fracture tested clinically and by radiography. If the fracture appears healed and x-ray shows good progress a short plaster up to the knee is applied for 3 weeks. The patient is advised to use his leg freely and to move the knee joint. If there is still movability of the fracture a long plaster must be applied for another 4 weeks. Sometimes a third plaster is required.

No definite time expressed in weeks can be given for all the cases. If the fracture is healed but swelling is persistent, Unna's paste bandages are applied for 2 to 3 weeks. After fractures of the leg, patients often complain of pain in the ankle joint when walking. This is due to traumatic valgus deformity as the result of disturbance of the muscular equilibrium which keeps the foot and its arches in the right position. In these cases a support is given to the foot to relieve the valgus position. Metal is certainly the most suitable material.

If there is displacement to the side and shortening, reduction is done under local or general anaesthesia and after alignment a U-slab is applied. A few days later the permanent plaster is applied. The course of treatment is the same as described above.

It is necessary to discuss at this point the treatment of compound fractures. Whereas in simple fractures our first and last aim is the anatomical and functional restoration in compound fractures, we must first endeavour to prevent or check infection, although we keep in mind the ultimate result. If seen within 6 hours, wounds in general can be considered as contaminated but not infected. The contamination occurred when through the skin opening bacteria from the surroundings have been brought into the wound. The bacteria find themselves in a medium to which they are not accustomed. Within 6 hours they get used to the new medium and their power for invasion, which was so far only potential, becomes a danger to the organism. The success of the bacteria will also be decided by the effectiveness of the resistance of the tissue. Crushed and devitalized it will easily succumb, whereas healthy tissue has natural powers of resistance. If a wound comes under our treatment within the first 6 hours after the accident, we can

remove most of the bacteria and of the devitalized tissue by excision of the wound margins and of the bottom of the wound. If this has been done the wound can be closed by sutures, but no deeper-lying tissue such as muscle tendons or fascia shall be sutured if the wound was grossly contaminated. The only exceptions are nerves and vessels whose suture should always be attempted. But the surgeon has to work very judiciously and must not put down the scalpel until his eye fails to discover any more dirt or crushed tissue. Even parts of muscle tendons and bones must be dissected if they are grossly contaminated. If the wound is very deep and with pockets which the surgeon cannot reach without serious injury to vital structures he has to leave the wound open. In many cases a compromise is possible by suturing the wound and inserting under it a cigarette or glove-drain which is put in from a stab incision 2 inches away from the wound (figure 5). The drain is removed after 24 hours and such a procedure leads in most of the cases to healing by first intention. No antisepsics are used, the wound is only cleaned with soap, water and ether. The wound margins are painted with tincture of iodine. Care is taken that none of the antiseptic touches the wound proper. All is left to the cleaning by the surgeon's scalpel.

Fig. 5.—Drainage of a recent compound fracture.

The same rules apply to compound fractures if seen within the first 6 hours. We first convert the compound fracture into a simple one by excision, suturing and eventual drainage. If there is not enough skin to cover the fracture, an attempt must be made to get it from somewhere else, either from the vicinity by incisions relieving tension so that the wound margins can be approximated over the fracture or even by skin grafting. Many cases have been reported where Reverdin grafts have taken nicely and thus the prolonged illness through a discharging compound fracture has been avoided. Thiersch grafts do not usually take well in compound fractures because the bone is often devoid of periosteum.

If a fracture lies open, infection to a lesser or greater degree is bound to occur, since bone is a very susceptible structure. In a comminuted compound fracture not too many bone pieces should be removed, failing which rule non-union often occurs. Protruding bone spikes should be removed with a Liston forceps and contaminated corticalis should be nibbled off. Only if thorough mechanical cleaning of a protruding fragment has been done, can it be brought back into the wound. If the wound is closed, it is covered

with sterile dressings and the fracture treatment is started; according to the type of fracture, plaster with a window over the wound or extension is used. If manipulation is necessary, e.g., in a displaced transverse fracture, it can be done at this stage. If however an x-ray control after 4 to 5 days reveals that there is still displacement, no attempt at reduction is justified until the wound is healed by first intention, because before this time a silent infection might be stimulated.

If as a rule plaster alone is used in the treatment of transverse fractures, we have to consider cases where for one or the other reason plaster cannot be applied. In compound transverse fractures with gas gangrene or cellulitis, it is better to use pin extension with a small weight, which keeps the fracture at rest and enables us to watch every spread of infection, since the leg is not in a plaster cast.

A transverse fracture can also occur at the head of the tibia through a fall on the ground in upright position. If there is no concomitant fracture line running into the joint and no shortening, the same treatment is used as in other transverse fractures.

Treatment of fractures with oblique lines

According to the force causing the fracture we can differentiate between five types in this group. Manipulation and immediate plaster mostly fail to give a good anatomical result. Extension for 2 to 3 weeks or longer has to precede plaster treatment.

Type 1.—This type of fracture is caused by shearing force. When in standing position the leg is hit by a violent force, such as a log rolling down a slope, the upper part is sheared off from the resting and fixed lower part. It results in an oblique fracture line with displacement to the side and shortening. A Kirschner wire or pin extension is established on the heel under local anaesthesia. Extension weight of 8 to 10 pounds is used and the leg is placed on a Braun-splint, or one of its modifications (Boehler, Eiselsberg). A stockinet sock is fixed to the skin of the forefoot by mastisol and the tip of the sock is tied to the horizontal bar of the upright frame, in order to prevent dropping of the foot. The fracture is open to inspection; blisters are left as they are. They are clipped off a few days after when epidermis has formed underneath. The knee is in a semi-flexed position. After a few days an x-ray examination of the leg in the splint is carried out by means of a portable machine. According to the position of the fragments weight is increased or diminished: if one fragment is displaced to the dorsal side, it can be lifted by a cotton pad placed beneath it. Displacement to the side can be corrected by side traction. A pulley is fixed to the side by a special frame mounted on the splint. If the alignment is good, plaster can be applied, after 2 to 3 weeks, on the orthopaedic table. The extension arch is fixed on the footpiece of the table.

To leave the pin with the arch has the advantage that we can still correct shortening without the help of an assistant. The dorsal plaster slab can also be more easily applied.

Many fractures show a spring-like resistance against alignment. By pressure with the palm on a fragment (it is in this type of fracture the upper fragment which is displaced medially) reduction is possible. But as soon as the pressure ceases the fragment returns to the old position. In these cases, I control, under the screen, where the pressure has to be applied and how much of it has to be used. Then a dorsal slab is applied up to two-thirds of the thigh. The nurse is advised to put only two plaster bandages in the water for immediate use. These are used only for plastering the lower leg. Then pressure is exercised on the fragment with the palm. Short screening reveals the effectiveness. If the fragments are reduced the pressure is maintained and the plaster allowed to harden. Another short screen control is done and then the plaster is completed by circular bandages and a walking-iron. The pin and arch are still included and removed after 2 to 3 days.

Further treatment is the same as described above. The period of plaster treatment will be slightly longer and the application of a second long plaster including the thigh will in most cases be necessary. If a wound on the heel prevents us from establishing pin extension, though the type of the fracture suggests it, a plaster is applied up to the knee. When the plaster has hardened a strap of lint 3 inches broad is put on its sides in a U-shape, the horizontal bar of the U forming a loop at the distance of 3 inches from the sole. The strap is then fixed to the plaster by a plaster bandage. The loop gives us a handle for extension which will act on the lower fragment. Over the heel, a window is cut out of the plaster and dressings applied to the wound. When the wound is healed necessary corrections in the position of the fragments are made and a plaster applied up to two-thirds of the thigh.

Type 2.—A wedge-shaped bone piece is forced out of contact from the resulting two fragments by a violent direct hit on the leg. If there is no displacement it can be hoped that the periosteum is not torn and that it will keep the fragments together. Primary plaster treatment can be tried. If there is considerable displacement of the wedge to the side, it is advisable to use extension. If a compound fracture of this type comes under our treatment within the first 6 hours the wedge should not be removed. In the case of osteomyelitis the wedge should be kept as long as there is no sign of necrosis. Removal will often lead to non-union and it could have been avoided in many cases.

Type 3.—Spiral fractures of the tibia and fibula occur through impetuous turning movement of the body when the foot is fixed.

there is no displacement and the fibula is not broken, as well as in green-stick fractures, primary plaster can be applied. Slight angulation and displacement however will induce us to apply extension because the displacement often becomes worse in a plaster cast. As a rule extension is applied. Care must be taken that bony spikes do not exercise pressure on the overlying skin and thus cause an ulcer. Angulations, displacement and shortening can be corrected in the same way as described before. If the upper fragment is displaced ventrally, this is due to the action of the quadriceps muscle. This can be relaxed by giving the knee a less flexed position through adjustment of the splint. When for some reason pin extension is impossible, a plaster-lint extension can be applied. After 2 to 3 weeks the leg is put in plaster under screen control. When attempting to correct drop-foot it often comes to recurvature of the fracture because the ankle joint is to some degree stiffened. This can be avoided by putting one hand under the fracture and correcting at the same time the position of the foot. Spiral fractures with short fracture lines sometimes show after 2 to 3 weeks' extension a more than usual movability. In these cases a second wire or pin is inserted through the head of the tibia. The fracture is reduced and plaster applied up to two-thirds of the thigh. The plaster between the two wires acts now as a strut and an inner unstable system is connected with an outer stable one. The patient can walk in this plaster and the wires are removed after 2 weeks.

Should a wound on the heel prevent wire extension in this type of fracture, plaster-lint extension is used.

Type 4.—Fractures of the head of the tibia with broadening of the head and fracture lines running into the joint occur through a fall on the heel in upright position. The two condyles are forced apart and broadening of the joint surface would, if not treated, result in a serious setback to function. Through extension on the heel, the shortening can be corrected, and partly the broadening. If the reduction is complete extension is left for 6 weeks. If there is still broadening after 3 weeks' extension treatment the patient is put on the orthopaedic table. Two wooden sticks with rectangular diameter (1 inch by $2\frac{1}{2}$ inches) are bound together by a rope so that the broad sides face each other (figure 6). They resemble now a nutcracker between whose branches the condyles are placed (figure 7). The fastened ends are at some

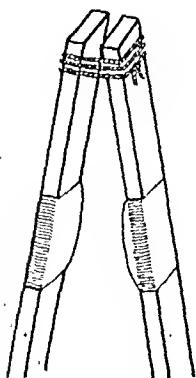

Fig. 6.—Nutcracker for compression of the head of the tibia.

between whose branches the condyles are placed (figure 7). The fastened ends are at some

distance below the knee. In order to avoid injury to the peroneal nerve the nutcracker is slightly turned so that the outer branch is more in front. The branches are padded with cotton-wool and pressure is exercised to approximate the condyles. If this is done plaster is applied up to two-thirds of the thigh for 4 weeks. Intra-articular fractures often lead to stiffening of the joint and we reduce the duration of the plaster cast to a minimum. After 4 weeks the plaster is removed. The leg still needs a support, but the knee joint must be allowed movement. A plaster is applied including the thigh, and after hardening, it is cut in the region of the knee joint leaving some space between the halves. The two parts have, however, to embrace the condyles of tibia and femur, respectively. Only over the patella a bigger half-circle is cut out of the upper cast. Then a hinge joint with longer iron bars is fitted to the plaster on the medial and lateral sides and fixed by plaster bandages. Their axis must correspond to the true joint axis. Thus, the pressure is taken from the fracture and movements are possible. The patient is advised to walk and to exercise his knee joint. After 4 weeks the plaster is removed and physical treatment started.

Type 5.—Fractures caused by gunshot, flying projectiles, or bomb splinters are mostly compound ones. The amount of damage done to the tissues and to the bone vary with the type of projectile, the velocity, the distance, and whether it is a direct hit or a ricochet. They range from simple holes in the skin and smashing of the corticalis to extensive crushing of the skin and comminution of bone. In cases where

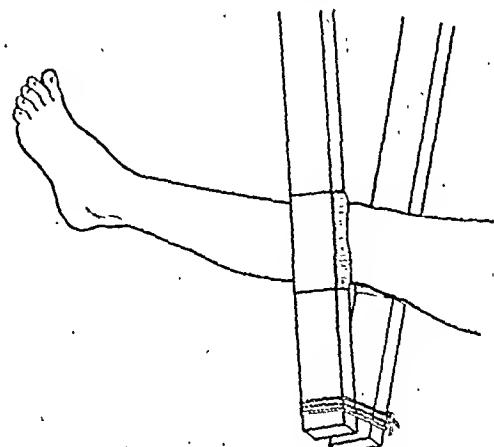

Fig. 7.—Nutcracker applied to the leg.

there is only a simple hole in the skin and the projectile is visible in the wound, excision of the wound margins and extraction of the foreign body and bone splinters can be done. If there is extensive crushing of tissues with comminution of the bone, no attempt is justified to probe the wound and to extract the bullet. If deep pockets are encountered, counter-incisions are done. But that should be the only surgical

MEDICAL PRACTITIONERS AND MEDICAL RELIEF AT THE MOGHUL COURT DURING THE REIGN OF AKBAR THE GREAT

By D. V. S. REDDY, M.B., B.S.
Andhra Medical College, Vizagapatam

Five classes of learned men at the court

ABUL FAZL classified the learned men of the time according to their knowledge. Five classes of men are mentioned as worthy of attention.

'The first class, in the lustre of their star, perceive the mysteries of the external and the internal, and in their understanding and the breadth of their views fully comprehend both realms of thought and acknowledge to have received their spiritual power from the throne of His Majesty.'

'The second class pay less attention to the external world; but in the light of their hearts they acquire vast knowledge.'

'The third class do not step beyond the arena of observation (*nazar*) and possess a certain knowledge of what rests on testimony.'

'The fourth class look upon testimony as something filled with the dust of suspicion, and handle nothing without proof.'

'The fifth class are bigoted and cannot pass beyond the narrow sphere of revealed testimony'.

The classes can be summarized thus; each class has many subdivisions.

First class: such as understand mysteries of both worlds.

Second class: such as understand the mysteries of the heart.

Third class: such as know philosophy and theology.

Fourth class: such as know philosophy.

Fifth class: such as understand sciences resting on testimony.

(Continued from previous page)

intervention on the wound, apart from a sterile dressing. If only one wall of the corticalis is smashed, a plaster should be applied with a window over the wound. If the fracture is a comminuted one, pin extension should be used.

Summary

1. The treatment of fractures of the tibia alone and of such combined with fractures of the fibula is decided by the type of fracture. Fractures with a transverse line do not need extension, whereas as a rule fractures with oblique lines will first be submitted to it.

2. Complications endangering the limb or the life, and those preventing us using the pin extension will induce us to modify this rule.

It is interesting to note that Abul Fazl includes the doctors in the fourth group. Blochmann explains that Abul Fazl takes the term philosophy to include 'testimony based on human reason'. In this wider sense, the scholar-physicians of the age naturally fall into the fourth group along with the mathematicians and astronomers.

Akbar's court was a permanent committee of intellectual co-operation, in philosophy and religion, literature, and medical science. The catholic tastes and liberal patronage of the Emperor attracted scholars and physicians of all nationalities, and religions. The Hakims, the Hindu physicians or surgeons, and European doctors stood side by side, basking in the brilliant sunshine of the Moghul patronage.

Moghul physicians and surgeons

Most of the Mohammedan physicians at the court were immigrants from Persia and Khoorassan. We have very little knowledge of many of the doctors beyond their names. Mulla Mir, Hakim Aristu, Hakim Nimatullah, Hakim Dawai, Hakim Talab Ali, Hakim Abdur Rahim, Hakim Rohullah, Hakim Fakhruddin Ali, Hakim Ishaq. Tabagat gives the following additional names: Hakim Jalal-ud-din Muhammad Ardisthani, Mulla Miran Sulaiman, Hakim Ahmed Tatui, Mullah Shahabuddin (a Gujarati Hakim), Hakim Ahmed Gilani (pupil of Hakim-Ul-Mulk).

More information is available about some other doctors. Hakim-Ul-Mulk, whose real name was Shamsuddin and who came from Gilan, was a very learned man. He knew philosophy and the science of medicine. Hakim Hassan, also from Gilan, was not very learned but was an excellent man. Hakim Zanbil Beg was a personal attendant on the Emperor. Hakim Fathullah, also from Gilan, knew a great deal of medical literature and astronomy; he wrote a Persian commentary on the 'qanun' of Avicenna. He left India during Jehangir's time, but his grandson Fathullah was a doctor during Shah Jehan's reign. Hakim Masih-ul-Mulk of Shiraj came to the Deccan and was a physician to Sultan Murad. Hakim Lutfullah came from Gilan and was a learned doctor in the service of Her Highness Mariam Makani. Hakim Shifai was a friend of Shah Abbas Cafawi and came to India. He was a poet also. Hakim Misri was a very learned man and a clever doctor. According to the fashions of the age, he also wrote poems. He was a man of most amiable and unselfish character. Abul Fazl visited him when he was on his death-bed in Burhanpur. Hakim Ruknuddin and Hakim Sadra arrived in India, in the later days of Akbar.

Brief but definite information has been preserved for posterity in the case of the following doctors:—Hakim Saiful Mulk Lang, came from Dama-wand and was in Agra during Bairam's regency. He was also a poet. He returned to his native place after some years at the Moghul's

court. Badaoni and *Tabaqat* both call him Saiful Mulk. He is said to have got the nickname of 'Saiful Hukuma' which means 'the sword of the doctors' because he killed his patients. Shaik Hassan and his son Shaik Bena came from Paniput, and were renowned surgeons. *Tabaqat* mentions that Shaik Hassan had great skill in surgery and was wonderful in the treatment of elephants. Father and son succeeded in curing a bad wound which Akbar had received from a buck at a deer fight. Shaik Bena's son is the well-known Shaik Hassan (Muqarab Kahn) who, under Jehangir, rose to great honours and was made governor of Gujarat, in which capacity he came into contact with the English at Surat in the early years of the 17th century. Muqarab Khan's son Rizqullah was a doctor at the court of Shah Jahan. Shaik Hassan may therefore be considered as the progenitor of a distinguished family of surgeons and physicians.

Another surgeon is mentioned in *Tabaqat*, 'Mulla Qutubuddin Kuhhal had great skill in surgery'. Hakim Jalaluddin Muzaffar came from Ardistan in Persia. He was first a doctor at the court of Shah Tahmasp and reached India when he was still young. Contemporary writers praised the purity of his character and walk of life. His theoretical knowledge is said to have been limited, but he was looked upon as a very experienced doctor. He is one of those physicians who had a political career. He served first in Bengal and later in Gujarat, during the reign of Jehangir. He was made a commander of three thousand. It is said that Jehangir was fond of him because he was one of the companions when he was a prince rebelling against Akbar. This Hakim was accidentally poisoned by his own compounder. He was also well known to contemporaries as a victim to a disease of the lungs, *garhah-i-shush*, for about 20 years before his death. It was believed that in spite of the disease he prolonged his life by his uniform mode of living. The interesting clinical condition from which he suffered has been recorded and will be reproduced in another place. Hakim Ain-ul-mulk Shirazi, a very learned man, had a high rank in the service of collyriums. Akbar liked him much. The Hakim later filled many high posts (Cadr of Bengal, Bhakshi of Agra).

Three eminent scholar physicians

One may now proceed to give sketches of the three most distinguished physicians at the court, who were also great scholars and personal friends of Akbar. Hakim Abul Fath, son of a learned Cadr of Gilan, fled to India with his distinguished brothers, Hakim Human and Hakim Nuruddin, when Shah Tahmasp conquered Gilan and began to persecute the people. They sought the patronage of the Moghul court and were well received. Abul Fath was first made Cadr and Amin of Bengal. Later, he went to the Moghul court and rose rapidly. He

was one of Akbar's favourites and possessed immense influence in state matters and on the emperor himself. Badaoni mentions Abul Fath's influence as one of the chief reasons why Akbar propounded his new religion. The Hakim went with the Emperor to Kashmir and from there to Zabulistan. On the march, he fell sick and died. During the return journey, Akbar stopped and prayed at Abul Fath's tomb. Abul Fath was as arrogant and insubordinate as he was learned and clever. It is said that Akbar ascribed the disastrous issue of a campaign in the north to the Hakim's insubordinate conduct and reprimanded him. Badaoni also mentions that he used to speak contemptuously of old Persian poets. There is, however, no doubt that he was both brilliant and learned. Abul Fazl and Badaoni speak of the vast attainment of Abul Fath. Even the contemporary poets sing his encomiums. Urfi of Shiraj and the great Shaik Faizi honoured him in their poems. The latter mentions the Arab doctors, Al-Faryall and Avicenna, before referring to Abul Fath as a doctor.

Hakim Huniam, one of the nine gems of Akbar's court, was the brother of Abul Fath. His real name was Humayun. He began to call himself Humayun Quli (slave of Humayun) when he reached Akbar's court. After some time Akbar himself gave the physician the name of Humam. He was the chief physician of King's harem. His official position was that of Bakawali Beg, or master of the kitchen. This was a very responsible post in the Imperial household, requiring sincerity, insight, and honesty, as the officer had to deal with preparation of the estimates for the foodstuffs, selection of articles and preservation, cooking of various dishes, and finally testing and safeguarding against possible mischief, in the transit to His Majesty's table. He was also a personal friend of Akbar and possessed great influence. He was a man of culture and wit and a brilliant conversationalist. Akbar often said that he did not enjoy his meals during Humam's absence, which was due to his being sent as an ambassador to Turan. Humam died in the fortieth year of Akbar's reign, leaving two sons, Hakim Haziq and Hakim Khushhal, who occupied some posts during Shahjahan's reign.

Hakim Ali of Gilan may be described as the greatest of the physicians at Akbar's court. He is also the best known amongst them. Ali came poor and destitute from Persia to India, but was fortunate enough to become, in course of time, a personal attendant and friend of Akbar. According to Badaoni, he learned medicine and science under Shah Fatullah of Shiraj, who excelled in natural philosophy and mechanics. On account of Ali's great learning, he was called the Mullah of Gilan and 'the Galenus of the age'. Jehangir writes that Ali composed a commentary on the 'Qanun'. Historians differ widely in their estimates of the

man. Jehangir's opinion of this brilliant physician is worth quoting. 'But his subtlety was greater than his knowledge, his looks better than his walk of life, his behaviour better than his heart; for in reality, he was bad and unprincipled man'. There is even a hint that Ali had killed Akbar. Badaoni states that Ali was a bad doctor, who often killed his patients. He is reported to have killed Fatullah by prescribing *harish* (a dish of crushed wheat, and ghee). To his credit, it may be said that he spent annually Rs. 6,000 on medicines for the poor. His knowledge was beyond question. Once, the Emperor himself tried a little trick to test him. Several bottles of urine of sick and healthy people and even of animals were shown to him, all in one lot. It is said that Ali correctly distinguished the different kinds, to the entire satisfaction of the Emperor. His astringent mixtures enjoyed a great reputation at the court. He treated Akbar immediately before his death. It is said the Emperor died of dysentery or acute diarrhoea, which no remedies could stop. The first attack was caused by worry and excitement, on account of the behaviour of Prince Khusru at an elephant fight for the championship. Akbar went home after the fight much annoyed and sent next morning for Ali, to whom he said that the vexation caused by Khusru's bad behaviour had made him ill. Ali had at last recourse to a most powerful astringent and, when the dysentery was stopped, costive fever and strangury ensued. The Hakim therefore administered purgatives, which brought back the diarrhoea, of which Akbar died.

In the 39th year of Akbar's reign, Hakim Ali constructed the wonderful reservoir (*hauz*) which is so often mentioned by Moghul historians. 'A staircase went to the bottom of the reservoir, from where a passage led to an adjoining small room, six *gaz* square, and capable of holding ten or twelve people. By some contrivance, the water of the reservoir was prevented from flowing into the chamber. When Akbar dived to the bottom of the reservoir and passed into the room he found it lighted up, and furnished with cushions, sleeping apparel and a few books. Breakfast was also provided. Jehangir visited this reservoir and made the Hakim commander of 2,000. But Ali did not enjoy the promotion long, as he died a year later.

Hindu physicians and surgeons

The information regarding the Hindu physicians at Akbar's court is very scanty. Abul Fazl mentions four physicians; Mahadev, Bhimnath, Narain, and Siwaji. *Tabaqat* adds two more names, Durga Mal and Abi. The same authority refers to three Hindu surgeons, Chunder Sen, Bhairam and Bairjiu. The last is said to be a Gujarati with much skill in surgery and in the use of collyriums. Professor Sri Ram Sharma, writing of the Sanskrit writers

of the age, points out that Kavichandra, Vaidyraja, Todar Mal and Nilakanth wrote treatises on medicine.

European doctors

That Europeans were in the Moghul service, even during Akbar's reign, is recorded by Abul Fazl himself. There was a colony of Armenians at Agra as early as 1562. Akbar came into contact with the Portuguese priests in 1573 and after that date, there was a regular intellectual free trade between Goa and Delhi.

There is a tradition that Juliana, an Armenian lady, who was in medical charge of the Emperor's harem, built the old church at Agra. Contemporary chronicles and tradition agree that there was a woman doctor, Juliapa by name, at the court of Akbar and that she was given by the Emperor in marriage to Prince Jean de Phillip de Bourbon of Navarre, when this adventurer appeared at the Moghul court. It is however believed that there was at Akbar's court another Juliana of Portuguese origin, with medical proclivities. This is further confirmed by a contemporary letter saying that the Portuguese first gained Akbar's favour through a lady doctor. As regards the European surgeons, no records are available which help us to ascertain the names. It is quite likely that there may have been some Armenian or Portuguese adventurers with some smattering of medical art. Manucci, who recorded the stories he heard in the middle of the 17th century, barely fifty years after the death of Akbar, has definitely stated that there were European surgeons in the service of Akbar and that Akbar was very fond of them.

Courtiers versed in medical lore

A few other learned courtiers and personal friends of Akbar were versed in medical lore, though they did not profess or practice medicine, as a calling. Amir Fathulla of Shiraz so excelled in all branches of natural philosophy, especially mechanics, that Abul Fazl said of him 'If the books of antiquity should be lost, the Amir will restore them'. Originally a native of Shiraz, he came to India to the court of Adil Shah of Bijapur, at the earnest solicitations of this king. After the death of this patron, he was invited by Akbar, who gave him positions of honour and titles. While staying in Kashmir in the camp of the Emperor, the Amir was attacked with fever and died. It is said that he sincerely believed that he understood the medical art. But, still, he could have taken the advice and prescriptions offered by Hakim Ali, the royal physician and also his own disciple. The Amir refused all medical advice and treated himself, with fatal results. He seems to have tried to cure himself by eating *harish*, which caused his death. He is best known for several of his mechanical inventions. Amir was loved and respected by Akbar, and was also instructor to the son of Abul Fazl. Faizi wrote a fine

ode on the death of the Amir. Sheik Faizi, the poet-laureate of the court and the instructor of Prince Saleem (Jchangir), was not only acquainted with medical science but had a fine collection of books on medicine and allied topics. Badaoni records that Faizi 'had no equals' in that age in such branches of knowledge as history, medicine, etc. He used to give lectures on 'Al-Qanun' of Avicenna. Some contemporaries mention Faizi as Hakim Faizi and also that he practised as a physician. It is known definitely that he had a charitable disposition and treated the poor free of charge.

Raja Todar Mal, a Kshatria by caste, rose to be the Dewan of the great King and remodelled the revenue system of the Moghul Empire. He was no less distinguished for his courage than for his financial abilities. In spite of his bad temper and bigotry, he was a faithful servant of Akbar. When old age and sickness compelled him to resign his high post, Todar Mal, like the orthodox Hindu and the scholar, retired to the banks of Ganges, for a life of study and contemplation. The work on medicine attributed to Todar Mal was probably written at this time.

The Portuguese Fathers at Akbar's court were not only learned in sciences but were also interested in the relief of human suffering. The Fathers were also on very good terms with Hakim Ali, physician to His Majesty. In the last decade of the 16th century, the Portuguese actually opened at Laliore (then the Moghul capital) a school for children of nobility to learn Portuguese. Akbar discussed philosophy and science with the Fathers and acquired a good collection of European books through these Fathers. Father Monserrate was a former professor of Lisbon, who tended the sick during the plague epidemic in Portugal and was acquainted with some elements of medical treatment. Father Xavier, in a letter dated 1598, tells of cases where persons were cured of illness by mere receipt of baptism or by hearing the gospel read to them. Akbar is also said to have approved a scheme for building a hospital and initiating what is now called 'a medical mission'.

Akbar's knowledge and alleged supernatural powers

Fazl also writes that His Majesty understood how to use elixirs and chemical processes, 'any kind of growth will alter the constitution of the body. Copper and iron will turn to gold and tin and lead into silver. The saying of the wise is true that the eye of the exalted is the elixir for producing the goodness'.

When Akbar became the spiritual guide, people began to believe in his supernatural powers. 'When His Majesty leaves court, in order to settle the affairs of a province, to conquer a kingdom, or to enjoy the pleasures of the chase, there is not a hamlet, a town, or a city, that does not send forth crowds of men and

women with vow-offerings in their hands, and prayers on their lips, touching the ground with their foreheads, praising the efficacy of their vows, or proclaiming the accounts of the spiritual assistance received. Other multitudes ask for lasting bliss, for an upright heart, for advice how best to act, for strength of the body, for enlightenment, for the birth of a son, the reunion of friends, a long life, increase of wealth, elevation in rank and many other things. His Majesty, who knows what is really good, gives satisfactory answers to every one, and applies remedies to their religious perplexities. Not a day passes but people bring cups of water to him, beseeching him to breathe upon it. He who reads the letters of the divine orders in the books of fate, on seeing the tidings of hope, takes the water with his blessed hands, places it in the rays of the world-illuminating sun, and fulfils the desire of the suppliant. Many sick people of broken hopes, whose diseases the most eminent physicians pronounced incurable, have been restored to health by this divine means'.

A passage in Murray's discoveries in Asia, (volume II, page 96) containing an account of the Moghul court derived from the Goa missionaries who came to Akbar in 1595 fully confirms the statement of Fazl.

'He (Akbar) showed himself every morning at a window in front of which multitudes canie and prostrated themselves; while women brought their sick infants for his benediction, and offered presents on their recovery'.

One of the occurrences was an outbreak of pimples in the body of prince Sultan Selim. This began on 12 Khurdad, divine month, and was accompanied by fever. The loving lord bent in meditation over the pillow of the nursling of fortune's garden and read in the pages of fate that he would be cured. So also did the ascetics, the astrologers and the soothsayers, give tidings of joy. But, as skilful physicians were not confident in diagnosing the disease, the ladies of the harem and the servants in general were not reassured. During this state of suspense, an eruption (*judain*) showed itself, and the physicians also now said that he would recover. In a short time it dried up and a feast was held in honour of his recovery. The world rejoiced and the auspicious gained knowledge about His Majesty's acquaintance with hidden things and made the prostration of benediction'.

A more remarkable case is the following : 'A simple-minded recluse had cut off his tongue, and throwing it towards the threshold of the palace, said, "If that certain blissful thought, which I just now have, has been put into my heart by God, my tongue will get well; for the sincerity of my belief must lead to a happy issue". The day was not ended before he obtained his wish'. The translator and editor of Ain-i-Akbari adds a footnote about the blissful thought of this fanatic. It is stated to be of the following nature : 'If Akbar is a prophet he must, from his supernatural wisdom,

find out in what condition I am lying here'. The poor fellow was perhaps observed and succoured.

Akbar's interest in dietetics

Ain 23, entitled Imperial Kitchen, begins with the following introduction : 'His Majesty even extends his attention to this department, and has given many wise regulations for it; nor can a reason be given why he should not do, as the equilibrium of man's nature, the strength of the body, the capability of receiving external and internal blessing, and the acquisition of worldly and religious advantages, depend ultimately on proper care being shown for appropriate food. This knowledge distinguishes man from beasts, with whom as far as mere eating is concerned, he stands upon the same level'.

Akbar as a surgeon

Fath Khan, the leopard keeper, was in despair about an illness of his eyes. 'Becoming hopeless about physicians he had recourse to supplications, and His Majesty cures him by breathing on him, with his Messiah-like breath'. Abul Fazl thus hints that this was one of the miracles of Akbar and adds 'physicians did not set up their acquired knowledge against the wisdom that was the gift of God and performed the prostration of supplication'. It is however known that Akbar cured Fath Khan's sore eyes by blood letting, a surgical procedure much in vogue at that time.

About the year 1570, occurred an event which throws some light on the current beliefs of the times. Abul Fazl writes, 'One of the occurrences was the arrival of the ambassador of the Rajah of Kajli which is a province of India near Malabar'. Some believe that it was from Cochin. The Rajah was distinguished among the landholders of that part for his territory and wealth. Having received some benefit from Jodis, he had since a year adopted their costume and treated them with honour. Anxious to send some rarities along with the son of his Vazier who undertook the adventurous journey to Delhi, but alive to the dangers of the road, this Rajah sent a knife made by former physicians of his country according to talismans and charms. 'Though in appearance it possesses no value, yet its virtue is that whenever it is applied to a swelling it removes it. I make over this rarity to you that you may put it into the hollow of staff and carry it with you so that it may be a memorial of me'. The ambassador set off and after paying homage to Akbar produced the rarity for which he was rewarded. Then comes the testimony of Abul Fazl on the personal experience of Akbar. 'To this day, the knife is in the general treasury. I have frequently heard from the holy lips of His Majesty that more than 200 persons who were near to death obtained health by touching that knife'.

It is said that Shaik Abdul Rahim of Lucknow drank so hard that he got frequently insane.

In one of these fits he wounded himself in Hakim Abul Fath's dwelling at Sialkot. Akbar looked after the wound himself.

Akbar treats a case of poisoning

'One of the occurrences was that Shaikh Jamal Bakhtiyar was saved from danger of his life by the blessing of the holy spirit of His Majesty. In accordance with this blame-worthy custom, many narrow-minded and envious ones were annoyed by the elevation of the Shaikh and took advantage of the carelessness of the butler to poison his drink. As soon as he swallowed it, there was a change in his condition. Darab, who was one of His Majesty's prominent servants, out of friendship drank some of the same fluid and he too at once fell into a confused state. They remained for a day and night in a dangerous condition. When His Majesty heard of this, he employed medical remedies and also somewhat of spiritual medicines and by the blessing of his attentions they recovered'.

Abul Fazl promises more case reports

Fazl concludes this section expressing a hope to write a full volume on this subject. Had he not been cut off in the middle of his life by a traitor, who knows what wealth of clinical material and therapeutic achievements of the age and of this sage, would have been available for posterity? 'But it is impossible, while speaking of other matters besides, to give a full account of the manner in which His Majesty teaches wisdom, heals dangerous diseases, and applies remedies for the severest sufferings. Should my occupations allow sufficient leisure, and should another term of life be granted me, it is my intention to lay before the world a separate volume on this subject'. The volume was never begun. Probably, Gods were jealous of Akbar, who would have also become deified, like Divodasa, King of Benares, now worshipped as Dhanvantri, an avatar of Vishnu.

THE TUBERCULOSIS ASSOCIATION OF INDIA (Report of sub-committee on classification of pulmonary tuberculosis)

THE lesson of the tower of Babel has been learnt. Whether we wish to build a tower to reach the skies, or, more ambitiously, to drive tuberculosis out of India, we must all speak the same language, and before we can do that it is necessary to decide what the best language for the occasion is to be.

The sub-committee of the Tuberculosis Association of India, after much labour, has produced a report on the classification of pulmonary tuberculosis.

There is no room for loose terms in the science of phthisiology and when one worker refers to the 'upper zone' or 'the apex', his friend at the other side of the bed, or of India, must know, not just more or less, but exactly what he means.

This is one of the many things that the committee decided (though it is a pity that the printer interposed a comma between apex and its verb). But, important though classification and definition is, there is much more than this in the report; there are valuable details of how to do such tests as the erythrocyte sedimentation rate and how to work out the rather confusing 'indices' which different workers apply to estimate progress.

Every serious tuberculosis worker in India must obtain and study a copy of this report and its valuable appendices.

ANNALS OF BIOCHEMISTRY AND EXPERIMENTAL MEDICINE

THERE is no dearth of medical publications in India. In recent years, these have increased in number very considerably and each province seems to feel that it must have its own medical journal, and often two or three. This sort of provincial pride will help nobody; it certainly does nothing to further medical knowledge in the country, for, frankly, many of these medical journals are not worth the paper on which they are printed. Their price is usually low, but, if they deflect the poor practitioner's few rupees a year that he can afford to spend on medical literature from being more profitably invested, they are doing positive harm; and everything should be done to discourage them.

A number of specialist journals have also appeared during the last few years. The motive behind the publication of these journals is a very different one; they are often published by some special society or association and though, as we have pointed out before, there is a danger that these journals will tend towards the segregation of specialist knowledge which is obviously undesirable, such journals, some of which maintain a high standard, will eventually take an important place in the country's medical literature.

There still remains the general research, as opposed to clinical, journal. The *Indian Journal of Medical Research* was first published in 1912 and except for its off-shoot the *Journal of the Malaria Institute of India* has stood alone as the main mouthpiece of the laboratory medical research worker in India. It is however an official journal and though it neither limits its contributions to one type of article, nor its contributors to members of the services or to employés of the Indian Research Fund Association, the majority of the contributors fall into one of these categories, and there is a very natural feeling amongst independent research workers that they should have a non-official journal in which they can publish the reports on their investigations. This is the particular hiatus that the *Annals of Biochemistry and Experimental Medicine* fills, and, we will add, fills remarkably well.

The format of this new journal is excellent; it is dignified and artistic, and compares very favourably with similar medical journals of other countries. The printers are to be congratulated and so are the editors, for the matter is well arranged, and in particular one notices that a considerable degree of uniformity in the presentation of references has been achieved, and this we know from experience means a very great deal of hard work on the part of the editorial staff.

We hope that we shall not be accused of 'admiring the frame'. The frame of a picture is of minor importance; the format of a journal is another matter, for, while the contents will vary from number to number, the format usually remains constant. There are in this number some extremely important contributions to medical science, and to dietetics in particular, and if this standard is maintained the journal will certainly take an important place amongst world medical literature.

We welcome this journal particularly because we receive from time to time scientific papers that should obviously receive early publication, yet we are unable to give them the preference that they deserve at the expense of clinical papers, or papers that have a more immediate clinical application. This type of paper will now have another outlet, and we shall be saved the

embarrassment of offending the writers by refusing or delaying the publication of, quite frequently, very important papers.

We congratulate all concerned in this new enterprise and wish it every success.

REPORT OF BOTANICAL SURVEY OF INDIA BENGAL FERN AND PLANT SPECIMENS

THE Superintendent and Curator of the herbarium of the Royal Botanic Garden at Sibpur botanized in parts of Darjeeling, Midnapur and Chittagong districts on behalf of the Bengal Government and brought several hundreds of flowering plant specimens and ferns for their studies and for incorporation in the herbarium at Sibpur.

It has been found that there are suitable localities in India for the cultivation of ipecac (*Cephaelis ipecacuanha*), a widely-used vegetable drug and one of the few known remedies for dysentery. A considerable quantity of the crude drug is now imported but it is believed that, with judicious cultivation, India may make herself largely self-sufficient.

An enquiry made on the tung oil or Chinese wood oil industry in the chief centres of cultivation revealed that there are considerable possibilities for the industry in India; tung oil is used in large quantities in India but much of it is imported.

There is ample scope for the manufacture of papain in India from the milk juice of the common papaya fruit, says the report. With the world demand for it increasing, the cultivation of the plant comparatively easy, and sites with requisite conditions of climate and soil numerous, the drug at its present attractive price offers good prospects for a large scale industry.

It has been discovered that the water-chestnut—*singhara*—a good source of clean and nutritious food, is available on a large scale and can replace sago, arrowroot and similar foodstuffs which find a good market in India. There are thousands of suitable sheets of water, says the report, which might yield rich crops of *singhara* root, with enterprise and cheap labour.

Quinine.—Sales from the Government of India stocks of quinine were confined to the centrally administered areas of Ajmer-Merwara and Baluchistan. The total stock of quinine was 97,071 lb. at the end of 1939-40 and the revenue realized amounted to Rs. 47,451. The stock has recently been supplemented by the purchase of a large quantity of quinine sulphate from Java for the use of the Government of India, the Provincial Governments, and some Indian States.

MORE SUBSTITUTES FOR FOREIGN DRUGS

More substitutes have been discovered for drugs formerly imported from England.

One of these is nikethamide, which has now been synthesized by an Indian firm. Another (sodium tauroglycocholate) a chemical used in bacteriological work has been manufactured by a Calcutta firm, and a sample approved by a Government bacteriological laboratory.

Soup-nuts are being tried by manufacturing depots as a substitute for quillaja cortex, an imported item used in the manufacture of liquor picis carbonis.

Tolu, largely used in the manufacture of syrup tolu, is now difficult to obtain and consequently experiments are being made to ascertain if tincture benzoin can replace tincture tolu, adding, if necessary, flavouring materials.

ASCORBIC ACID TABLETS FOR THE DEFENCE FORCES' NEED

Various firms in India are trying to produce ascorbic acid tablets, which might be suitable for the defence services. Samples of two firms are being tested and it is expected that with further advice and development the firms will be able to produce the desired article in the near future.

JUNE, 1941]

ABSTRACT OF THE MINUTES OF THE BENGAL COUNCIL OF MEDICAL REGISTRATION DATED 11TH FEBRUARY, 1941

1. The Council decided that after 11th February, 1941, no medical diploma granted in the Kingdom of Italy should be entered in the Register as a registrable qualification.

2. The Council decided that with effect from 1st April, 1941, the fee for registration should be raised from Rs. 15 to Rs. 20.

3. The Council resolved to recommend to Government for an amendment of section 6 of the Indian Medical Degrees Act, 1916, by insertion of the following words after the words 'United Kingdom' in the section:—

'or that he holds a degree, diploma, licensee, certificate or other documents issued in contravention of section 4'.

4. The Council decided that the attention of the Government of Bengal be drawn to the recommendations made by them in 1937 for improving the curriculum of the licentiatehip course on the lines which correspond very closely to the standard laid down by the Indian Medical Council.

THE FACULTY OF TROPICAL MEDICINE AND HYGIENE, BENGAL

THE following students are declared to have passed the D.T.M. Examination, session 1940-41.

Passed

(Arranged in alphabetical order)

1. Miss Cecilia Deevana Abraham, M.B., B.S. (Delhi), Dufferin Fund Service, U.P.
2. Altaf Uddin Ahmed, M.B. (Cal.), assistant surgeon, Government of Bengal.
3. Shaikh Tamizuddin Ahmed, M.B., D.P.H. (Cal.), private practitioner.
4. Hamindra Shankar Andleigh, M.B., B.S. (Lucknow), private practitioner.
5. Monoranjan Banerjee, M.B. (Cal.), private practitioner.
6. Miss Kaniz Bano, M.B., B.S. (Punjab), Women's Medical Service, India.
7. Dwijendra Krishna Bose, M.B. (Cal.), private practitioner.
8. Prafulla Kumar Bose, L.M.P. (Burma), L.T.M. (Bengal), demonstrator, pathology department, Burma Government Medical School, Rangoon.
9. Probodh Kumar Bose, M.B. (Cal.), private practitioner.
10. Nand Lall Chittkara, M.B., B.S. (Punjab), private practitioner.
11. Miss Seemah Cohen, M.B. (Cal.), private practitioner.
12. Miss Merlyn Colledge, M.B., B.S., D.G.O. (Madras), Women's Medical Service, India.
13. Hirendra Nath Dutta, M.B., B.S. (Rangoon), private practitioner.

14. Nirmal Ganguli, M.B., D.P.H. (Cal.), private practitioner.
15. Pashu Pati Ghosal, M.B. (Cal.), private practitioner.
16. Sachipati Ghosh, L.M.F. (Bengal), sub-assistant surgeon, Government of Bengal.
17. Shyam Sundar Ghosh, M.B. (Cal.), private practitioner.
18. Arin Kumar Gupta, M.B. (Cal.), private practitioner.
19. Mohan Hatangdi, M.B., B.S. (Bombay), private practitioner.
20. Harshadrao Ishverlal Jhala, L.C.P.S., M.B., B.S. (Bombay), private practitioner.
21. Pran Nath Luthra, M.B., B.S. (Punjab), private practitioner, Awarded the 'Chuni Lal Bose' Gold Medal, 1941.
22. Chhabildas Trikamjee Mehta, M.B., B.S. (Bombay), private practitioner.
23. Sadhan Kumar Mitra, M.B. (Cal.), medical officer, Naihati Municipality.
24. Hari Narayan Mukherjee, M.B. (Cal.), private practitioner.
25. Bibhuti Bhushon Mukhopadhyaya, L.M.F. (Cal.), pathologist, Matri Seva Sadan, Calcutta.
26. Benoy Krishna Nayak, L.M.F., L.T.M. (Bengal), private practitioner.
27. Surendralal Pande, L.M.F. (Dacca), assistant medical officer, Moran Tea Estate, Assam.
28. Harendra Chandra Paul, L.M.F. (Dacca), senior assistant medical officer, Central Hospital, Labac.
29. Balajapalli Lakshmi Kanta Sastri, M.B., B.S. (Andhra), private practitioner.
30. Kailash Narain Saxena, M.B., B.S. (Lucknow), honorary clinical assistant, Thomason Hospital, Agra.
31. Daiboki Nandan Sen Gupta, M.B. (Cal.), medical officer, Nuddea Jute Mills & Co., Naihati.
32. Sudhendu Sekhar Sen Gupta, M.B. (Cal.), private practitioner.
33. Hari Prosad Sinha, M.B. (Cal.), private practitioner.

THE ORDER OF THE HOSPITAL OF ST. JOHN OF JERUSALEM

THE King has been graciously pleased to sanction the following promotions in, and appointments to, the Venerable Order of the Hospital of St. John of Jerusalem:—

As Commanders (Brothers)

Major-General Norman Methvan Wilson, C.I.E., O.B.E., I.M.S., M.R.C.S.

Colonel Hugh Stott, O.B.E., M.D., F.R.C.P., D.P.H., I.M.S.

As Officers (Brothers)

Colonel William Galder Paton, I.M.S.

Lieut.-Colonel Martin Melvin Cruickshank.

As Associate Officers (Brothers)

Colonel P. B. Bharucha, O.B.E., D.S.O., I.M.S..

Sulphathiazole in the Treatment of Gonorrhœa: A Preliminary Report

By EDGAR G. BALLINGER, M.D.

HAROLD P. McDONALD, M.D.

and

REESE C. COLEMAN, Jr., M.D.

(Abstracted from the *Southern Medical Journal*, Vol. XXXIII, September 1940, p. 911)

Our experience with sulphathiazole and sulphapyridine has been encouraging. Although sulphathiazole and

sulphapyridine are both effective against the staphylococcus, the former is decidedly the drug of choice. In addition, sulphathiazole has been shown to be of value in the treatment of infection due to *Streptococcus faecalis*, a property which in so far as we know is not common to any other sulphonamide compound. Both derivatives are capable of producing urinary concretions because of the insolubility of their acetyl derivatives. We have not encountered clinical evidence of kidney or bladder stone in the patients we have treated. However, we have seen urines which would lead us to consider the patient a likely candidate if medication were continued. As regards gastric tolerance, very few

of our patients complained of sulphathiazole, while nausea and vomiting were observed in about 20 per cent of our sulphydryidine patients. It was interesting that patients who complained of being intolerant to other sulphonamides were able to ingest sulphathiazole without difficulty. This is an important advantage of sulphathiazole over the pyridine derivatives of sulphanilamide. It should be remembered, however, that large doses have been continued for short periods only.

CLINICAL RESULTS

Soon after the report of Carroll and his associates of their experiences with sulphonethylthiazole in the treatment of staphylococcal infections at the 1939 meeting of the Southern Medical Association we obtained a supply of sulphathiazole. We administered this product cautiously to patients who were unable to tolerate adequate doses of sulphanilamide as well as to patients with infections which were known to be resistant.

As our investigations proceeded it was observed that nearly all patients could ingest adequate doses without toxic reactions sufficiently disturbing to cause its discontinuance.

It was observed also that gonococcal infections which had been resistant to sulphanilamide often responded promptly to sulphathiazole. Patients who had first taken sulphanilamide or sulphydryidine were almost unanimous in their praise of sulphathiazole. Its use was naturally extended to the usual genito-urinary infections. This present report, however, is limited to our experiences with the use of sulphathiazole in the treatment of gonorrhœa.

The chief trouble experienced at first was in the somewhat limited supply of sulphathiazole available. Patients who were started with it usually were dissatisfied if the supply became exhausted and other chemicals had to be employed before they were well.

Duration of the infection and previous treatment led to the following classification:

- (A) Patients who come for treatment within the first two days after the urethral discharge appeared.
- (B) Patients with acute infections who reported after the discharge had been present for longer than two days.
- (C) Patients in whom sulphanilamide was not effective.
- (D) Patients who could not tolerate sulphanilamide because of its disturbing reactions.
- (E) Patients who could not tolerate sulphydryidine.

For the patients in group A, those in whom the discharge had not been present for more than two days, 20 minims of a freshly made silver protein solution was sealed in the anterior urethra once daily for 4 days. The intake of fluids was restricted so that the argyrol could be retained in the urethra for 4 hours at each treatment. Eighty grains of sulphathiazole were given daily for the first two days. For the next two days the dose was reduced to 60 grains daily. The sulphathiazole was given after meals and at bedtime. After the fourth day, all treatment was discontinued in order to determine at once if the infection had been eradicated.

In the group treated by this plan there were five. All obtained an immediate cure. By this we mean that the discharge disappeared after the first day, and the patient was well after the fourth treatment. The usual tests for cure were made in each case and the patient carefully followed for a period of four weeks.

These results in beginning infection will be misleading unless it is borne in mind that the not generally used plan of sealing silver protein in the urethra was employed in all of them. Similar good results have followed this procedure when sulphanilamide and sulphydryidine were used. In this group of patients the chemotherapeutic advantages of sulphathiazole were not so obvious as was its better tolerance by the patients.

In group B with infections of more than two days' duration there were 40. With them routine treatment with injections and irrigations was employed to supplement the use of sulphathiazole, the dose of which was about 40 grains a day. In those without complications the discharge usually disappeared within 2 to 4 days. The last glass of urine not infrequently became clear about the third day. The first glass as a rule became clear within 6 to 7 days. Shreds often persisted for about a week, sometimes two weeks, sometimes longer. The average time required for the patients in this group without urethral strictures, prostatitis, or epididymitis was 12 days. In the group with complications the average time was 21 days.

There were 8 patients in group C without complications who failed to respond to sulphanilamide. These patients, like those in whom the acute infection had subsided before sulphathiazole was started, usually yielded with promptness. The average time required for them was 14 days.

In group D, those unable to tolerate sulphanilamide, there were 3. In none of them was sulphathiazole sufficiently disturbing to require its discontinuance and the time necessary to effect a cure averaged 12 days.

In group E, those unable to take sulphydryidine, there were 3. All were able to take adequate doses of sulphathiazole. The average duration of their treatment was 12 days.

REACTIONS

The toxic reactions from sulphathiazole were about like the mild ones from sulphanilamide, rarely requiring more than a reduction in the dosage.

Sulphathiazole, like sulphydryidine, has a tendency to precipitate in concentrated urine when large doses are administered. As already stated, no stone formations in the kidney or bladder have been observed by us. We have, however, taken care to reduce the dosage or increase the fluid intake when the urine became hazy with precipitated sulphathiazole.

Peripheral neuritis, which sometimes arises from sulphanilyl-sulphanilamide, sulphanilyl-dimethyl sulphanilamide and sulphamethylthiazole was not noted in any of the patients treated with sulphathiazole.

The curative effects of sulphydryidine are generally conceded to be better than sulphanilamide in gonorrhœal infections. The chief disadvantage of sulphydryidine is its disturbing effect upon the stomach.

Our impression of sulphathiazole is that it is as effective as sulphydryidine in the treatment of gonorrhœa and far less disturbing to the patient.

Regardless of the mildness of the toxic reactions of sulphathiazole, it should be remembered that careful supervision is just as necessary during its administration as it is with other sulphonamide preparations.

SUMMARY

(1) Sulphathiazole was used in the treatment of 45 patients with gonorrhœa.

(2) It was observed to have fewer and less severe toxic reactions than sulphanilamide or sulphydryidine. No serious by-effect has so far been noted.

(3) It was more effective than sulphanilamide in the treatment of gonorrhœa.

(4) The doses used were about the same as those of sulphanilamide.

Treatment of Compound Fractures in War

[Reports of Practical Experience in the Spanish Civil War]

By LEO ELOESSER, M.D.

(From the *Journal of the American Medical Association*, 30th November, 1910, Vol. CXV, p. 1848)

It was evident to surgeons who took part in the late civil war in Spain that modern warfare was to differ greatly from previous wars and that the difference would be due to advances in the mechanics of transportation and especially to extensive use of aviation.

It was apparent that surgeons had much to learn and to unlearn in matters of organization, in evacuation of wounded and also in the treatment of war injuries. Especially noticeable was distrust in chemical antisepsis. Irrigations, Dakin's tubes and the complicated ritual of antisepsis that ornamented military hospitals in 1918 were unused or forgotten. Their place was taken by extensive incisions and plaster-of-paris splints. Rapid military movements and the need, after the bombing of thickly populated centres, of attending great masses of wounded called more than ever for surgical methods that were rapid and safe and that permitted of prompt evacuation with a minimum of postoperative attention. Trueta has written of these methods in his monograph on the *Treatment of War Wounds and Fractures*. The interest his manual has aroused is evidence of our concern for military preparedness.

For this reason a few further notes based on experiences gathered during the Spanish Civil War may not be amiss.

Rapidly moving warfare dominated by aviation makes simple surgical methods imperative. The necessity of concealing formations from view from the air and of moving men, wounded and supplies quickly, often under the cover of night, compels economy of materials, space and effort. Supplies and essentials are liable to be scanty or wanting entirely, either because they cannot be brought up or because they have been destroyed. Water, especially hot water, is liable to be short; liquid solutions and glass containers are liable to be spilled or broken. However, one learns to adapt oneself, and as the late Dr. Bethune wrote from China, 'I find I can get along and operate as well in a dirty Buddhist temple . . . as in a modern operating room with a thousand accessories'. The necessary economy and simplicity may by foresight and preparedness work rather to the advantage than to the disadvantage of the wounded.

PREPARATION

The most satisfactory easily transportable and easily procurable skin disinfectant, both for the surgeon and for the patient, is chlorinated lime.

The surgeon cleans his hands with a cream of chlorinated lime and soda worked well into the skin with a brush. If running hot water is scarce this paste is washed off by having a tiny stream of water trickle on the hands from an irrigator or a can with a spigot. Cleansing is as thorough as though a much larger stream were used. Following disinfection with lime and soda, alcohol, iodine-alcohol or a mercurial in alcohol acetone solution makes it easier to dry the hands and to put on gloves, but is not essential.

The patient is thoroughly shaved, either wet or dry, the hair being removed over the whole area which is subsequently to be encased in plaster. One applies a thick paste of chlorinated lime and soda to the skin of the operative field and removes the paste with moist gauze, working outward from the wound as a centre. This really cleans the skin of sweat, mud, dirt and grease; it may then be painted with one of the usual alcoholic antiseptic solutions, iodine or a mercurial.

Draperics should be small, so that the surgeon can keep the field under his eye and watch what unskilled assistance is doing. Large expanses of white sheeting are no guarantee of asepsis but are rather in the way. Four drapes about a yard square clipped or sutured to the skin are enough. The skin edges are further protected by large moist gauze squares. A well constructed metal sacral rest is indispensable; improvisation of boxes and enamel basins is most unsatisfactory, but a fracture table is not essential. Two pairs of small pulleys in the form of a block and tackle arranged overhead with other pulleys fastened to the wall at the foot of the table are just as serviceable and much easier to transport than a heavy fracture table. However, a fracture apparatus such as a Depuy or Zimmer apparatus makes the placing of Kirschner or Mathews wires easier.

ANÆSTHESIA

Some form of anaesthesia is desirable in which the patient is not entirely unconscious but is able to co-operate to some extent. His co-operation facilitates transportation to and from the operating room and saves work for stretcher-bearers, surgeons, orderlies and nurses. Soldiers at the front are notoriously easy to anaesthetize; they are usually in good physical condition, not overfed nor alcoholic and, when wounded, are often more or less on the verge of shock, so that a little morphine, a little sedation with barbiturates and a little inhalation anaesthesia go a long way toward freeing them of pain.

Thus preparation with morphine plus procaine hydrochloride infiltration around the site of injury is often all that is needed for the accomplishment of a thorough débridement and reduction of a compound fracture.

Plexus anaesthesia is very satisfactory for injuries of the upper extremity. Twenty c.c. of 1 per cent procaine hydrochloride plus two drops of 1:1,000 epinephrine are injected just above the middle of the clavicle; the needle is pointed toward the spinous process of the first dorsal vertebra. As it strikes the plexus, the surgeon feels a sudden tingling pain in the fingers. One should inject the full amount of procaine solution as soon as this pain is felt, moving the needle about a little to inject the various cords of the plexus. Anaesthesia follows almost immediately. If the needle misses the plexus it strikes the first rib; it should be moved about until the plexus is found. If injection is made too squarely into the plexus but around it, anaesthesia may take from fifteen to twenty minutes to develop. This interval may be used to attend to other wounded.

For lesser injuries, injection around the site of injury is all that is needed.

A little ethyl chloride inhalation given when all in readiness is sufficient for the few minutes needed to amputate a mangled arm through the site of fracture; the man wakes up immediately, may often walk to his bed, travel seated in an ambulance, and can be given hot drinks without nausea and vomiting. It is especially important that deep general anaesthesia be not used for injuries of the upper extremity, for thoracoplasty and plaster of paris is easy to apply if the man is seated but difficult or impossible if he is lying unconscious on a table.

For fractures of the lower extremity, low spinal injection of 100 mg. of procaine hydrochloride dissolved in 3 c.c. of spinal fluid injected while the man is seated with one or both legs hanging over the edge of the table produces an ideal anaesthesia. The injured man retains the use of his arms and can help balance himself on a pelvic support while plaster is being applied. Evipal or pentothal sodium injected slowly until a light narcosis is reached is satisfactory for men who are shocked or frightened. By injecting the drug slowly drop by drop, one can maintain a constant light narcotic level. Evipal, however, is not satisfactory in skull injuries with unconsciousness and delirium. It seems to increase the delirium and makes the wounded more unruly.

Ethyl chloride administered by dropping it, nebulizing it, spraying it, on an open face mask is a most satisfactory anaesthetic for short manoeuvres requiring good relaxation. At the moment when the patient first goes under the anaesthetic, when he takes a few deep sighing respirations, the mask should be slightly lifted to allow room for plenty of air. If this is done a sudden inhalation of highly concentrated ethyl chloride vapour is thus avoided, the anaesthetic is safe: there is no excitement stage and no struggling, which to wounded with fractures are harmful; relaxation is perfect, and consciousness returns without nausea or vomiting a few minutes after the anaesthetic has been stopped. No other inhalation agent seems to meet all requirements for short anaesthesia so well. Five minutes is to be regarded as the maximum duration of ethyl chloride anaesthesia; if more prolonged narcosis is likely to be needed, ethyl chloride should not be given; anaesthesia should be changed to ether. Bulky apparatus, inflammability and the need for expen-

anaesthetists preclude the wide use of gas in advanced hospital formations.

X-RAY EXAMINATION

It is seldom necessary to take an x-ray film of a compound war fracture before débridement. Inspection of the limb before operation and of the fracture during operation usually gives the needed information. Foreign bodies and the position of fragments are usually self evident in the course of a proper débridement. It is seldom necessary to take an x-ray film immediately after operation and immobilization if the operation is properly done and splints are properly applied. Radiography at the front is time consuming and cumbersome, fluoroscopy still more so.

The time and place for x-ray examination is at the evacuation hospital and farther back, at a time when fractured bone ends may have slipped or osteomyelitis and sequestration may be demonstrable.

The mobile surgical unit which I headed in Spain was equipped with a good modern portable x-ray apparatus and a dark room included in a mobile unit on wheels. They were not once used. The same was true of other advanced units which I had occasion to observe.

Conceivably radiography and fluoroscopy might be advantageous for chest wounds with suspected intrapleural foreign bodies or for abdominal wounds. It is questionable, however, whether its limited application in small advanced hospital formations calculated for rapid movement and intense activity justifies the time, weight, bulk and personnel needed for its management.

POSITION ON THE OPERATING TABLE

For injuries involving the front and sides of a limb, the wounded are placed on their back; if both front and back have to be dealt with, the limb is elevated or suspended so that the posterior surface is accessible. The man may also temporarily be placed on his side, but the fracture is likely to be considerably displaced in this position.

The arm may be placed on the operating table at the side of the wounded or laid across the chest; it may be held suspended from a pulley or abducted on an arm board or on a side table. It should be placed in the position in which final reduction is likely to be most easily accomplished and maintained. Draperies should not be so bulky that the fracture may be displaced by their removal; they should allow access to the arm and hand so that slings and pulls may be applied for maintenance of position while the limb is being splinted. The same consideration holds good for fractures of the lower extremity. The patient lies on his back; if the posterior surface of the limb is injured it may be placed in a Böhler frame or held suspended by slings and pulleys to allow access from underneath. In any event slings are best laid under the limb before débridement is begun so that the fracture may not be displaced later.

In amputation much blood can be saved and the tourniquet dispensed with if the limb which is to be amputated is suspended vertically upright from an overhead pulley by a clove-hitch passed around the ankle or the wrist. All its venous blood is returned to the circulation in this position, while with a tourniquet, however quickly and efficiently it may be applied, some venous stasis occurs while it is being tightened and the venous blood in the limb is lost.

DEBRIDEMENT

After everything is properly prepared and in readiness and not before, operation is begun; shaving should be complete, draperies adjusted with a view to their subsequent removal, slings and traction apparatus applied or laid under the limb ready for application; for it should be remembered that after débridement the soft parts and bones are to lie in the position which they are to maintain during healing. It is distressing both to the wounded and to the surgeon to see the limb jostled and moved during the application of retention apparatus, splints and bandages often to an

extent that should call for a new débridement before the plaster is finally applied. A tourniquet usually makes accurate inspection and operation easier. It should be used only if it can be rapidly and efficiently put on. It can be kept from slipping down on the limb by a towel clip through the skin or one or two sutures. A pneumatic sleeve is the best tourniquet for the arm, a wide rubber tube or an Esmarch bandage for the thigh.

Everything being in readiness, local, spinal or general anaesthesia having been induced, the skin edges are excised in the classic manner, retractors are inserted and held gently but firmly, devitalized muscle, contaminated bone chips, foreign bodies, missiles and pieces of clothing are removed. Special attention is paid to visible shreds of clothing and dirt. The position of the limb on the operating table is likely to differ greatly from that which it had when the missile struck it. Contaminated particles may be dragged up and down from a line drawn between the wound in the skin and the fracture; soft parts, muscle and fascia may have slid one over the other, occluding the tract. In order to lay all of these recesses wide open, the skin and fascia should be widely incised so that the recesses are not under tension and forcible retraction is not necessary to expose them. If forcible retraction is necessary at the time of débridement, the wound will be under tension later. Wide incisions into skin and fascia are unimportant and can be repaired perfectly; insufficient ones are very important and will determine future loss of the limb, sepsis, spreading osteomyelitis, gas gangrene and phlegmons of the soft parts. If the unimportant superficial structures of the skin and fascia are widely incised, more important deeper structures, muscle and bone, will be spared.

The wound should not be dabbed, rubbed and prodded with gauze sponges. If vessels bleed and it is necessary to use gauze in order to see them, the wound should be firmly compressed with a piece of flat gauze held in the fingers; the gauze should then be slowly rolled back until the bleeding point can be seen and caught with a haemostat. Wiping the wound with gauze makes it bleed more and wipes dirt into its crevices.

Necrotic and contaminated muscle should be excised; severed and contaminated nerve ends may be freshened and brought together with a single fine black silk suture left long and allowed to hang out of the wound if it is thought that suppuration is inevitable, or cut short if it is thought that the wound may heal. Formal accurate perineural nerve suture is rarely indicated.

Severed vessels should be caught and tied. Arterial suture is almost never possible or permissible. A compound fracture with a cold pulseless limb calls for amputation unless exceptional vigilance is possible during the first few days after injury.

Tendons lying in a contaminated area may be allowed to remain if they can be cleaned and covered by clean viable soft parts not under tension. If they are severed, their clean freshened ends may be approximated by a single suture and similarly covered. If it is not possible to cover them they had better be allowed to retract into their sheaths, for if they remain exposed in a wound they will certainly slough. More of them will be saved for secondary suture later if they are allowed to retract.

Open and exposed joints should be similarly covered. If it is possible to sew clean synovia over them without tension, their function may be preserved, but in no case should they be covered by skin sutured under tension.

Entirely loose fragments of bone should be removed. Grossly contaminated bone ends from which the periosteum has been stripped should be removed with the rongeur until clean covered bone appears. Grossly contaminated periosteum should be removed.

If the bone ends hold their position without internal fixation, so much the better. If they tend to slip they may be held by a wire passed through drill holes if it is possible to drill the holes without stripping the periosteum and traumatizing the fracture by dislocating its ends from the wound. Oftener it may be possible to grasp the bone ends and hold them approximated

with a towel clip, which should be left in the wound. If its branches cannot be closed, the handles may be tied together with a piece of silk or twine. Only if a bone is widely exposed and will obviously sequestrate is it permissible to use metal plates, which should lie fully exposed in the surface of the wound. Their application in the depths of a wound entails needless trauma and exposure of the bone.

Whether packing should be placed about the fracture depends on the extent and duration of contamination and the completeness of débridement. More or less sequestration will almost certainly ensue if the fracture is surrounded by gauze packs. If it is possible to surround it with soft parts without tension, it may heal without suppuration.

A few sutures are permissible when it seems expedient to cover vulnerable structures—tendons, cartilage, blood vessels—which die when exposed or which it is dangerous to allow to remain so. Such sutures should be of fine 00 or 000 catgut or fine silk (if the operator is incorrigibly silky) and should not create tension. If liberating incisions cannot loosen the parts to be sutured, suture had better be withheld.

If all structures lie perfectly loose and naturally, packing may be omitted. If contamination of the fracture site is such that the wound must be left unclean, it may be better to introduce a pack of iodoform gauze or plain gauze. In any event, it seems, in the light of newer experience, that it may be wise to sprinkle the wound liberally with sulphanilamide powder.

During the whole operation, which frequently it does not take as long to perform as it does to tell about, instruments should be changed or wiped and cleaned constantly with moist gauze. This applies especially to scissor blades and the teeth of tissue forceps. The gauze should be discarded each time, and no sponge or gauze should be introduced into the wound twice. Ample incision into the skin and easy exposure will make débridement, even of extensive wounds, not too time consuming.

SUTURE

After each débridement the question arises 'Shall the wound be closed by suture?' The answer is usually like Thackeray's to the young man about to marry: Don't. If the pros and cons are weighed each time, the cons will so outweigh the pros that there will be little doubt what to do. The pros reduce themselves to the advantage of a small linear scar—a negligible advantage. Shortening of time of hospitalization scarcely comes into question; for even though the wound is left open and allowed to granulate it will be closed or may be closed by secondary suture or skin grafting by the time the fracture is consolidated. The contras are overwhelming, for it will rarely be possible, in spite of the promptest and most complete débridement, to assure asepsis in extensive war injuries that warrant the performance of a débridement at all. And if such wounds are closed by skin suture producing even the slightest tension, danger to life and limb is great. In the best of events, if suppuration ensues, hospitalization will be measured in terms of years instead of months. Exception may be permissible in wounds of the hand, wrist and ankle, when the danger of serious sepsis is not great, when the skin can be approximated without tension and when valuable tendons will slough unless they are covered.

The wound is covered with small dressings of sterile gauze and the limb is immobilized for evacuation. In wounds that are likely to bleed, sterile gauze is preferable to Orr's petrolatum pack; wounds covered with petrolatum ooze and bleed much longer than when covered by sterile gauze.

APPLICATION OF PLASTER SPLINTS

The use of plaster of paris may justify a few generalities. In surgery, as in every other art, each material calls for its own technique and what is valid for one medium may not be so for another.

In the United States plaster of paris is used on crinoline or starched gauze bandages; in Spain and

France plain unstarched gauze bandages are used. Crinoline plaster bandages have more body and are easier to apply without wrinkles; however, their starch content delays setting and makes it necessary to use rapidly setting plaster of high quality (alabaster or dental plaster) if the cast is to set reasonably quickly. The casts are probably not quite so hard but are tougher than the ones made with unstarched bandages. Plaster on plain unstarched gauze is somewhat more difficult to apply smoothly, especially for those used to starched bandages; however, it sets more quickly without the starch, so that slower plaster of inferior quality can still be used satisfactorily. The casts are harder but more brittle than those with starched bandages; they are likely to be a little thicker. In France and Spain flannel cut to a pattern and immersed in a plaster cream is occasionally used. This is especially useful for jackets, body casts and half body casts (plaster shells). It saves time and trouble when properly applied. For general use when good plaster is available the crinoline bandage is probably preferable; if plaster of a poorer grade, and ordinary commercial plaster such as can be bought at most lime kilns, is all that can be had, unstarched plain coarse mesh gauze bandages are better.

Plaster-of-paris bandages conform to the shape of the body by being moulded to it; they have no elasticity and cannot, like gauze or flannel bandages, be pulled or stretched into shape. Their cohesiveness is great; they will not work or slip or stretch. Every crease and every wrinkle in them becomes petrified when the plaster sets and will cause intolerable pressure if it overlies a bony prominence. To pad plaster with absorbent cotton or some such material is to frustrate the purpose of plaster. It will immobilize imperfectly, for the limb will work up and down in its cotton sheath; it will be more and not less likely to cause pressure sores, for it is impossible to mould it accurately to the limb if it is separated from it by an uneven surface, such as that of cotton padding; and lastly and most important the immobilization due to the plaster sticking to the underlying skin is lost, and traction against muscle pull can be secured only by pressure of the plaster splint against flaring surfaces, such as the knee, the ankle, the dorsum of the foot, the heel and the hand below the wrist, instead of being equally distributed throughout the whole limb, as when plaster is applied directly to the skin.

It is obvious that some way of holding a limb must be devised that will keep it in position while the plaster is being put on. It is equally obvious that unless the limb will hold its position by itself, which it will not often do in fractures, its position cannot be retained by the hands of an assistant, for he must let go each time a turn of bandage or a splint is to come between his hands and the patient's skin. Some form of traction is necessary which can hold its place, at least until the plaster hardens, a metal pin, a bandage or some material that can be incorporated into the splint or retain its position under it. It is obvious again that the hands of an assistant do not meet these requirements. Plaster should be applied with regard for what it can do and what is required of it, and (especially in advanced hospitals where the wounded cannot be kept under observation) with more of an eye to what the next few days, weeks and months may bring than with regard to the needs of the moment.

The limb is kept in position by suspending it or pulling on it with bandages which are greased and are incorporated into the cast but are withdrawn before the man leaves the operating table, for they will cause pressure if allowed to remain. Or at times metal pins may be convenient. The need for these will not be great if unpadded casts are used. Traction should not be too forcible if there has been much loss of osseous substance, for a wide gap between bone ends is likely to lead to nonunion. The perfect relaxation of spinal anaesthesia increases the risk of wide distraction.

Dressings should be small, just large enough to prevent plaster of paris from leaking into the open wound; they should be held in place by a few small

narrow strips of adhesive and not by a bandage encircling the limb; slings should not be too wide; as much skin as possible should be left uncovered for the plaster of paris to adhere to. Painting the area around the wound with compound tincture of benzoin will prevent acne pustules from old wound secretions and help dressings and plaster to stick to the skin.

The plaster should be applied with due regard for the stresses and strains involving both the fracture and the neighbouring joints. Lateral strips are laid on first, a few layers at a time, two or three, not more than four. The fit of the cast depends on the neatness and accuracy of these inner layers. They are moulded with the hand to the shape of the limb. Creases and folds are removed by notching the strips or removing a V shaped dart, so that the plaster lies perfectly smooth. A half dozen layers or so are laid on and allowed to set a little; reinforcements are added by using shorter strips at the site of fracture or at the joints or by laying on longer strips folded lengthwise. After these longitudinal strips are hard enough to retain their shape and not buckle or dent, they are held in place by a circular bandage one layer only in thickness; no turns or folds are made in this bandage, but it is cut across and started again as soon as it ceases to run smoothly over the longitudinal strips and the limb. Care should be taken that the layers do not accumulate at the bend of the knee and the elbow. It is just here, where pressure is most likely to be harmful, that several layers of circular bandage are likely to overlap. When additional reinforcement is thought necessary, because the man is unusually robust or heavy or because profuse drainage is likely to wet the cast at the site of fracture or because transportation is likely to be long and hard, metal material may be added, but only after the cast is dry enough to resist pressure. If metal reinforcements are added before the plaster is quite set they will dent it and cause pressure points. Cramer splints (wire ladder splints) are particularly likely to do this. The metal, if rationally applied, need be only light and thin. Strips an inch wide cut from an ordinary tin can are just right. They can be bent and moulded by hand to fit the cast accurately. If they do this they are stronger than heavier metal which cannot be accurately applied. They are firmly attached to the surface of the cast with a single layer of circular plaster bandage pulled tight. They are placed at the level of the fracture or over joints so that their width resists bending strain; i.e., two pieces at each side of the knee, three or four pieces around a fractured femur, two pieces laterally for leg fractures. If thin aluminum sheeting is at hand this is to be preferred, being previous to the x-rays. The cast may be made thin in certain spots so that it can break, e.g., it is desirable to put a few spica turns around the hip and pelvis in high fractures of the leg, but it is not necessary to immobilize the hip. The cast should be thin at the hip so that it can break here. The ankle should be included in casts for fracture of the femur; but, if the cast is thin at the ankle, motion may be preserved.

Suspension strips and especially hitches about the wrist and ankle must be removed before the man leaves the operating room. If the cast inclines to bend or buckle at the point where it is cut for their removal, reinforcements may be added.

Finally, as long as the wounded can be constantly and carefully watched in the same hospital the circular turns may be allowed to remain; if, however, débridement and immobilization are only preparatory to prompt evacuation, before the man leaves the hospital the circular turn should be slit all the way either up the front or the back of the limb and the cast should be wrapped not too tightly with an ordinary gauze bandage. The cast will be less likely to break if it is thoroughly dry before it is slit, if it is possible to wait twenty-four hours, but it should be slit before the wounded man is evacuated, even though it is not thoroughly dry. In dubious wounds it is better not to wrap the cast but to slit it and leave it open. If

this is done there need be little fear of constriction or gangrene.

In fractures of the leg the cast is ordinarily applied with the leg lying flat on the operating table; lateral strips are first laid on, as far posteriorly as possible, they are allowed to set, and the circular bandage is then applied. If the leg lies on a rubber sheet the circular turns can be slid under it without lifting it from the table.

Fractures of the femur are put up with the man placed on a sacral rest, his shoulders supported by a box of equal height; the leg is held suspended from overhead pulleys with the knee slightly flexed; traction is made on the ankle by means of a hitch; another sling about the site of fracture keeps the femur from dishing. In the absence of overhead pulleys and in a pinch the femoral sling and the sling about the knee may be held by an assistant who stands on the table, one foot at each side of the fractured femur, facing the patient's feet. He brings the slings about his neck while his back is a little bent; as he straightens up the slings are tightened and the extremity lifted. A thick cotton pad is placed over the abdomen before the plaster is applied to allow for distension.

Fractures of the arm and forearm are put in plaster with the patient seated, on a stool if possible, on the operating table if not. It is almost impossible to put on a thoracobrachial plaster splint with the man lying on his back; hence the need for avoiding ether or prolonged gas anaesthesia. The so-called airplane splint, with the shoulder abducted at 90 degrees, is never used. Such a splint, whether of metal or of plaster, works only when the man is flat on his back; when he is up or has his head raised in bed the weight of the splint causes a valgus angulation of the humerus and produces the deformity it seeks to avoid. If transportation is to be comparatively easy, the arm is put up in 45 degrees abduction or less, with the forearm at right angles to the body in the sagittal plane; the cast should include the chest, both shoulders and the arm to the wrist with a turn or two around the hand, in what is known at the Bastos position, after Bastos, formerly professor of surgery at Madrid, now prisoner in a fascist concentration camp. Care should be taken not to tighten the turns about the chest; before they are applied the man should be called on to blow his chest up. If he cannot do this the lower part of the chest should be padded. The cast may be reinforced by a stick of wood or a Cramer splint leading from the chest to the elbow. It is not easy to apply and, unless it is fairly heavy, is likely to break at the elbow, and no great matter. The weight of the forearm sticking out at right angles to the body tends to twist the whole apparatus outward in order that the arm may drop inward. The projecting forearm makes transportation somewhat awkward; the man is likely to be jostled and bumped unless he is seated, when his knees protect the forearm. If, therefore, evacuation is likely to be troublesome it may be better to let the man carry his arm at his side and his forearm across his chest in a sling. Cotton pads are put under the arm and between the forearm and the chest; the sling, arm, forearm and chest are then encircled with a few layers of plaster of paris applied circularly. This position creates an inward rotation deformity of the lower fragment, but it makes evacuation easier, particularly if the man is to lie recumbent, to walk or to stand. The rotation can be corrected later on reaching the base and a Bastos splint applied in correct position. The man should be tagged to this effect when he is evacuated. Evacuation in a 90-degree abduction splint (airplane splint) is torture to all concerned.

A Wartime Pharmacopœia

By M. H. PAPPWORTH, M.D. (L'pool), M.R.C.P.
(Abstracted from the *Laneet*, Vol. I,
4th January, 1941, p. 3)

At present drugs are being used regardless of difficulties in replenishing stocks. We heed not the

JUNE, 1941]

morrow. Most doctors appear to be unaware of the supply problems with which the chemical firms will be faced in the near future. The writer suggests the following prescriptions as suitable for present conditions:—

Bromide mixture

R. Sodii bromidum	gr. 20
Liquor arsenicalis	m 3
Aqua chloroformi ad	5 1/2

Carminative mixture

R. Sodii bicarbonas	gr. 10
Tinctura cardamomi composita	..	m 30	
Liquor ammoniae aromaticus (B.P.C.)	..	m 30	
Aqua chloroformi ad	5 1/2

Rapid carminative mixture

R. Spiritus etheris	..	m 30	
Acidum sulphuricum aromaticum (B.P.C.)	..	m 10	
Aqua menthae piperitae destillata ad	..	5 1/2	

Colchicum mixture

R. Extractum colchici liquidum	..	m 5	
Sodii bicarbonas	..	gr. 10	
Sodii salicylas	..	gr. 10	
Aqua menthae piperitae destillata ad	..	5 1/2	

Antacid mixture

R. Kaolinum	gr. 15
Sodii bicarbonas	gr. 30
Caleii carbonas	gr. 20
Aqua chloroformi ad	5 1/2

Expectorant mixture

R. Amonii carbonas	gr. 3
Ammonii chloridum	gr. 10
Emulsio chloroformi (B.P.C.)	..	m 10	
Aqua ad	5 1/2

Sedative cough mixture

R. Diamorphinæ hydrochloridum	gr. 1/10
Tinctura chloroformi et morphinæ (B.P.C.)	..	m 5	
Liquor atropinae sulphatis (B.P.C.)	..	m 1	
Aqua menthae piperitae destillata ad	..	5 1/2	

Rhubarb and soda mixture

R. Pulvis rhei	gr. 5
Sodii bicarbonas	gr. 10
Ammonii carbonas	gr. 2
Aqua menthae piperitae destillata ad	5 1/2

Diuretic mixture for alkalinizing urine

R. Sodii citratis	gr. 30
Sodii bicarbonis	gr. 30
Aqua chloroformi ad	5 1/2

Diuretic mixture for acidifying urine

R. Ammonii chloridum	gr. 30
Aqua chloroformi ad	5 1/2

This is a simple but efficacious mixture.

Tonic mixture

R. Ferri et ammonii citras	gr. 10
Extractum nucis vomicae liquidum	..	m 2	
Infusum quassiae reeens ad	..	5 1/2	

Hæmatinic mixture

R. Ferri et ammonii citras	gr. 30
Emulsio chloroformi (B.P.C.)	..	m 10	
Aqua ad	5 1/2

Diaphoretic mixture

R. Liquor ammonii acetatis dilutis	5 2
Spiritus etheris nitrosi	..	m 30	
Sodii citratis	gr. 15
Aqua chloroformi ad	5 1/2

Anti-syphilitic mixture

R. Sodii iodidum	gr. 10
Liquor hydrargyri perchloridi	..	m 30	
Aqua chloroformi ad	5 1/2

Analgesic mixture

R. Phenacetinum	aa gr. 7 1/2
Acidum acetyl salicylicum	
Pulvis tragacanthæ compositus	
Aqua menthae piperitae destillata ad	5 1/2

Salicylate mixture

R. Sodii salicylas	gr. 20
Sodii bicarbonas	gr. 20
Aqua chloroformi ad	5 1/2

Chloral draught

R. Chloralis hydros	gr. 10
Sodii bromidum	gr. 20
Aqua chloroformi ad	5 1/2

Paraldehyde draught

R. Paraldehydum	5 2
Extractum quillaiae liquidum (B.P.C.)	..	m 10	
Aqua cinnamomi destillata ad	5 1/2

Reviews

SURGERY OF MODERN WARFARE.—Edited by Hamilton Bailey, F.R.C.S. Part II. Compiled by Sixty-Five Contributors. Section II—(Continued):—Wounds, Special Considerations. Section III—Wounds of the Trunk. Section IV—Wounds of the Blood Vessels. 1940. E. and S. Livingstone, Edinburgh. Pp. iv plus from 161 to 320. Illustrated. Price, 12s. 6d. Postage 6d.

The reader is referred to the review of part I in last month's number of this journal.

In the first twelve pages of part II the general treatment of the subject is concluded. Maggot therapy is given a detailed description: this original, but by no means untried, form of treatment has not been adopted much in this country where we believe it would be useful. It is advocated as a first-aid measure

where there is much destruction of tissue and where surgical treatment is likely to be delayed.

The first 'special' section is on wounds of the trunk; there are special chapters on the thorax; stomach, duodenum, liver and spleen; large intestine; rectum and buttocks; kidney; bladder; urethra; and scrotum, testicles and penis. More general chapters are on the evolution of abdominal war surgery, long-distance transport of the wounded, the care of the patient in hospital, the treatment of burns, and complications. The writers include Sir John Fraser, Sir Charles Gordon-Watson, and Messrs. Gordon-Taylor, Tudor Edwards, and Kenneth Walker.

The next section is on wounds of blood vessels. In this section, the first chapter is on the tourniquet; the authors describe the various tourniquets in common use and the methods for their application; it is a

chapter that will be appreciated more by those teaching first-aid than by the experienced surgeon, but it is a useful contribution. There are two chapters on the exposure of the main arteries of the limbs, and with the next chapter, on wounds of arteries, part II finishes.

The very great importance of this valuable and opportune publication need not be stressed.

MODERN MEDICAL THERAPY IN GENERAL PRACTICE. Edited by David Preswick Barr, A.B., M.D., LL.D. Volume II—Infectious Diseases, Diseases of the Nervous System, Diseases of the Digestive System. 1940. The Williams and Wilkins Company, Baltimore (Md., U. S. A.). Pp. from 1201 to 2446 plus xxxix in volume II. Illustrated. Obtainable from Messrs. Baillière, Tindall and Cox, London. Price for three volumes, £9 12s. 6d.

VOLUME II of this comprehensive publication includes infectious diseases, diseases of the nervous system, and diseases of the digestive system.

Infectious diseases are subdivided into those due to bacilli, cocci, spirochaetes, rickettsiae, viruses, mycotic organisms, protozoa, and metazoa, and diseases of unknown origin.

Typhoid is given first place and as far as diet is concerned the writer is uncompromisingly in favour of the high-calorie diet. (This diet is no new fad; it has been practised continuously in many countries since it was first advocated *thirty-three* years ago. It is a funny thing that the physician in this country who will scour the advertisements for the latest sulphanilamide preparation and put it into use almost before it has passed the experimental stages will still starve his typhoid patients.) We are reminded that Robert Graves wished 'He fed fevers' to be inscribed on his tombstone.

The next subject is also an important one in this country; it is on bacillary dysentery. The impression gained is that the writer's experience has been mostly amongst cases of the milder type of dysentery, especially that of children, but nevertheless there are some very valuable suggestions contained in this section. He will not entertain bacteriophage, but considers that vaccines may have an important place in the treatment and he quotes a forgotten (or have we missed it?) experiment in prophylaxis, undertaken at the end of the last war, with a mixed bacillary dysentery vaccine, in which some millions of subjects were involved; the result was apparently very satisfactory.

The treatment of diarrhoea is given in the section on diseases of the digestive system. There is, however, no overlapping; there is a useful classification of diarrhoea which will help the physician to run through the possible causes of diarrhoea before rushing into treatment. The treatment of ulcerative colitis is given under three headings which really represent three schools of thought as to the aetiology of this condition; he then gives his own routine, which seems to us to be the soundest (on p. 2309 he advocates the previously described diet on p. 2395; the error is however the printers', for the diet is on p. 2295).

For the reviewer's opinion on this important and valuable publication, the reader is referred to the review of volume I in our last issue.

A SHORT PRACTICE OF SURGERY.—By Hamilton Bailey, F.R.C.S. (Eng.), and R. J. McNeill Love, M.S. (Lond.), F.R.C.S. (Eng.). Fifth Edition. 1941. H. K. Lewis and Company, Limited, London. Pp. viii plus 1015, with 880 illustrations of which 116 are coloured. Price, 30s.

It is not hard to understand why this book has become so popular among medical students in this country.

Within the pages of a single volume of modest size are to be found the principles of surgery described in simple, but not telegraphic, language, and illustrated by splendid pictures wherever possible. Surgery that has only historical value is omitted, and advanced surgery is given in small type.

This, the fifth edition, shows numerous alterations in order to bring the material up to date; there is even a skiagram from a soldier wounded at Dunkirk.

The student of to-day is lucky indeed to have such a beautiful book to help him with his surgery, and we have no doubt of its continued success.

W. McN. N.

ORTHOPÆDIC OPERATIONS: INDICATIONS, TECHNIQUE AND END RESULTS.—By Arthur Steindler, M.D., F.A.C.S. 1940. Baillière, Tindall and Cox, London. Pp. x plus 766. Illustrated. Price, 50s.

This book is an important addition to operative orthopaedics by a well-known authority. In his preface, Professor Steindler describes it as a final account of his experience.

There is a short introductory section dealing with general principles, followed by a second section of twelve chapters on operative technique. A final section, to which 323 pages have been devoted, deals exhaustively with end results, selection of operation and operative indications. This layout is original and unusual, and, though it necessitates cross-references, is of more value to the surgeon in actual practice than more orthodox arrangements which are designed to facilitate the passing of examinations.

The writer has limited his text to the description of procedures actually used by himself. This entails some omissions, but increases the authoritative value of the work. It can be confidently recommended to all surgeons who are called upon to perform orthopaedic operations.

J. C. D.

PRINCIPLES OF HAEMATOLOGY.—By Russell L. Haden, M.A., M.D. Second Edition. 1940. Henry Kimpton, London. Pp. 362, with 104 Illustrative cases and 167 Illustrations including 173 original photomicrographs and 100 original charts and drawings. Price, 21s.

The reviewer has kept the first edition of this book close at hand since it was published two years ago, and has probably referred to it more frequently than to any other book on haematology; he has also used the diagrams as the basis for many of his class diagrams, and on occasions he has frankly copied the originals. The changes that have been made in the present edition are few, and would not have called for a new edition had the previous one not been exhausted; nevertheless, there are a few important additions, e.g., in connection with haemorrhagic diseases, which bring the book up to date, and on blood typing, which tend towards making it more complete. There are still no coloured plates, but there are some really excellent photographs of blood cells which are almost as useful. The author takes the view, and we are tempted to agree with him, that the identification of the cells found in a bone-marrow smear is the job of an expert.

The author's technique strikes us as being curiously defective in places. We have recently tried very hard to use his special haemoglobinometer and have found it neither convenient nor accurate. Accuracy is obviously not aimed at, as it only estimates to the nearest gramme.

The first edition has been the joy and despair of the reviewer for a period of over two years; the second edition is neither better nor worse, but is up to date and more complete. No teacher of medicine, pathology or physiology should be without this book, but no student, physician or laboratory worker should depend on it solely.

L. E. N.

CEREBRO-SPINAL FEVER.—By Denis Brinton, D.M. (Oxon.), F.R.C.P. (Lond.). 1941. E. and S. Livingstone, Edinburgh. Pp. vii plus 163. Illustrated. Price, 8s. 6d. Postage, 6d.

The publication of books on human ailments has seldom been so timely as the publication of this little book on cerebro-spinal fever. The increased prevalence

of meningococcic meningitis and the continued unfavourable conditions that this war imposes on the people of Britain has given the disease that increased importance which it invariably assumes in war-time. This alone would be sufficient to create a demand for a small and easily-read book like this one, for the use by physicians with little practical experience of the disease, but the introduction of sulphonamide compounds in the treatment of meningitis and the numerous scattered reports of its successful therapeutic action has created a need for a small book in which the subject is briefly reviewed and the essential features of the new treatment simply stated. This the author set out to do and has succeeded.

The summaries at the end of chapters 2 and 3 are so good that one regrets that summaries to the other chapters are not available; a summary at the end of the chapter on treatment would have been useful to the practitioner.

It is unfortunate that the author considered it necessary to include the confusing and impracticable distinction between recrudescence on the one hand and relapses and second attacks on the other. A recrudescence is said to arise from a dormant *meningeal* focus waking into activity after the main infection is overcome and is to be distinguished from relapses and second attacks in which reinfection by the *nasopharyngeal* route is presumed. This distinction will remain a confusing and impracticable one until a simple method for determining whether a recurrence has originated from a nasopharyngeal or meningeal focus is evolved.

The résumé of the treatment with the sulphonamide drugs is simple and to the point. The attention drawn to the danger of administering sodium sulphapyridine intrathecally is timely. The high degree of alkalinity of this compound, equivalent to deci-normal sodium chloride, produces a tissue necrosing action with serious degenerative effects on the cauda equina. The drug rapidly reaches the cerebro-spinal fluid after administration intravenously, so that the necessity for intrathecal administration is not apparent.

This book will find a ready sale, not only in Great Britain but also in India where cerebro-spinal fever is becoming increasingly prevalent in overcrowded cities, Calcutta, Bombay, and Delhi.

THE CHILD'S DISCOVERY OF DEATH. A STUDY IN CHILD PSYCHOLOGY.—By Sylvia Anthony, M.A. 1940. Kegan Paul, Trench, Trubner and Company, Limited, London. Pp. xvi plus 231. Price, 11s. 6d.

As Professor J. C. Flugel observes in the introduction he has written to this book, it is high time that man was brought face to face with the psychology of death. We can afford no longer to seek satisfaction in the mass of magical belief and practice which mankind has elaborated to bolster up his refusal to accept the fact of natural death. That Mrs. Anthony had a very hard task to perform when she set out to collect data about the ideas children entertain about death, no one who reads this book can doubt. As most people realize it is very difficult by direct questions to find out about what children really do think on account of resistance children offer to certain types of questions, particularly when addressed to them by strangers. Hence in this investigation direct questions with personal implications had to be ruled out, so Mrs. Anthony had to utilize two main lines of approach, (i) to record children's spontaneous remarks, questions and behaviour, and (ii) the story-completion test. This test consists of a series of brief story-openings which the child is invited to complete, verbally. Although none of the story-openings make any reference to death, the test when first applied in Geneva resulted in no less than 66 per cent of the children making some reference to death. Mrs. Anthony's researches have led her to hold the opinion that the idea of death occurs very readily in the phantasies of

normal children. She thinks that most children are pre-occupied in 'working over' the personal emotional significances of death. She is led to suppose that a child is liable to a strong sense of guilt when a member of his family dies and the reaction thereto is either excessive excitability or sullen unsociability, although different ages will react in somewhat different ways. The child's desire not to be separated from the dead loved-one may evoke a desire to be dead too with a corresponding fear of the fulfilment of this desire. On the other hand, children may seek to allay the anxiety they may experience through phantasies about death by denying that they can die. The book is provided with a very adequate bibliography and index.

O. B.H.

MALARIA CONTROL BY ANTI-MOSQUITO MEASURES.—By Gordon Covell, C.I.E., M.D., D.P.H., D.T.M. & H., Lieut.-Col., I.M.S., Director, Malaria Institute of India. Thacker, Spink and Co. (1933), Ltd., Calcutta. Second Edition. 1941. Pp. xi plus 224. Illustrated. Price, Rs. 7-8

TEN years have elapsed since the first appearance of this work, and in this second edition the author has summarized the published experiences of workers during this period from all over the world, involving the collation of no less than 1,148 references, which is double the number dealt with in the first edition.

It is illuminating to re-read the unchanged letter-press of the first part of the work, and to see how many of the methods advocated ten years ago have passed into the limbo of historical curiosities. None the less, it is likely that they will from time to time re-appear as fresh 'discoveries', and so it is very useful that they should remain on record, for relegation to their correct status.

It is unfortunate that certain investigations called for in the first edition have even now not been undertaken. For instance, whilst the wire mesh aperture necessary to exclude the very small Anopheles of the *funestus*-group has been worked out, the mosquito netting aperture necessary for the same purpose has not been, and the standard British Army mesh (p. 1 and fig. 1) appears to be too large for safety.

The use of adult check catches, so rightly stressed in this edition, has not been standardized, either in time, in location of catching stations, or as to whether (p. 33) morning catching of resting adults or the use of traps operating all night is preferable, either for the world as a whole, or for any particular malaria vector. It is true that studies on the adult habits of individual species are only now beginning to demonstrate how varied these are, but meanwhile each particular worker pursues his own preferred method, rendering results obtained by various workers incomparable.

In very recent years work on larval biology has been rather neglected in favour of work on adult bionomics, hence no further work has been done as to whether the anti-malaria effect claimed for clover (p. 27) may not have a basis quite unenvisioned by d'Herelle, by the raising of the nitrogen content of the soil and thus of the surface water (p. 84), whilst very little more has been done on the effects of various water plants on breeding (p. 82).

The effect of Paris green on the growth of rice, which has been the cause of so much debate in this country in particular, owing to the opposition born of ignorance that the procedure engenders among villagers, is left with no further comments in this than in the first edition (pp. 69 and 89). The author certainly gives a series of new references, but this is a subject on which an authoritative pronouncement is long overdue.

The change in the author's opinion of the comparative value of *Gambusia* over all other fish (pp. 79 and 118) is very interesting, and is one with which almost all other workers will find themselves in agreement.

A few minor points on which the reviewer could wish the author had been more explicit are:

P. 38. Breeding of *A. maculatus* can take place in weep holes in pukka drains, and, in localities where this species is a vector, requires dealing with by oil swabs, a rather laborious procedure.

P. 41. Expanded metal is better than vertical rods in preventing the entrance of small animals into subsoil drains.

P. 105. The reviewer is completely at variance with the opinion that the use of special 'spreaders' with mosquito oils is unjustified. The work quoted on p. 46, in his opinion, still stands. Without the addition of 1 per cent cresol, Diesel fuel oil, so much cheaper than Malariaol, can hardly be used.

P. 55. It is usually more important to know the number of linear feet of drain edge coverable by one gallon of oil discharged from the usual pressure sprayer, than the number of gallons required to treat one acre of water surface. The figure usually accepted varies from 500 to 750 feet, though Malayan workers will probably consider even the lower figure excessive.

P. 59, p. 66 (footnote). Where a very light diluent is used all the Paris green has often dropped out of the cloud, whilst the latter is still visible. Thus, if a fresh line of application is taken up from the line where the cloud disappeared, an area which is actually untreated is likely to remain. Soft stone powder has the advantage that its weight is not greatly different from that of Paris green, but there are many places, such as Italy, using road dust, where the point is of importance.

The work makes its appearance in the middle of a world war which so far has largely taken place in malarious countries. The anti-malaria officers of the armies are largely being drawn from young medical officers given some training before going on to this line of work. To such the book will be absolutely indispensable, whilst to those who have longer experience, both in civil and military, the mine of collected information comprised in the references will as before be invaluable. The author has again earned the gratitude of all workers in applied malariology.

R. S. W.

IDEAL MARRIAGE: ITS PHYSIOLOGY AND TECHNIQUE. By Th. H. Van de Velde, M.D. 1940. William Heinemann (Medical Books) Limited, London. Pp. xxvi plus 335. Illustrated. Price, 12s. 6d.

It is an astonishing thing, when one comes to think of it, that mankind after existing for 50,000 years on this planet, is still in need of instruction as to how and when and where he should copulate. This book is in its fourteenth impression. It has been translated into eighteen languages and is being translated into seven more, including Hindustani. It might seem that in time *Ideal Marriage* will be more widely read than the Holy Bible. Are we to deduce from these astonishing figures that at long last man is determined to prove his claim to the title *sapiens*? It looks very much as if this might be so, in which case the credit for establishing the claim will belong to this wise and cultured Dutch doctor. To any student of sexology, it should be evident that a knowledge of sex is in inverse ratio to what is ordinarily termed civilization. We do not reach full awareness of sex and all that it connotes until we are among quite primitive people. The reason for this state of affairs is by no means evident. Oriental asceticism and the teaching of St. Paul and the early Christian Fathers may account for a fraction of the prevailing ignorance of sex, but by no means all of it. Mahammed told his followers to 'go in unto your women they are as a tilth unto you'. He showed no concern about what his male followers would do when they arrived. Presumably he took it for granted that they knew what to do. If we are to believe Dr. Van Velde and there is no reason at all why the early converts to Islam were any less ignorant of how to copulate properly than 20th century Europeans and Americans.

No doctor and particularly no gynaecologist can afford to disregard this book. It were well were it included as a book for compulsory study in all colleges throughout the world. No doubt in time a chair of sexology will be recognized as essential a feature of a university as a chair of economics, or even more so. Had the author provided diagrams to chapter XI, part III, the book would be even more wonderfully interesting than it is.

Abstracts from Reports

BENGAL PUBLIC HEALTH REPORT FOR THE YEAR 1938

Cholera.—Cholera was responsible for 71,133 deaths in 1938 with a death rate of 1.4 per mille against 32,710 deaths with a death rate of 0.7 per mille in the previous year showing an increase of 100 per cent over the latter. It was also 40 per cent more than the average of the previous quinquennium (1.0). 5.4 per cent of the total provincial deaths in 1938 was due to cholera.

Cholera is usually seen at its worst in the month of April in which water scarcity is acutely felt in Bengal. But during the year under report, the disease attained its apex in November as the aftermath of the previous months' very extensive flood.

Smallpox.—Large scale epidemics of smallpox usually occur in a cycle showing its worst at every fourth or fifth year. Experience in Bengal in this respect has been rather different during recent years. Its course has been irregular and spasmodic rising suddenly as in 1936 with an unusual fall during the succeeding years. Nine thousand two hundred and eighty-nine persons died from smallpox in the province during 1938 against 27,944 deaths in 1937 with death rates of 0.2 and 0.6 per mille respectively. There was, therefore, 66.7 per cent decrease in smallpox mortality rate in 1938 compared with the previous year. Compared with the previous quinquennium, the rate also decreased by 50 per cent. Smallpox accounted for 0.7 per cent of

the total provincial mortality in 1938. Four hundred and sixty-one registration circles out of 712 and 2,599 villages out of 86,361 were affected with smallpox in 1938 against 470 registration circles and 5,983 villages in 1937.

Fevers.—Fevers took a heavier toll of lives in 1938 than the previous year.

Sale of quinine.—9,934.3 lb. of quinine were sold through post offices in 1938 against 8,729.8 lb. in 1937 and 6,007.3 lb. in 1936. Compared with the previous year, 14 districts showed an increase and 13 districts a decrease in the sale of quinine in 1938. While the average consumption of quinine per head from this source rose by 13.8 per cent, the fever indices rose by 5.9 per cent.

It has been estimated that for treatment of malaria cases Bengal has the capacity easily to consume 350,000 lb. of quinine every year. But during 1937-38 the amount of quinine used in Bengal was 112,353 lb. of which 51,839 lb. were locally produced and the balance of 60,514 lb. were purchased from foreign sources. The quinine factory at Mungpoo has the utmost capacity of producing 60,000 lb. of quinine per annum. The actual production of quinine at present is below the capacity of the factory (48,000 lb.) owing to deficiencies in bark supply. We may aim at the immediate production of at least 200,000 lb. and later 350,000 lb. It is essential that Bengal should strive

Specifications of fever deaths in 1937 and 1938

Causes	Number		Death rates per mille		Percentage of increase + or decrease — in 1938	Percentage to total fever mortality	
	1937	1938	1937	1938		1937	1938
Malaria fever ..	372,992	416,521	7.5	8.3	+ 10.6	48.1	50.8
Enteric fever ..	8,978	9,808	0.18	0.20	+ 11.1	1.1	1.2
Measles ..	4,875	2,969	0.10	0.06	- 40.0	0.6	0.4
Relapsing fever (spirochaetal) ..	2	3	0.00004	0.0001	+ 50.0	0.0003	0.0001
Kala-azar ..	21,227	21,642	0.42	0.43	+ 2.4	2.7	2.6
Influenza ..	2,422	2,143	0.05	0.04	- 20.0	0.3	0.3
Cerebro-spinal fever ..	938	1,337	0.02	0.03	+ 50.0	0.1	0.2
Typhus fever ..	2,814	4,034	0.06	0.08	+ 33.3	0.4	0.5
Blackwater fever ..	229	212	0.004	0.004	± 0	0.03	0.03
Other fevers ..	361,109	361,094	7.2	7.2	± 0	46.5	44.1

to increase her quinine output so that the provincial demand could be adequately met.

Dysentery and diarrhoea.—The total number of deaths reported from dysentery and diarrhoea in 1938 was 69,232 with a death rate of 1.4 per mille against 56,800 with the death rate of 1.1 per mille in 1937. The death rate increased by 27.3 per cent both against the last year's rate and that of the last quinquennial average. Thirty-six thousand one hundred and twenty-six males and 33,106 females died from these causes during the year under report. Taken separately, dysentery accounted for 37,966 and diarrhoea 31,266 deaths in 1938 against 31,289 and 25,511 deaths, respectively, in 1937, the ratios being 0.8 and 0.6 per mille against 0.6 and 0.5 respectively, in 1937. Dysentery and diarrhoea accounted for 5.3 per cent of the total provincial mortality in 1938 against 4.6 per cent in 1937.

Pneumonia.—After a temporary halt in 1937 pneumonia resumed its onward march in 1938, which commenced in 1923. The increase in deaths from this disease in the rural areas has been kept up ever since without any drop. During the year under report there was a slight reduction in deaths from this cause in the urban areas but in the rural areas and in Calcutta, the mortality was higher than in the previous year. In the province, the increase was by 7.1 per cent—in Calcutta by 3.2, in the rural areas by 8.7 per cent, while in the urban areas the decrease was by 5.7 per cent.

Pulmonary tuberculosis.—There was striking identity in the total number of deaths from pulmonary tuberculosis during 1937 and 1938, the figure being 14,668 in both the years with the same death rate of 0.29 per mille, although variations occurred under the heads making up the total. In the rural areas, the slight decrease in the total number did not disturb the last year's rate, but in the urban areas the death rate increased merely by 2.3 per cent. In Calcutta also, the slight increase in the death rate was equivalent to 1.1 per cent. Of the total number of deaths in the urban areas Calcutta alone was responsible for 68.4 per cent.

ANNUAL REPORT OF THE PUBLIC HEALTH DEPARTMENT IN THE CENTRAL PROVINCES AND BERAR FOR THE YEAR 1939

The year 1939 was less unhealthy than the average and was appreciably better for the public health than the preceding year. The death rate fell from 37.57 per mille in 1938 to 31.07 in 1939 owing to a large drop in cholera cases and reduction of mortality under all heads except smallpox and plague. The urban death rate was almost the same as the rural death rate. Infant mortality showed some improvement over the last year's rate especially in the urban area. The birth rate was slightly less than in 1938. The comparative figures of the death rate, especially infant mortality, in

this and other provinces constitute a challenge to increase the effort to better the conditions affecting public health in this province. While the province has the third highest birth rate in India, it has the highest death and infant mortality rates. Government hopes that with the reorganization and expansion of the public health department by the appointment of a sub-assistant health officer in each taluk it will be possible to effect substantial improvement in the whole of the province.

As compared with 1938, the year 1939 showed a decrease in deaths recorded from all diseases except plague and smallpox. The death rate from cholera (0.10 per mille) showed a welcome decrease over the previous year's figure (2.71 per mille) which was the result of a serious epidemic. There were 1,661 deaths compared with 45,332 in the preceding year. It is significant that rural areas suffered from the epidemic more than the urban areas, mainly owing to the unsatisfactory nature of water-supply in the province. This emphasizes the urgency of the need for improving the sources of water-supply on which the rural population depends. A sum of Rs. 2 lacs out of the Government of India grant of Rs. 6 lacs for rural reconstruction made in 1936-37 has been earmarked for improvement of rural water-supply, but Government regrets to observe that so far insufficient advantage has been taken of this offer. The main cause of the slow progress is the lack of the prescribed local contribution.

As usual, malaria took a heavy toll of life, the mortality attributed to this disease being as much as 54 per cent of the total mortality from all causes. The only defensive weapons against this disease at present are einchona and its products and every effort was made to increase the supply and free issue. Government had reduced the sale price of the drug but is now handicapped by the increase in prices occasioned by war conditions.

Smallpox was prevalent in a mild form in all districts except Bhandara. The Vaccination Act was extended to sixty-one villages in the Chanda district and the entire rural area of the Amravati district, but Government regrets to note that there is still considerable apathy and sometimes even opposition to the extension of compulsory vaccination in spite of its efficacy in combating the disease. Government also considers that at least one re-vaccination should be given to all children, although under the present law this is not compulsory.

Mortality from plague slightly increased, indicating that the comparative freedom of many districts from this disease for some years past may have bred a false sense of security. Certain municipalities have even suspended anti-rat campaigns on the withdrawal of the Government grant-in-aid for the purpose. It is needless to observe that sustained effort is necessary if the possibility of recurrence of the disease is to be entirely ruled out. The number of deaths was 852, compared with 535 deaths of last year.

Leprosy is widely prevalent in the province, particularly in the Bilaspur, Raipur, Drug, Chanda, Wardha and Chhindwara districts and in Berar, and the number of deaths from this disease increased to 1,804 (1,579). The number of persons found to be suffering from the disease was 117,577, 1,181 persons having been found to be newly infected. Attendance for treatment increased from 87,599 to 117,577; 112 cases were discharged symptom-free and 2,459 were recorded as improved. These figures sufficiently indicate the magnitude of the problem presented by this disease which increasing knowledge shows to be even more prevalent in this province than was apprehended. During the year the campaign against the disease was intensified. Four additional leprosy centres and seven sub-centres were opened, making a total of 41 and 58, respectively. Five 'leprosy district councils' were established as an experimental measure in the Amraoti, Chanda, Wardha, Buldana and Yeotmal districts, and a scheme for training all sub-assistant health officers on epidemic duty in leprosy survey, propaganda and treatment work, by opening classes under the leprosy specialist at Raipur was initiated. Government would like to pay its grateful tribute to the Mission to Lepers for the shelter, care and treatment given by them in their settlements in which no fewer than 2,155 lepers and 191 healthy children are given a home.

The mortality from pulmonary tuberculosis fell from 0.11 per thousand in the previous year to 0.07. The four tuberculosis clinics, one each at Nagpur, Jubbulpore, Amraoti and Raipur, are carrying on useful work. In response to Her Excellency the Marchioness of Linlithgow's appeal a provincial tuberculosis association was formed during the year and has been affiliated to the central association. The association is at present planning its campaign for anti-tuberculosis work in the province.

The mortality among infants under one year of age was 138,806 (157,634) or 218.62 (238.20) per thousand births, against a quinquennial average of 233.76.

The main causes of infant mortality are prematurity, inanition, malnutrition (chiefly owing to want of mother's milk), diarrhoea (due to faulty and dirty feeding), respiratory causes, and 'fevers'. Smallpox caused 241 (145) deaths among children under one year.

Government regrets to note that in spite of the increasing popularity of child welfare centres as shown by the all-round larger attendance at the existing centres there was no increase in the total number of centres. With the highest infant mortality in the country in this province no area can afford to neglect the welfare of infants and there is wide scope for local bodies and philanthropic persons to take up this vitally important work, especially in the rural areas.

Noteworthy among the activities of the department during the year were the introduction of a motor travelling dispensary at Nagpur which caters for the needs of the population with a radius of 20 miles and gives every promise of success, the increase in the number of epidemic dispensaries from 43 to 68 and the opening of 14 travelling dispensaries out of the Government of India grant for rural reconstruction.

REPORT ON THE STATE OF PUBLIC HEALTH IN BURMA DURING 1939

Birth rate.—This year's birth rate is 35.34. It is the highest since 1918. Compared with the five-year mean it shows an improvement of 2.01. Male births exceed female births in all but five districts.

Death rate.—The current year's death rate 25.09 shows a fall of 0.64 compared with the previous year but it is in excess of the five-year mean by 2.41. Decreases in mortality were noticed under plague, respiratory diseases, injuries and smallpox, while increases were noticed under fevers, cholera and dysentery and diarrhoea.

PRINCIPAL DISEASES

The major epidemic diseases in Burma are cholera, plague and smallpox. These diseases are notifiable

both in rural and urban areas. The responsibility for taking preventive measures rests upon the local bodies concerned.

Cholera.—The death rate from cholera, viz., 0.12 is higher than the previous year by 0.07 but it is below the five-year mean by 0.09. Though there was the usual rise in the incidence of the disease from April to July, it was in the month of December that the highest number of deaths was recorded. The Irrawaddy and the Pegu divisions were most affected. During the year, especially in the months of October, November and December, 23,468 anti-cholera inoculations were performed.

Plague.—The death rate from plague is 0.27. This figure is an improvement over the last year by 0.11 but is above the five-year mean by 0.07. Out of 3,266 deaths from plague reported during the year 2,282 were in rural areas.

Smallpox.—The total number of deaths recorded from smallpox is only 125 and the rate 0.01 is the lowest since 1872, the first year from which figures are available. Six per cent of the deaths in 1939 were among children under one year and 15 per cent among children between one and ten years. There was no marked seasonal variation in the incidence of the disease.

Enteric fever.—Though this disease is notifiable in all urban areas there is no true record of its incidence. Apart from admissions to hospitals the number of cases reported by private medical practitioners are few. Even in these, the diagnosis is more often based on clinical symptoms than on bacteriological investigation. The mortality figures also cannot be taken as accurate as the medical registrar has in most cases to rely on the history given by the relatives of dead persons and on the examination of dead bodies. During the year 383 deaths were recorded in towns from this cause and the rate of 0.27 is less than the previous year by 0.05. Very high rates have been recorded in the towns of Alannyo 1.52, Taunggyi 1.16, Yandoon 1.01 and Zigon 0.94.

Dysentery and diarrhoea.—This group of diseases accounted for 6,431 deaths and the death rate 0.53 is the same as last year. The highest mortality was, as usual, recorded in the month of July but the lowest was recorded this year in the month of February.

Respiratory diseases.—The total number of deaths returned under this head is 13,292. The provincial rate 1.10 shows an improvement of 0.08 compared with the previous year and 0.01 compared with the five-year mean. The rate for rural areas is 0.28 and that for towns is 7.29. It will thus be seen that the urban rate is 26 times that of rural. It is probable that poor housing conditions in towns are more favourable to the spread of these diseases than in rural areas, where the people lead a more out-door life. The number of deaths recorded in towns under this head is 10,300. Of these, 4,461 are ascribed to pneumonia, 2,520 to pulmonary tuberculosis, 6 to whooping cough and balance to other respiratory diseases.

Beri-beri.—The disease was prevalent in certain districts resulting in a fair number of deaths in some areas. In the urban areas 243 deaths were reported from this cause and the death rate of 0.17 shows an improvement of 0.16 compared with the previous year.

Malaria.—This disease forms one of the most widely prevalent diseases in this country and is responsible for a great deal of incapacitation and economic loss especially in the rural areas. It is, however, difficult to gauge its exact degree of incidence, as the registration of deaths is carried out by village headmen who are apt to include all fatal cases of malaria under 'fevers'. Nevertheless, spleen census taken in various parts of the province and the increasing number of malaria surveys undertaken by the Malaria Bureau have given a fair idea as to the areas in which the disease is endemic.

This year 39.82 per cent of the total mortality was due to fevers. If half the fever deaths in rural areas be taken to be due to malaria, it is seen that approximately 60,600 people died from this disease in Burma during the year under report.

Leprosy.—The number of deaths ascribed to leprosy in towns during 1939 is 365, the rate being 0.26. The largest number of deaths have been recorded in Rangoon and Mandalay. The presence of leper asylums in these towns, which attract lepers from all adjoining districts no doubt accounts for the greater mortality.

Colonies for housing, isolation and treatment of lepers continued to flourish at Mônywa, Mintu, Meiktila, Sale, Magwe, Shwebo and Nyaunglebin. In the Federated Shan States nine colonies were run by the American Baptist Mission and two by the Roman Catholic Mission. A new colony was started during the year at Satthadaw village in Insein district and proposals are on foot for establishing colonies at Bhamo, Thayetmyo, Nyaung-U, Thatôn, Pakôkku and Henzada. Many of the colonies have clinics attached to them in which leper patients both indoor and outdoor are treated by specially trained doctors on specified days every week.

This department took action during the year to implement the recommendations made by Dr. J. Lowe in his report. Two nominees of the executive committee of the Burma Tuberculosis and Leprosy Relief Association, two nominees of the British Empire Leprosy Relief Association, Burma Council, and two nominees of Government, *viz.*, the Inspector-General of Civil Hospitals, Burma, and the Director of Public Health, Burma, who constituted the *ad hoc* committee to study Dr. Lowe's Report have been constituted into a permanent Leprosy Advisory Board with the Special Leprosy Officer, Burma, as its honorary secretary to act as a consultative body on the subject of leprosy. Arrangements have been made for the further study of the problem of leprosy in Burma by carrying out four limited but intensive surveys in upper, middle and lower Burma and the Tenasserim area. The other recommendations contained in Dr. Lowe's Report, such as the entertainment of whole-time Superintendents for the three leper colonies at Mônywa, Shwebo and Meiktila, the amendment of rules under the Burma Village Act to allow segregation of lepers within villages and others are under correspondence with Government.

Tuberculosis.—Deaths from tuberculosis are recorded only in towns, while in rural areas they are classified under deaths from respiratory diseases. Out of 2,766 deaths from tuberculosis recorded in towns 2,520 were ascribed to pulmonary tuberculosis, 14 to tuberculosis of joints and the rest to other tuberculous diseases. The death rate from pulmonary tuberculosis is 1.78. This rate shows a drop of 0.17 compared with the previous year but is in excess of the five-year mean by 0.06.

Professor S. Lyle Cummins, C.B., C.M.G., LL.D., who came to Burma to advise the Burma Tuberculosis and Leprosy Relief Association on the measures necessary to control tuberculosis in Burma, spent six weeks in Rangoon studying the conditions in the city and its environments, visiting hospitals and performing tuberculin tests on school children and others. In the subsequent six weeks he inspected important places in Burma such as Mandalay, Shwebo, Kyaukse, Maymyo, Myingyan, Thayetmyo, Akyab, Moulmein, Bassein and Prome, studying housing conditions in each place, performing tuberculin tests and judging the suitability of sites for sanatoria. He has furnished the Association a very valuable report, recording his impressions and suggesting the lines of action to be taken. As a result of tuberculin tests made on over 9,000 people Dr. Cummins remarks that the incidence of infection is very low in Upper Burma, low in Lower Burma and that only in Rangoon its incidence is high. In Rangoon though the exposure to infection is as high as in England, the deaths are about four times as high, which would indicate that the people here are far from being as well able to resist the infection as the people in England. The mode of infection is chiefly respiratory. Housing conditions are such as to favour the spread of infection. The great need is for somewhere to place persons suffering from tuberculosis.

An *ad hoc* committee of the Burma Tuberculosis and Leprosy Relief Association considered Professor Cummins' Report and on its recommendation the Executive Committee of the Association has decided to make an offer of Rs. 2½ lacs to Government towards the construction of a tuberculosis hospital in or near Rangoon requesting Government to share the rest of the cost of construction and charges for equipment, maintenance, etc., with the Corporation of Rangoon.

Yaws.—Reports from districts reveal that campaigns for the treatment of yaws have been initiated by the Medical Department in a number of places. In the Upper Chindwin district the total number of cases treated since the commencement of the campaign was 10,210. In the Lower Chindwin district, a special sub-assistant surgeon was posted to Kani township for this duty. Treatment campaigns were also carried out in Mandalay and Tavoy districts by a special sub-assistant surgeon posted to each of these districts.

Goitre.—This disease is widespread in certain parts of the Northern Shan States. Kachins and Palaungs suffer severely. In some villages everyone has an enlarged thyroid gland. Towards the end of the year the Government of Burma deputed Captain R. L. Raymond, I.M.S., to conduct a survey of the incidence of goitre in the Chin Hills district, to investigate the causes of the disease and to report on the medical needs of the district. Two sub-assistant surgeons of this department were deputed to assist this officer in the survey. The Inspector-General of Civil Hospitals, Burma, has addressed the civil surgeons in nine districts, where goitre is known to be prevalent, to commence treating all school children by giving them half a grain of potassium iodide in solution twice a month. The medical officers in charge of the hospitals in the above districts were advised to carry out a census of the children attending schools in their areas to estimate the incidence of goitre and the civil surgeons were requested to enlist the co-operation of the administrative and educational authorities in bringing the scheme into operation.

REPORT OF THE DIRECTOR OF PUBLIC HEALTH, MADRAS, FOR THE YEAR 1939.

THE total mortality rate in the year was 25.26 compared with the average of 24.12 for the five years ending 1938. Both the urban and rural mortality increased. The number of infantile deaths accounted for 26.8 per cent of the total mortality, the total urban and rural infantile mortality being 179.69 and 175.08 per thousand respectively.

The mortality from cholera, *viz.*, 2,115 deaths in the year, was the lowest on record during the past 58 years. It is observed that out of these 2,115 deaths, the districts of South Arcot and Tanjore alone accounted for 854 and 806, respectively, the municipalities of Kumbakonam and Mayavaram alone in the Tanjore district accounting each for 27 and 21, respectively, against a total of 67 in nine municipalities. The report on the investigation of the high rate of mortality in these districts is awaited from the Director of Public Health.

The number of deaths from plague registered during the year, *viz.*, 324, was the lowest on record since 1898. Only five municipalities were affected recording in all seven deaths. The remarkable reduction in the incidence of the infection generally in the province is ascribed to cyanogas fumigation. The plague research work, which had been conducted under the auspices of the Indian Research Fund Association, was taken over by the Government; contributions were made by the association, the Government of Travancore and the Madura District Board.

The mortality from small-pox showed a large increase from 2,273 in 1938, to 3,120 during the year, the number of deaths from the disease in the Chingleput district alone being as high as 838.

'Fever' were responsible for 28 per cent of the total mortality. 'Other causes of deaths' again included 52 per cent of the total mortality. It is

unfortunate that there should be so much inexactitude in the recording; but there is at present no practicable means of avoiding it. Respiratory diseases were responsible for 21 per cent of the total deaths in municipalities giving a mortality rate of 6.81 as against 2.12 in rural areas. If the basis of classification is uniform this indicates the favourable conditions for the spread of respiratory diseases in big towns.

Anti-malaria work was continued in a few places, where there were reasons for special efforts. Anti-mosquito campaigns were organized in several municipal towns and *panchayats* and the results are reported to be satisfactory.

The health unit at Poonamallee continued its useful activities. The department maintained the progress achieved in health propaganda, rural sanitation, vaccination and maternity and child-welfare work. The percentages of cases that received skilled aid at child-births in rural and urban areas were 5.43 and 38.77, respectively. But the recorded maternal mortality rate per 1,000 births in those areas was as high as 12.13 against 8.63 in rural areas.

Maternity and Child Welfare

Maternity and child-welfare work in this province progressed steadily during the year.

One hundred and thirty-six thousand five hundred and thirty-two mothers, 105,679 ante-natal cases, 60,783 labour cases, 36,571 infants and 22,997 pre-school children came under the care of the maternity and child-welfare staff. Fourteen thousand two hundred and fifty-six clinics were held at which the attendance was 123,947 ante-natal cases, 133,900 infants, 111,266 pre-school children and 87,125 nursing mothers. Women medical officers, health visitors and midwives paid 57,493, 115,014 and 917,617 home visits respectively. Health talks were given in 821 girls' schools at which the total audience was 48,433.

From January to December 1939, four batches of rural medical practitioners, aggregating 115 have been trained in public health work and many of them have been entrusted with public health work.

The execution of the water-supply schemes for Arkonam and for Manapparai was completed and the schemes were brought into operation during the year under review. The number of towns, municipal and *panchayat*, having a protected water-supply was 45 as against 43 in the previous year. Thirty-two water-supply schemes, including extensions and improvements to existing schemes, were under execution during the year.

ANNUAL REPORT OF THE RAMAKRISHNA MATH CHARITABLE DISPENSARY, BRODIES ROAD, MYLAPORE, MADRAS, FOR THE YEAR 1940

AMONG the centres of the Ramakrishna Mission, the *Math* at Madras, now in existence for over 40 years, is a very influential one. As a side-activity of the *Math* the dispensary sprang up fifteen years ago. It was started in 1925 when Rao Sahib Dr. B. Raghavendra Rao, Retired Civil Surgeon of Madras, placed his voluntary service at the disposal of the institution, and undertook to meet the then recurring expenditure required for the work.

During the first year of its existence the total number of patients treated was only 970 whereas in the year 1940 the number was 61,543, which clearly shows that there has been rapid progress in its service.

Till recently there was only the allopathic department conducted on up-to-date lines. The homeopathic department was started three years ago.

Like all other philanthropic activities of the Mission the dispensary also is run mainly by private financial support. Due to general depression door-to-door collection, which has always been unstable, has now become very insubstantial. It is a pity that the institution may be compelled to limit the range of service to the poor under the circumstances. We are

glad, however, to mention a generous donation received this year from Sri M. V. Ramaswamy Mudaliar of a sum of Rs. 2,000 for the permanent fund.

The immediate needs of this institution are (a) a permanent endowment fund procuring a monthly income of at least Rs. 350 for the maintenance of the dispensary. (This amount is required for the purchase of medicines, bandages, doctor's allowance, salary of a paid clerk and an attendant boy and the bare expenses of four workers.)

(b) Suitable donations in kind or cash making available for the dispensary up-to-date medical appliances and necessary outfits for the surgical, pathological, medical, radiological and ear, nose and throat departments.

We appeal to the generous public to continue their active sympathy and co-operation, and to come forward with liberal contributions for fulfilling the immediate needs of the institution. Donors wishing to perpetuate the memory of their friends or relatives may do so by creating memorial endowments for the maintenance of the charitable dispensary. A tablet bearing the names of the persons whose memory is to be perpetuated will be fixed in a suitable part of the building. Contributions, however small, will be thankfully received and acknowledged by Swami Saswatananda, President, Sri Ramakrishna *Math* and Mission, Mylapore, Madras.

THE RAMAKRISHNA MISSION SEVASHRAM (CHARITABLE HOSPITAL), RANGOON: REPORT FOR 1940

THIS report is particularly concerned with the activities of the Rangoon Sevashram which is the premier medical institution of the Ramakrishna Mission.

Started in 1921 on a humble scale in response to a local demand, the Ramakrishna Mission Hospital has steadily grown in importance and usefulness until to-day it occupies a unique position among the medical institutions of Burma. Just after the great war, the authorities, apprehending an epidemic of influenza in Rangoon, put up a few temporary cottages on a marshy plot of land in East Rangoon which was then an undeveloped area. Fortunately, there was no epidemic and these cottages formed the nucleus of the present hospital. In 1921, the Government allowed the use of the land and the corporation the use of the cottages as a hospital on certain conditions. In 1926, the Government, in recognition of the valuable service rendered by this institution, gave an assurance of 'undisturbed occupation' of the site. In 1938, the main portion of the site, just sufficient for a permanent hospital of 300 beds, was demarcated and a general plan for the future development of the hospital was approved by the Government. Recently, the Corporation of Rangoon has also transferred to the Mission by a Deed of Gift all temporary cottages which had been previously erected by the corporation. These concessions gave the hospital a permanent status. The management of the hospital conveys its sincere thanks to the Government and the corporation for their sympathy and help and the tangible form in which they have expressed their trust and confidence in the Ramakrishna Mission and its ideals.

Indoor department.—The year closed with 200 beds for indoor patients. Of these, 34 beds were for women and children and 22 for maternity cases. The rest were divided into different sections of the male wards. In the male wards, besides surgical and medical sections, the hospital has provision for special departments for eye, venereal and pulmonary tuberculosis cases. The total number of indoor patients treated during the year was 6,681 against 5,263 in the previous year.

Outdoor department.—The outdoor department is very popular as will be evident from the number of attendance. The daily average attendance at the outdoor section was 1,025 in 1940 against 833 in the previous year.

ANNUAL REPORT OF THE HAFFKINE INSTITUTE, PAREL, BOMBAY, FOR 1939. BY LIEUT.-COLONEL S. S. SOKHEY, I.M.S., DIRECTOR

THE year under review did not see any radical changes in the organization or in the activities of the institute. As in previous years the institute produced large quantities of plague prophylactic and other vaccines and carried out diagnostic work for hospitals and private practitioners. The quantities of vaccines produced were:—Haffkine plague vaccine 2,887,527 c.cm., cholera vaccine 404,798 c.cm., typhoid vaccine 17,207 c.cm., and anti-rabic vaccine, 5 per cent suspension, 733,805 c.cm. Research activities of the institute were aided by a grant of Rs. 50,000 from the Indian Research Fund Association. Lady Tata Memorial Trust gave two scholarships for research work at the institute.

Chemotherapy of plague.—Researches into the chemotherapy of plague have yielded very important results and beget the hope that an effective remedy for bubonic plague is within sight. During the year syntheses of new sulphonamide compounds were undertaken at the institute by a research chemist endowed by the Lady Tata Memorial Trust. Of the 35 compounds prepared six were tested for their action on mice which had been experimentally infected with plague. One of these, sulphathiazole, the synthesis of which had also been reported by the workers abroad, was found to show a very remarkable power to cure plague. When given in adequate dosage this drug was found to save 80 to 90 per cent of the plague-infected mice, which have a mortality of 100 per cent if they are not treated. Another well known sulphonamide compound, sulphapyridine (M. & B. 693), was tested at the same time and it was found that it also had considerable curative action but only if it was given very early in the course of the disease. If the administration of this drug was delayed until 72 hours after the induction of infection, it saved no more than 10 per cent of the infected mice, while sulphathiazole still saved 80 per cent. Thus in animal experiments sulphathiazole proved to be superior to sulphapyridine (M. & B. 693).

At the time of writing the results are also available of a field trial on human cases carried out at Bettiah, Bihar, with the co-operation of the Bettiah Raj. During this trial Haffkine Institute anti-plague serum, sulphapyridine and sulphathiazole were tested for their curative action in plague. No selection of cases was made for a particular kind of treatment, admissions in rotation were given different treatments. But because the different treatments were brought into use at different stages of the field trial the number of patients in each group did not work out to be equal. Two hundred and thirty-seven cases were dealt with as follows:

All cases of bubonic plague treated

Treatment	Number of cases	Deaths	Case mortality, per cent
Anti-plague serum ..	70	20	28.5
Sulphapyridine ..	53	13	24.5
Sulphathiazole ..	32	5	15.6
Controls—treated with iodine solution intravenously.	82	43	52.4
TOTAL ..	237	81	..

During the field trials it was noticed that the most important single factor which decided the issue in human plague was the development of septicaemia. If the lymph glands prevented the spread of the infection to the blood stream and the infection remained

localized spontaneous recovery usually resulted. On the other hand, if the organisms passed the lymph glands and septicaemia resulted death invariably followed unless an effective curative agent was given to control the infection. Therefore, a truer picture of the results is presented if only those cases are considered in which septicaemia was present at the time the treatment was started.

Plague cases with plague septicaemia at the commencement of the treatment

Treatment	Number of cases	Deaths	Case mortality, per cent
Anti-plague serum ..	33	20	60.6
Sulphapyridine ..	30	13	43.3
Sulphathiazole ..	12	5	41.7
Usual hospital iodine treatment (controls).	40	38	95.0
TOTAL ..	115	76	..

Synthetic organic chemistry has during recent years yielded compounds of the greatest value to medicine. It is certain that this particular branch of research is destined to become even more important in the near future, particularly the chemotherapy of bacterial diseases. There is a great deal of chemical talent available in India, but chemists working in isolation by themselves cannot achieve much. For worthwhile work intimate collaboration of chemists and pharmacologists is essential. The institute is admirably suited as a centre for such collaboration. It would be a great gain if a permanent department of chemotherapy is organized at the institute.

Plague vaccine.—The study of physical conditions, the temperature of incubation and the duration of incubation under which the most effective plague vaccine can be produced, was continued. It was found that the specific immunogenic portions of the plague organism go into solution when the organism is grown in broth or when agar growths are suspended in water. It seems that the rejection of the bacterial debris from both the broth-grown vaccines and the agar-grown vaccines would yield decidedly less toxic but equally effective vaccines.

Serology of plague.—Carefully conducted agglutination and agglutination-absorption tests failed to show any serological difference between the various local strains of *P. pestis* studied. No serological difference was detected even between the virulent and avirulent forms of the organism.

Epidemiology of plague.—From 1931 to 1936, a steady reduction in the susceptibility to plague infection of Bombay rats (*Rattus rattus*) was observed. The mortality resulting from the standard infective dose declined from 9.3 per cent to 0.0 per cent. During the same period the number of plague infected rats found in Bombay during the routine examination of about 200,000 rats yearly, declined from 748 to 0. Since 1936 no plague infected rats have been found in the city. Because of the large number of rats examined it may be taken that plague epizootic among rats in the city has entirely come to an end. It is interesting to observe that the susceptibility to plague infection of the house rat in the city has begun to increase, as indicated by the increase in mortality from standard plague infective dose from 0.0 per cent in 1936 to 10.0 per cent in 1939. These observations indicate that with the dying out of the epizootic the susceptible strains of rats have begun to multiply again. This fact coupled with the other tendency observed that a highly susceptible species, *Gnomomys varius*, is gradually invading the city, and is now forming something like 40 per cent of the rat population indicates that the

position of the city as regards the possible recrudescence of plague is deteriorating.

Pharmacology.—The nature of the destruction of plasmoquine by the body tissues was investigated further and it was shown that the agents responsible for its destruction were probably enzymes and the organs chiefly concerned in order of their activity were, brain, liver, spleen, testis and kidney. The destructive product was isolated and its pharmacology was studied. Researches into the action of atebrin in monkey malaria showed that the drug did not act directly on the parasites but through the mediation of reticuloendothelial cells. It was also observed that plasmoquine stimulated the oxygen uptake of body tissues.

During the year there was an increased demand for the services of this department for the biological assay of drugs. This work the department cannot very well undertake as it is a purely research department maintained by the Indian Research Fund Association. Further, as legislation was recently passed to control the preparation and the sale of drugs, the province will have to establish a Pharmacological Department to carry out this control effectively. Such a department can be organized most effectively at the institute because of the facilities already existing there.

Besides carrying out analyses for testing the purity and strength of drugs for control work, the new department will discharge another even more valuable function. Strict control of the manufacture and sale of drugs will give an impetus to the production of drugs in the province itself. At the start, and perhaps for some considerable time to come, the manufacturing firms will not be able to afford highly developed scientific departments of their own for final exact testing of the products. This aid the institute can provide quite inexpensively. The department will thus by testing and advice promote the development of the industry.

Biochemistry.—Besides the routine diagnostic work for hospitals and private practitioners, the department continued its studies of the blood urea clearance test. One hundred normal Indian male subjects were examined. The average values obtained were 44 c.c.m. for maximum clearance and 34 c.c.m. for standard clearance. The corresponding averages for Americans were 75 c.c.m. and 54 c.c.m. respectively. This is a most useful set of observations for clinical work. McIntosh and van Slyke's blood urea clearance test is now very commonly used in India for determining renal efficiency in diseased conditions and if the American figures are relied upon the results obtained would be very misleading.

The department has also been working to prepare basal metabolic standards for use in India. This was made imperative by the studies carried out in the department which showed that the B.M.R. for Indians was lower than that for Americans by about 8 per cent. The use of American standards for evaluating B.M.R. for Indians was consequently misleading.

Entomology.—Investigations into the effects of different constant temperatures and humidities on the rate of growth of early stages of the three common Indian rat-fleas of the genus *Xenopsylla* were carried out. As the increase and decrease of flea population during different seasons of the year is a factor of extreme importance in the spread of plague, these studies are filling the gaps in our knowledge of the epidemiology of plague.

Anti-rabic treatment.—The policy of decentralizing anti-rabic treatment was continued and 14 new centres were opened making a total of 101 in the province. The easy availability of anti-rabic treatment near the patients' homes is making the treatment popular. It is hoped that more centres will be opened in the near future.

Service Notes

APPOINTMENTS AND TRANSFERS

COLONEL H. STOTT, O.B.E., V.H.S., is appointed Honorary Surgeon to The King, 30th July, 1940, vice Colonel F. F. S. Smith, v.h.s., retired.

The Viceroy and Governor-General has been pleased to make the following appointment on His Excellency's personal staff—*To be Honorary Surgeon*.

Lieutenant-Colonel J. B. Hance, C.I.E., O.B.E., vice Colonel E. S. Phipson, C.I.E., D.S.O., vacated. Dated 10th March, 1941.

Lieutenant-Colonel J. Rodger, O.B.E., M.C., an Agency Surgeon, is appointed as Residency Surgeon, Kashmir, with effect from the forenoon of the 2nd April, 1941.

Lieutenant-Colonel F. H. Whyte is appointed Civil Surgeon, Simla West, with effect from the forenoon of the 19th April, 1941.

On reversion to the Military Department, Lieutenant-Colonel C. M. Nicol, Director of Public Health, Punjab, made over charge of his duties to Khan Bahadur Dr. Abdul Hamid Butt, on the afternoon of the 20th April, 1941.

The services of the undermentioned officers of the Indian Medical Service (Civil) are placed temporarily at the disposal of His Excellency the Commander-in-Chief, with effect from the dates stated against their names:

Major H. W. Mulligan. Dated 17th February, 1941.

Major F. M. Khan. Dated 17th January, 1941. (afternoon).

Major G. W. Miller has been appointed as Principal Medical Officer, Royal Indian Navy, with effect from the 14th February, 1941, with the rank of Surgeon Commander, R. I. N.

Major B. N. Khan is appointed as Deputy Assistant Director-General (Medical Stores), Madras, with effect from the forenoon of 27th March, 1941, vice Major W. T. Taylor, appointed as D. A. D. G. (Medical Stores), Bombay.

Major R. L. Frost, Civil Surgeon, Myingyan, was transferred to the Military Department, vice Captain S. W. Allinson reverted to Civil employ. He relinquished charge of his duties as Civil Surgeon, Myingyan District, on the forenoon of 29th March, 1941.

Major W. T. Taylor is appointed as Deputy Assistant Director-General (Medical Stores), Bombay, with effect from the afternoon of 31st March, 1941, vice Lieutenant-Colonel W. M. Will granted leave.

Major K. H. A. Gross, M.C., an Agency Surgeon, is employed as Administrative Medical Officer in Rajputana, with effect from the forenoon of the 7th April, 1941.

On transfer from Dera Ghazi Khan, Major J. P. J. Little assumed charge of the office of Civil Surgeon, Murree, on the afternoon of the 16th April, 1941.

Captain S. W. Allinson, on reversion from the Military Department to the Civil Medical Department, was posted to duty in the Air Raid Precaution Department in Rangoon.

Captain W. S. Morgan, an Officiating Agency Surgeon, is appointed as Agency Surgeon, Bundelkhand, with effect from the afternoon of the 31st March, 1941.

Captain C. C. Harvey, Civil Surgeon, Sholapur, reverted to Military duty, with effect from the afternoon of 14th April, 1941.

INDIAN LAND FORCES

(Emergency Commissions)

To be Captains (on probation)

Kundan Lall Jetley. Dated 2nd December, 1940,
with seniority from 2nd December, 1933.

Coimbatore Venkatramana Krishnaswami. Dated
2nd December, 1940, with seniority from 17th February,
1939.

Chuni Lal Bhola. Dated 15th January, 1941, with
seniority from 15th January, 1936.

To be Lieutenants (on probation)

2nd December, 1940

LEAVE

The Governor is pleased to grant leave for 6 months to Major-General P. S. Mills, K.H.P., C.I.E., Surgeon-General with the Government of Bengal, preparatory to retirement, with effect from the 16th May, 1941, or the date of availing.

Lieutenant-Colonel W. M. Will, Deputy Assistant Director-General (Medical Stores), Bombay, is granted leave on medical certificate for 3 months, with effect from the forenoon of 1st April, 1941.

PROMOTIONS

To be Acting Major-General

Colonel J. Taylor, C.I.E., D.S.O., K.H.S., I.M.S. (Retd.) whilst holding the appointment of Director, Central Research Institute, Kasauli. Dated 14th February, 1941.

Colonel to be Major-General

A. A. C. McNeill, K.H.S. Dated 27th March, 1941.

Captains to be Majors

H. B. MacEvoy. Dated 3rd February, 1941.

F. C. Jackson. Dated 8th April, 1941.

J. D. Grant. Dated 20th April, 1941.

J. W. Bowden. Dated 20th April, 1941.

The seniority of the undermentioned officers in their present rank is antedated to the dates specified:—

Captain S. Rameshwar. Dated 5th March, 1935.

Captain J. R. Vaid. Dated 24th June, 1935.

RETIREMENTS

Major-General I. M. McCrae, C.B., C.I.E., O.B.E., K.H.P. Dated 27th March, 1941.

Colonel J. Taylor, C.I.E., D.S.O., K.H.S. Dated 14th February, 1941.

Lieutenant-Colonel J. H. Smith. Dated 15th March, 1941.

Lieutenant-Colonel H. C. Tait, M.B.E. Dated 7th April, 1941.

Lieutenant-Colonel L. A. P. Anderson. Dated 18th April, 1941.

Notes

HEXOBARBITONE

HEXOBARBITONE (N-methyl-cyclohexenyl-methylbarbituric acid) is now issued by Burroughs Wellcome and Co. as Tabloid hexobarbitone and as the sodium salt, soluble hexobarbitone, the latter for producing anaesthesia of short duration for which it is injected intravenously. Soluble hexobarbitone is of particular value in minor surgery, in simple tooth extractions and to intensify gas-and-oxygen anaesthesia. It may also be used for the induction of general anaesthesia in operations of not more than 20 to 30 minutes' duration, and, by rectal administration, to produce hypnosis and in the treatment of acute and chronic alcoholism. Soluble hexobarbitone (B. W. and Co.) is issued in phials of 0.5-gm. and 1-gm., each strength in boxes of 5 and 25 phials. Each phial is accompanied by a Hypoloid ampoule containing sufficient sterile distilled water to prepare a 10 per cent solution of Hypoloid soluble hexobarbitone.

Tabloid hexobarbitone, gr. 4, is given orally to produce light hypnosis. It is issued in bottles of 25, 100 and 500.

METHEDRINE

METHEDRINE (*d*-methylisomyn), the issue of which is announced by Burroughs Wellcome and Co., Snow Hill Buildings, E.C.1, is a recently discovered synthetic compound belonging to the sympathomimetic amine group. Given orally, it produces a prolonged rise of blood pressure and stimulation of the central nervous system, especially of the cerebral cortex. Methedrine is particularly indicated in the treatment of narcolepsy; it may also be of value in certain depressive psychopathic conditions, as an analeptic in barbiturate poisoning, and as an antispasmodic in the x-ray visualization of the gastro-intestinal tract.

The compound is issued for oral administration as Tabloid Methedrine hydrochloride, 0.002 gramme, in bottles of 25 and 100.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints gratis; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more, after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributors should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

TOXIC COMPLICATIONS OF SULPHANILAMIDE THERAPY

(AN ANALYSIS OF 6,070 CASES TREATED IN THE VENEREAL DEPARTMENT OF THE GOVERNMENT GENERAL HOSPITAL, MADRAS)

By R. V. RAJAM, M.B., M.S. (Madras), M.R.C.P. (Edin.)
Venercal Specialist, Government General Hospital, Madras

and

N. VASUDEVA RAO, M.B., B.S.

Honorary Assistant Medical Officer, Government General Hospital, Madras

THE extensive use of sulphanilamide and its derivatives in the chemotherapy of coccal and bacterial infections has resulted in a certain

afforded us an opportunity for clinical study of the toxic manifestations of the drug.

The majority of the cases undergoing treatment in the department are ambulatory and only those whose illnesses are very acute or who develop a serious toxic complication are admitted to hospital. During the three-year period (October 1937 to October 1940) 6,070 cases were under treatment, of whom 5,076 were males and 994 females. A smaller number of female children were treated in the clinic, but are not included in this paper. Sulphanilamide is the drug in routine use and the costlier, though therapeutically more effective, sulphapyridine was used only in a very small number of cases.

Table I gives an analysis of the toxic reactions noted.

Fever.—This is the commonest of the toxic reactions observed in the course of sulphanilamide therapy and occurs in the majority of the cases between the fifth and the tenth day of treatment. Fever either occurs alone or is

incidence of toxic reactions. An increasing volume of literature has been appearing in the medical press regarding the frequency and the severity of these toxic side-effects. The routine treatment of a large number of cases of gonorrhœa, chancroids and venereal lymphogranuloma with sulphanilamide in the venereal department of the Government General Hospital during the past three years has

associated with the development of some other complication such as dermatitis, leucopænia, or breathlessness. Four types of fever were recognized among the cases :

1. A low intermittent fever, the temperature rarely going beyond 100°F., with the evening rise and morning remission, lasting for a few days.
2. A sudden rise of temperature to 103°F. or 104°F., preceded by a chill and coming down by crisis in about 24 hours.

3. The third type is similar to the second except that the fever continues for about three days, slowly coming down to normal on or about the fourth day.
4. In this type, there is severe shivering followed by high fever 104°F. or 105°F.; patient looks very ill and toxic. Blood count reveals a profound granulocytopenia or agranulocytosis.

Graphs showing different types of febrile reaction.

The development of fever is indication for stoppage of therapy and it is our practice to admit these cases as in-patients for observation, and performance of blood count. Only in about 6 per cent of these cases did the blood count show any abnormality. The resumption of treatment brought on the fever of a more severe form in the majority of the patients. In a few cases, change to another derivative of the drug failed to produce the fever and the treatment was continued successfully. It is our impression that the fever in all the cases may not be directly due to the toxic effect of the drug, but may be caused by the liberation and circulation of toxins from some buried focus of infection. The drug fever should be carefully distinguished from fever incidental to the infection for which sulphanilamide is administered. For example, in metastatic complications of gonorrhoea and in venereal lymphogranuloma, fever of varying degree is usually present even before the treatment is started.

Cutaneous reactions.—There were 57 cases of drug eruptions in our analysis, of whom 48 were males and nine females. Table II gives a detailed description of the type and distribution of the rash, the dosage of the drug, the day of appearance of the rash, etc.

The eruptions appeared any time from the third to the fourteenth day of sulphanilamide therapy; but in the majority of cases the rash developed between the seventh and the twelfth day of treatment. Two distinct types of rash were observed from the point of view of distribution. The first one (26 cases) was a diffuse eruption involving the trunk, face and limbs. The second type (22 cases) was a localized rash, confined to the parts exposed to direct sunlight—face, neck, extensor aspects of the forearms and hands and dorsal aspects of the feet. A third type (nine cases) complained of intense itching all over the body without any visible eruption.

The following is the classification of eruptions observed :—

Morbilliform	18
Urticarial	12
Follicular	6
Papulo-macular and papular	5
Erythematous	4
Scarlatiniform	1
Bullous	1

The morbilliform type of eruption seems the commonest. Constitutional disturbance, such as fever and malaise, was present in many of the cases. Ten per cent of these patients with eruptions showed a definite leucocytosis, the leucocytes ranging from 12,000 to 21,000 per c.mm. One case developed a slight leucopenia and in two severe cases, there was a leucopenia with granulocytopenia. Most of the eruptions disappeared in a few days on cessation of therapy. In one case of diffuse urticarial eruption, marked breathlessness, and mental confusion were associated features. A moderate desquamation was observed in four cases of severe diffuse type.

From the table it may be seen that the cutaneous intolerance due to sulphanilamide therapy does not depend so much on the total dose of the drug ingested as on the time factor, seventh to twelfth day of therapy appearing to be the most favourable period for the development of the eruption. The question of resumption of therapy in these cases could not be studied with any precision as many of these patients failed to report again. But in quite a few cases of the light-sensitization type, who reported after a few months for treatment either for the original uncured venereal infection or a fresh infection, we were able to administer the same drug, with a warning to the patients not to expose themselves to direct sunlight, without the recurrence of the skin trouble. Patch tests were not performed to determine the sensitiveness.

Another observation we have made is the relation between the severity of the skin reaction and the therapeutic response of the infection to the drug. In many cases of the diffuse severe type, no matter on what day of treatment they developed, the therapeutic response, particularly in gonorrhoea, was very dramatic and the clinical and bacteriological cure was permanent.

A third of the cases of drug eruption, in our series, were of the light-sensitization type; this is in contrast to the relative infrequency of such eruptions reported by other clinicians from the temperate regions of the world. The strong and powerful sunlight prevalent during the greater part of the year in these latitudes will easily account for the increased incidence of this type of rash. It is our impression that even some of the diffuse types of eruption belong to this light-sensitization type, as many of our

TABLE II

Serial number	Type of cutaneous eruption	Day of rash	Total dose of sulphanilamide (gm.)	Distribution of rash	REMARKS

poorer patients wear only a loin cloth exposing the greater part of their skin to direct sunlight.

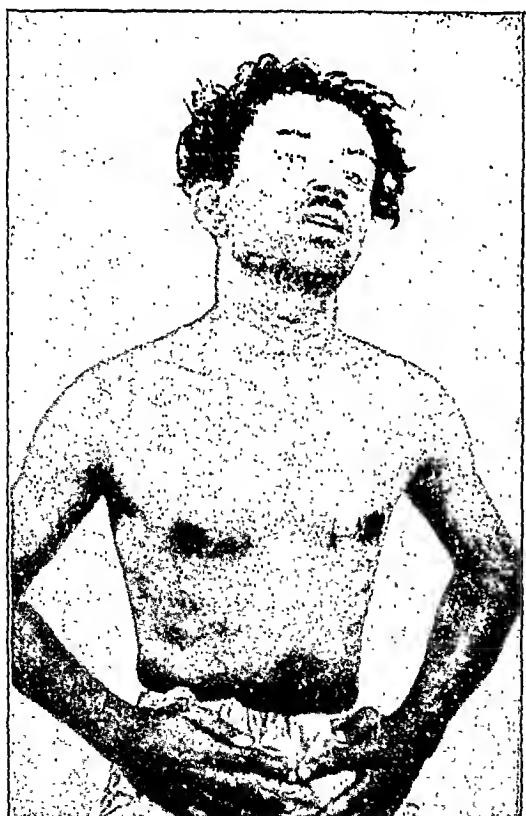

According to Tedder (1939), three factors are involved in the causation of sulphanilamide

family resemblance to the ninth-day erythema met with the arsenobenzene compounds. Another theory put forward by the same author (1938) is the activation of some buried focus of infection by sulphanilamide liberating toxins from the focus.

We have not encountered a case of true allergy, in which a single dose of the drug has induced the cutaneous intolerance. The theory of sensitization is advanced on two grounds:—

1. In such allergic cases, a normal elimination of the drug in the urine is demonstrated.
2. They remain sensitive to the drug for months and a single small dose brings on the rash in a few hours. In our opinion, the toxic factor appears to be the more important cause of drug rash, particularly of the generalized type in which retention of the drug occurs in the body, due to faulty or inefficient elimination in the urine. The associated or coexistent constitutional disturbance of malaise and fever observed in the majority of cases of generalized eruptions in our analysis lends support to the toxic factor as being the main cause of the diffuse type of drug eruptions.

Rimington and Hemmings (1938) have shown that during sulphanilamide therapy there is an increased production of porphyrin together with coproporphyrin I. This latter substance is a photo-sensitizer and its production varies in degree in different individuals. Epstein (1939) distinguishes true light sensitization from photo allergy. The former is a direct light sensitization caused by the drug and the latter is indirectly due to the drug by the production of porphyrin and coproporphyrin I. The relative infrequency of the photo-sensitive type of drug eruptions noted by clinicians in temperate latitudes, where powerful sunlight is a desideratum, is accounted for by the variation in the production of porphyrin in individual cases.

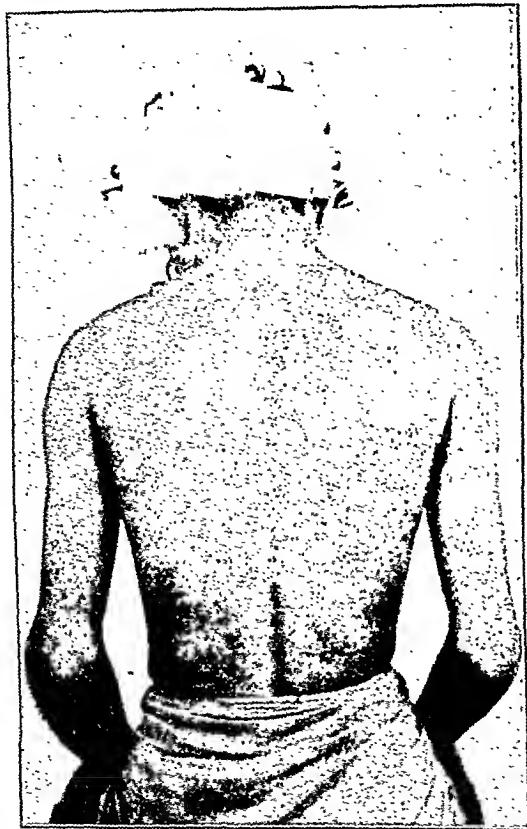

Morbilliform rash (sulphanilamide). Anterior view.

rash:—1. Sensitization. 2. Toxic effect. 3. Light sensitization. Erskine (1939) is of opinion that these eruptions, occurring mostly towards the end of the first week of therapy, bear a close

The greatly increased incidence of this type of cutaneous reaction in our latitudes suggesting that the increased production of photo-sensitizing substance during sulphanilamide therapy may be dependent more upon the sunlight than upon individual bodily tissue reaction; or it may be that the cases of light-sensitization type of eruption in our series are cases of true light sensitization caused directly by the drug.

The notes of our only severe case of cutaneous and mucosal lesions caused by sulphanilamide is given below:—

The patient, a male, aged 30 years, was admitted to the wards of the venereal department on 23rd August, 1940, with a purulent urethral discharge, acute strangury, and difficulty in micturition. Investigation showed him to be suffering from an acute gonococcal urethritis with prostatitis. He was put on sulphanilamide tablets at the rate of $4\frac{1}{2}$ gm. daily. He received

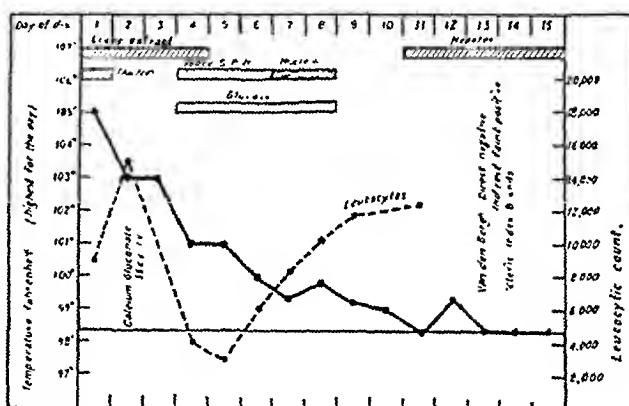

Morbilliform rash (sulphanilamide). Posterior view.

$4\frac{1}{2}$ gm. daily for seven days and 3 gm. daily for two more days and as his condition greatly improved, he was discharged from the wards on 31st August, 1940, and advised to continue treatment as an ambulatory patient. He had taken $37\frac{1}{2}$ gm. of the drug in nine days.

On 2nd September, two days after discharge from the wards, he reported very ill and was immediately admitted. On examination, he had extensive eruptions all over the face, trunk, limbs and genitals. The lesions were pleomorphic on the first day, consisting of papular and bullous types, the latter predominating. He had severe cheilitis, stomatitis with fissures and ulcers on the lips, palate, pharynx with a considerable edema so that the patient was scarcely able to open the mouth. Intense conjunctivitis with blepharitis in both eyes was present. The patient looked extremely toxic with an initial temperature of 105°F , pulse 132 and

respiration 40. Within 48 hours the entire skin of the body, face and limbs was covered with grouped and confluent bullous lesions, of varying sizes and shapes, which rapidly burst leaving large raw weeping areas. The eyelids were swollen, shut with discharge and crusts. The mucous membrane of the lips, tongue and palate was grossly inflamed, fissured, ulcerated and easily bleeding. The blood count showed an initial leucocytosis on the first two days of admission but suddenly dropped to 4,000 and 2,750 leucocytes on the fifth and sixth day after admission. The other findings of the blood were normal.

After about five days' treatment the patient turned the corner and started to mend. The temperature came down, the leucocyte count went up, the skin lesions started drying up and exfoliating. The inflammation of the mucous membranes with the exception of the right eye showed a gradual subsidence. An acute ulcer of the right cornea developed with prolapse of the iris which ultimately seriously compromised the vision in that eye. During the involution stage of the skin lesions the patient shed all his nails, and the skin of the palms and soles was coming away in thick flakes. A few subcutaneous abscesses were opened and drained. The healed bullous lesions on the skin of the trunk and face left pigmented, mottled and vitiliginous patches. Towards the end of the second week, recovery was almost complete except for the eye condition. The accompanying chart shows the progress in the temperature and blood findings and also the treatment adopted in the case.

Leucopænia and granulocytopænia.—A reduction of the total leucocyte count or granulocyte count, or both, was discovered in about 26 cases. In all the patients, the drug was immediately stopped and they were kept under observation. Regular daily leucocyte counts were performed on them. All the cases, after a few weeks, completely returned to normal. In a few of them, sulphanilamide therapy was restarted without their developing any recurrence of this blood dyscrasia. In three cases, the reduction in leucocytes was observed towards the end of the first week of therapy, the rest occurring at the end of the second week.

Agranulocytosis.—This grave complication of sulphanilamide therapy is reminiscent of a similar grave intoxication of arsenobenzene therapy, i.e., encephalitis, in that both conditions are almost unpredictable and occur with startling and dramatic suddenness from an almost unclouded sky without any premonition. It is usually asserted that the clinician will be forewarned of the grave complication if daily blood counts are performed on patients receiving sulphanilamide therapy. Our observations on the very large number of cases receiving

sulphanilamide in the venereal clinic of the General Hospital do not bear out this contention. There seems an inevitability about the development of agranulocytosis, which appears to occur on a basis of individual idiosyncrasy, rather than as a toxic manifestation. The rarity of this complication, considering the thousands of patients treated with this drug all over the world for the past few years, is evidence of an as yet undetermined susceptibility in a few individuals. In the three years of routine sulphanilamide therapy in the venereal clinic of the Government General Hospital, approximately 2,70,000 grammes of sulphanilamide were administered to about 6,000 patients. Three cases of acute agranulocytosis, in one male and two females, occurred during the period under review. All the three cases ended fatally in spite of treatment.

The male patient, who was receiving treatment for acute gonorrhœa, completed three weeks' course of sulphanilamide totalling 72 grammes. The day after the last day's sulphanilamide the patient suddenly took ill with shivering and fever. The initial temperature was 105.6° F. The patient looked extremely toxic and within 12 hours became delirious. Blood examination revealed 1,500 total leucocytes with a complete absence of granulocytes. For four days he was swinging between life and death and died on the fifth day of a terminal pneumonia. Anginal symptoms were absent. In this case the routine weekly blood counts in the first and second week of sulphanilamide therapy did not reveal any abnormality. The other two fatal cases were young adult women who were treated for gonorrhœa. Both cases had 14 days' treatment with sulphanilamide. One of them developed high fever four days and the other six days after cessation of therapy. The leucocyte count in one was 500 and in the other 1,600, with complete absence of granulocytes in the former and 3 per cent in the latter. One of the women suffered also from a severe angina of the throat. In spite of treatment with sodium pentose nucleotide, glucose and blood transfusion, both cases terminated fatally, the one five days and the other three days after onset of the illness.

A mild anaemia has been noted in nine cases during therapy, with a reduction in the red cell count and haemoglobin content. We have not regarded these cases of mild anaemia as grave toxic manifestations. Temporary cessation of therapy with administration of iron by mouth has enabled us to restore the defect and then continue the therapy without any ill effect. No case of haemolytic anaemia was encountered in our series.

A number of cases of unexplained bleeding from different orifices of the body was observed in our cases :—ten cases of epistaxis, two of profuse menses, two of haemoptysis, one of bleeding from the rectum and one of bleeding from the

gums. In all these cases the bleeding stopped with the cessation of therapy, but recurred with resumption of treatment. Examination of the blood failed to reveal any abnormality. It is curious that there was no case of haematuria in our series treated with sulphanilamide.

Slight breathlessness with or without cyanosis was present in about one per cent of the cases and with a marked predominance in the male patients. It was observed as early as the second day of therapy or was delayed up to the end of the second week. This complication was usually associated with slight fever, dry throat, and retro-sternal pain. In almost all the cases the treatment was continued without any mishap. In two cases of marked cyanosis with breathlessness, the patients were admitted to hospital for a few days with cessation of treatment. Spectroscopic examination of the blood failed to reveal any abnormal bands. In most of the cases the breathlessness was noticed only on exertion.

Numbness and tingling of the fingers and toes were complained of by a little more than one per cent of cases of either sex during treatment. There was no definite peripheral neuritis.

Diminished acuity of vision was present in six cases—all males; but, in only one case after four days of therapy, the ophthalmologist reported early optic neuritis with a central scotoma for blue in the left eye. With the stoppage of treatment the vision returned to normal in all the cases. In the other five patients, the complaint was purely subjective and came on after the second or third day's therapy.

There were four cases of *vestibular dysfunction* characterized by vertigo, tinnitus and slight deafness, which passed off. This mild occasional toxic involvement of the optic and the auditory nerves, is usually evanescent and the treatment was in no way interfered with.

A solitary case of *herpes zoster* in the distribution of the seventh dorsal nerve in a woman who was treated for a particularly resistant type of Neisserian infection was seen in the clinic. The complication occurred on the seventeenth day of treatment after a total dosage of 51½ gm. of sulphanilamide. The condition was accompanied by mild fever, headache, severe neuralgic pain along the nerve and intense burning over the crops of herpetic vesicles. Treatment was stopped and the condition subsided gradually with forcing of fluids and glucose and exhibition of vitamin B₁.

Clinical acidosis has not been encountered in any of our cases since it has been the routine practice to prescribe an alkaline mixture to be taken along with the sulphanilamide.

In about 0.8 per cent of either sex, gastrointestinal upset and diarrhoea were prominent minor reactions of the drug.

Some of the minor reactions like *giddiness, headache, nausea and vomiting* were complained

of by the patients in the first two or three days of therapy, but tended to disappear with the continuation of the treatment.

A minority of patients complained of pain in different parts of the body, chest, abdomen, joints and muscles.

Mental disturbance, a sort of toxic psychosis, in the form of mental confusion was observed in one case of drug dermatitis associated with breathlessness. Muscular weakness was found to be twice as common in women patients as in men, but it did not interfere with the maintenance of therapy.

Toxic hepatitis with or without jaundice was conspicuously absent with sulphanilamide in our series, but two cases of jaundice were met with among a smaller number of selected paying cases treated with sulphapyridine in the clinic. As only 30 cases were under sulphapyridine treatment during the period under review the toxic complications of this drug are not included in this study.

Comment.—The incidence of the toxic complications of sulphanilamide seems to be almost equally distributed between the sexes with a slight preponderance of the blood dyscrasias in women. Taking agranulocytosis alone, the incidence in women is one in about 500 patients, whereas in men it is about one in 5,000 patients. The danger of this often fatal complication seems to be ten times more frequent in women. It is obvious from the analysis of the toxic reactions that with the single exception of agranulocytosis the other toxic effects of sulphanilamide therapy are not grave reactions jeopardizing life. In most of these cases the treatment could be safely continued with proper precautions with or without a certain interval of rest. We are also convinced that, with the exception of agranulocytosis, the other toxic manifestations occurring in the first two weeks of therapy can be recognized by daily and careful observation of the patients. An attitude of over-cautiousness seems to prevail among sections of the medical profession regarding the dangers of the new chemotherapy. It is our opinion that sulphanilamide and its derivatives should be used with greater resolution than has hitherto been shown and that clinicians should not hesitate to administer this drug in therapeutically adequate doses. Having said so much it is essential to emphasize that patients receiving sulphanilamide or one of its derivatives should be kept under daily and careful observational control. Enquiry should be made for symptoms such as fever, headache, malaise, vomiting and pain. Examination of the skin for rash, of the mucous membrane for pallor or jaundice, and observation of the temperature for drug fever, should form part of the daily routine of sulphanilamide therapy. As many of the toxic manifestations occur towards the end of the first week of treatment, observation

of the patient should be more detailed and careful from and after the end of the first week.

It has been our routine practice to have a blood count performed at the end of the first and second weeks of therapy, or whenever the patient develops fever, rash, breathlessness, or suffers from the persistence or increase in severity of a minor toxic manifestation such as headache or vomiting, etc. Daily blood counts are no doubt ideal, but, in the exigencies of the out-patient venereal practice, when 200 to 300 patients have to be dealt with and disposed of daily, blood examination on an average of 100 patients who would be receiving sulphanilamide for one or the other of the venereal diseases, would be a terrible strain on the medical staff of the department.

Since our analysis of the drug rash has shown that nearly a third of the skin eruptions is of the light-sensitive type, patients should be strictly warned not to expose their naked skin to direct sunlight during sulphanilamide treatment.

In conclusion, the clinician should bear in mind that if a patient has drug fever, rash, leucopenia, cyanosis, or persistence of a seemingly minor trouble such as vomiting and diarrhoea, the drug should be immediately stopped; and the rapid excretion of the drug should be promoted by the ingestion of fluids and glucose. Oral administration of nicotinic acid has been recommended both for prevention and the treatment of the toxic complications of sulphanilamide and its derivatives. In cases where further therapy is indicated, either the same drug or one of its other derivatives in a much smaller single dose should be cautiously administered and a watch should be kept for the recurrence of the toxic manifestations.

SUMMARY

1. An analysis of the toxic complications of sulphanilamide therapy in the venereal department of the Government General Hospital is attempted.
2. Over 6,000 cases of both sexes who had received between them 2,70,000 grammes of sulphanilamide are reviewed.
3. Some of the complications are discussed in detail, particularly the cutaneous reactions and the blood dyscrasias.
4. The much greater frequency of the light-sensitive type of sulphanilamide rash is noted.
5. A plea is made for an optimistic attitude towards the new therapy and for the use of the drug in therapeutically adequate doses.
6. Necessity for daily careful observation of the patients receiving the new therapy aided by frequent blood count estimation is stressed.

A STUDY OF CARDIAC SOUNDS AND MURMURS IN SEVERE ANAEMIA

By P. C. GUPTA, M.B., B.S., P.M.S. (Agra)

(Formerly Research Fellow to the Lucknow University, Department of Medicine, Lucknow). Medical College, Agra

THE presence of cardiac murmurs in cases of severe anaemia is a very common finding. The murmur is mostly a systolic one, heard best at the mitral area. So frequent is its occurrence in cases of anaemia, that this murmur is called a haemic murmur.

In the present series of cases an attempt was made to study the cardiac sounds and murmurs in anaemias, and also to see the frequency and character of the diastolic and pre-systolic murmur in these cases. Again, an attempt was made to correlate the blood picture with these murmurs. With this end in view, frequent blood counts were made and the cardiac changes recorded daily or less frequently.

An interesting finding was the presence of diastolic murmurs. These diastolic murmurs in cases of anaemia have always been regarded sceptically by clinicians, and their *modus operandi* is not well understood. It was found in some cases that a pericardial rub was also detected with the diastolic murmur. Both the rub and diastolic murmur cleared up on treatment of the anaemia, showing that they were not due to any organic lesion of the heart. In cases where a definite diastolic murmur was detected, an electro-cardiogram and teleradiogram were taken to find out if there was any chance of the lesion being an organic one.

Technique

1. Selection of cases.—Only cases of very severe anaemia likely to give a total red cell count of about a million per c.m.m. were selected. Ankylostome cases were preferred because they present varying grades of

(Continued from previous page)

We are thankful to the superintendent of the Government General Hospital for permission to utilize the records of the department and to the staff of the Barnard Institute of Radiology for the clinical photographs.

anaemia, are mostly free from other complications and are more amenable to treatment. Cases of other types of anaemia were also included and thus the report represents fairly the conditions prevalent in this part of the United Provinces.

Cases of anaemia of pregnancy were avoided because of the alteration in cardiac findings in these cases due to enlarged abdomen. For this same reason cases with ascites had to be excluded.

2. Examination of cases.—After a careful clinical examination a detailed blood study was undertaken. All blood studies were carried out by using counting chambers and pipettes which were certified by the United States Bureau of Standards to be correct. For haemoglobin estimations, Hellige's haemometer was selected using Sahli's standardized scale so that 14.5 gm. were equivalent to 100 per cent (Wintrobe, 1930).

The detailed blood investigation consisted of the following observations repeated bi-weekly, or less frequently:—Total red cell and white cell counts, haemoglobin estimation, differential leucocyte count and the general blood picture, the average cell diameter by Eve's halometer, and the reticulocyte percentage; the last named was repeated daily during the early stages of anti-anæmic treatment.

3. X-ray findings.—Teleradiogram and electro-cardiogram were taken under standard conditions in the x-ray department of King George's Hospital. For the teleradiogram, the patient was kept in the erect posture; he was instructed to take shallow breaths. After his initial excitement, due to new surroundings, had passed off, he was instructed to hold his breath in mid-inspiration when the plate was exposed (White, 1937).

Observations

A very frequent finding was the presence of murmurs, mostly systolic, which either disappeared altogether or altered in character with the improvement of anaemia. The murmur was systolic, as mentioned above, and was best heard on left side of chest about the fourth intercostal space, though in a fair number of cases it was equally well heard in the pulmonary area. However, murmurs other than systolic were also found.

Three cases in the series presented a definite diastolic murmur which was sharply localized to the apex. These cases were carefully observed and electro-cardiograms and teleradiograms taken (plate XVII, figs. A, B, and C and plate XVIII, figs. 1, 2, and 3) but no evidence of any organic lesion could be found. On the contrary, it was shown that the murmurs were functional only, since they disappeared a few days after admission. In two of these cases the murmur disappeared on improvement of anaemia, while in one case it developed after blood transfusion, and disappeared a week later.

One case (case 2) presented a pericardial rub along with a diastolic and systolic murmur at the apex. She looked a typical case of mitral lesion with secondary failure but electro-cardiogram and teleradiogram showed no mitral involvement. The case proved to be a functional one by the complete disappearance of all signs and symptoms on her regaining the normal blood count, and when seen eight months

after discharge, she was free of all signs and symptoms.

The following is a brief summary of cardiac findings:—

TABLE
Summary of the auscultatory findings in the heart

Serial no.	On admission	On discharge	Observed changes
1	Soft systolic murmur in the mitral area not conducted except for a short distance towards axilla. Pulmonary area also a soft systolic murmur.	Mitral and pulmonary murmur much less marked.	Murmurs have markedly diminished in intensity.
2	(1) Systolic murmur in all the four areas. (2) Mitral systolic conducted up to the axillary line. (3) A short rough late diastolic murmur in mitral area in the 6th space not conducted. (4) Pericardial rub at the 5th space nipple line.	No murmur at all	All the murmurs have disappeared.
3	Both sounds clear. No murmur in any area except mitral, where a short, soft systolic murmur localized in that area is heard.	No murmur in any area	Murmur has disappeared.
4	1st sound in the mitral area replaced by harsh systolic murmur conducted to mid-axillary line. Pulmonary 2nd sound accentuated.	Systolic murmur much softer. 1st sound audible. Conduction of murmur much less.	Altered in character.
5	(1) A harsh systolic murmur in the mitral area conducted to anterior axillary line. (2) 1st sound replaced by murmur. 2nd sound clear. (3) Pulmonary and aortic areas also show harsh systolic murmurs.	A short, soft systolic murmur in mitral and pulmonary area.	Murmurs much less marked.
6	Both cardiac sounds distinctly heard in all the areas. No murmur detected at all.	No murmur in any area	Had no murmur on admission.
7	1st sound in mitral area prolonged into a soft systolic murmur, conducted an inch towards the axillary line.	Sounds clear. No murmur	Murmur disappeared.
8	A short soft systolic murmur in the mitral area conducted slightly towards the axilla. Pulmonary and aortic areas also reveal short soft localized murmur.	1st sound in mitral area prolonged only. No murmur in any area.	Murmurs disappeared.
9	Soft systolic murmur in all the areas. Mitral systolic localized in the 5th space about the nipple line.	Murmur just the same. No change.	No change.
10	(1) Systolic thrill in the praecordium. (2) In mitral 1st and 2nd sounds heard. A harsh systolic murmur conducted only for an inch to axilla. (3) At the 4th rib in the mammary line, there is a short, harsh late diastolic murmur heard over an area $1\frac{1}{2}$ inches in diameter. 2nd sound inaudible in this area. Systolic murmur was also heard at the base of the heart.	Very feeble systolic murmur in mitral and pulmonary area. Following (4 months after) no murmur at all.	All murmurs including diastolic have disappeared.
11	(1) 1st sound in the mitral area replaced by a soft systolic murmur conducted to the anterior axillary line. (2) Other areas also show a systolic murmur.	Mitral systolic murmur still heard. It is conducted to anterior axillary line.	Not much alteration in murmurs.
12	(1) Mitral area shows a short soft systolic murmur localized round about the nipple. (2) Systolic murmur was also heard at the base of the heart. (3) Pulmonary 2nd sound accentuated.	Mitral murmur faintly audible on careful examination. Others also almost absent. Pulmonary 2nd still accentuated.	Murmurs have almost disappeared.
13	1st and 2nd sounds distinctly heard. No cardiac murmur detected.	No murmur	Had no murmurs at all on admission.
14	Soft systolic murmur in the mitral area conducted towards the anterior axillary line. Sounds clear. Pulmonary area shows a clear systolic murmur.	Systolic murmurs though present are much less marked.	Diminished in intensity.
15	(1) A short soft systolic murmur best heard in pulmonary area. (2) Short soft systolic murmur in mitral area not conducted except for a short distance towards axilla. (3) Both mitral sounds clear. (4) Pulmonary 2nd accentuated.	Murmurs though audible are much less marked. Pulmonary 2nd still accentuated.	Do.

TABLE—*concl.*

Serial no.	On admission	On discharge	Observed changes
16	(1) A clear, softish systolic murmur in the mitral area not conducted. (2) Sounds distant and feeble. (3) Pulmonary 2nd accentuated and reduplicated. Has a systolic murmur at the base as well.	(1) Pulmonary rough murmur as before. (2) Pulmonary 2nd sound accentuated. No reduplication. (3) Mitral murmur less marked.	Diminished in intensity.
17	(1) Soft systolic murmur in mitral area conducted to anterior axillary line. (2) 1st mitral sound replaced by murmur. (3) Pulmonary area also shows localized systolic murmur. (4) Pulmonary 2nd accentuated, systolic murmur in other areas also.	Died	
18	Sounds distant but clear in all the areas. No murmur at all. 2nd pulmonary sound accentuated.	Mitral sounds clear. No accentuation of pulmonary 2nd now.	Alteration in character of sounds.
19	1st sound in mitral area is prolonged into a short systolic murmur. Pulmonary area shows a clear systolic murmur.	Mitral area shows no murmur. Pulmonary systolic murmur still heard.	Disappearance of mitral systolic murmur.
20	Sounds are rather distant but clear. No murmur in any area.	No murmur. Sounds clearly heard.	Sounds became more clear. Had no murmur.
21	No murmur in any area. Sounds clearly heard.	There was no murmur on admission.	Never had a murmur in the heart.
22	(1) Soft systolic murmur in the mitral area not conducted to axilla. (2) Soft systolic murmur at the base as well.	A short soft systolic murmur in the mitral area slightly conducted towards axilla. Patient has also since a week developed a <i>short late diastolic murmur localized strictly to 5th interspace just below the left nipple</i> .	Had a diastolic murmur also. Systolic murmurs unaffected.
23	Mitral area shows a soft systolic murmur conducted to the axillary line. Pulmonary area also shows a systolic murmur.	No change in murmurs	No change.
24	(1) A short soft systolic murmur in the mitral area conducted slightly to axilla. (2) Clear short systolic murmur in pulmonary and aortic areas.	1st sound in mitral area rather prolonged. No murmur. Pulmonary systolic also indistinct.	Murmur has disappeared.
25	(1) A short soft systolic murmur localized in mitral area. (2) A more distinct murmur in pulmonary area.	No murmur at all	Murmurs have disappeared.
26	A rather short soft systolic murmur in the mitral area conducted for a short distance towards the axilla. Murmur in pulmonary area best heard.	No murmur in any area	Do.
27	No murmurs in any area.	No murmur in any area	Had no murmur on admission.
28	(1) A short soft systolic murmur in the mitral area not conducted to axilla. (2) A loud systolic murmur in pulmonary area.	1st sound in the mitral area slightly prolonged. No murmur at all.	Murmurs have disappeared.
29	A harsh systolic murmur in the mitral area conducted to anterior axillary line.	Soft systolic murmur in the mitral area.	Murmur has become soft in nature.
30	Soft systolic murmur in the mitral area conducted to anterior axillary line. More definite systolic murmur in pulmonary area.	Not followed for a long period	No change.
31	Soft systolic murmur in mitral area. Less distinct in pulmonary area.	...	Do.
32	Short soft systolic murmur in mitral area; also in pulmonary area.	...	Do.
33	No murmur. Sounds clear.		
34	Nil abnormal except for a short systolic murmur in the mitral area.	Died	

Summary abstract	Incidence	Percentage
1. Murmurs present ..	29 out of 35	82.8
2. Murmurs absent ..	6 out of 35	17.2
3. Murmurs disappeared on improvement of anaemia.	10 out of 27	37.0
4. Murmur diminished in intensity.	6 out of 27	22.2
5. Murmur altered in character.	2 out of 27	7.4
6. No alteration in murmur at all.	6 out of 27	22.2
7. Diastolic murmur ..	3 out of 35	8.6

Two patients died and so were not followed for any length of time.

Discussion.—It is thus found that no less than 82.8 per cent of cases of severe anaemia present cardiac murmurs. These murmurs disappeared completely on improvement of anaemia in 37 per cent, while in another 33 per cent they either diminished in intensity or altered in character: the harsh blowing murmurs became soft, while soft murmurs became practically inaudible. Thus, about 70 per cent of cases admitted with cardiac murmurs showed definite changes in murmurs with the improvement of anaemia.

It is interesting to note that 17.2 per cent of cases of very severe anaemia had no murmurs at all even on admission. It is difficult to account for this difference in behaviour of two hearts with the same kind of blood picture.

Discussion and reference to literature

Diastolic murmurs have been recorded from time to time in cases of anaemia. As early as 1861, Friederich (1861) described a patient with secondary anaemia who presented a diastolic murmur during life, but in whom post-mortem examination revealed no abnormality in any of the heart valves. Subsequently von Noorden (1891) described three such cases in one of which a post-mortem examination was performed. In one the murmur was diastolic, and in the other two pre-systolic; in one patient the murmur disappeared as the anaemia improved. Sahli (1895) recorded two cases of severe secondary anaemia with cardiac enlargement and diastolic murmur at the left border of the sternum. Cabot and Locke (1903) and Ortner (1923) were the next to report such observations. Morse (1924) noticed diastolic murmur with water-hammer pulse and pistol-shot sounds in the arteries in infants and children with marked anaemia, and observed their disappearance with the improvement of blood. Again, Kraus (1905) observed diastolic murmur in eight cases of pernicious anaemia amongst a group of 47, and also found such reports in ten of eighty-three cases that he collected from the literature.

The latest reports have been from Goldstein and Boas (1927) and Gunewardene (1933) who also have recorded functional diastolic murmurs

in cases of severe anaemia. White (1937) has described functional mitral stenosis producing a mitral diastolic murmur, which is attributed to considerable dilatation of the left ventricle with normal valves. High grades of anaemia from any cause is mentioned as one of the causes of this clinical condition.

Though the diastolic murmur has been detected in cases of severe anaemia, it has by no means been a common experience. The hospital records of the last five years of King George's Hospital have been looked up, but there has been only one case of a Hindu male admitted for anaemia who presented a functional diastolic murmur. In the present series of cases, it has been found in 8.6 per cent of cases, probably because the murmur was especially looked for in all cases. The murmur in all these cases disappeared a few days after admission, thus establishing that it was not an organic one.

The murmur is usually best heard on the left side of the sternum at the fourth intercostal space about the nipple line, though in one case it was apical. In one case the diastolic murmur was accompanied by a pericardial rub, and a systolic murmur. The picture of the patient with oedema of the feet, tender liver, and distended jugulars, suggested a case of mitral lesion with secondary heart failure, but it was shown to be a non-mitral one by a normal electrocardiogram and teleradiogram. The disappearance of all signs and symptoms and the return of the heart to normal on improvement of anaemia also confirmed the non-organic nature of the lesion. This case was seen eight months after discharge from the hospital and was found to be free of all evidence of cardiac abnormality, and had a normal blood picture. In two other cases, the diastolic murmur was transient, lasting for two days in one, and about a week in the other. These diastolic murmurs, though observed by various workers, have not yet been satisfactorily explained.

Summary and conclusions

Cases of severe anaemia occurring in the United Provinces of Agra and Oudh were investigated from the point of view of cardiac findings, particularly the heart sounds and the cardiac murmurs.

A detailed study of the blood was made on admission and the cases treated for anaemia. A detailed record of the cardiac sounds and murmurs was made on admission and then followed from day to day *pari passu* with the improvement in anaemia. The following conclusions have been drawn:—

(1) That presence of systolic murmur in these cases is a very common finding. The systolic murmur is mostly found in all the areas, but is often well marked at the apex. In some cases it was most distinct in the pulmonary area.

PERFORATION OF A MECKEL'S DIVERTICULUM WITH GASTRIC MUCOSA

By M. G. KINI, M.C., M.B., M.Ch. (Orth.),
F.R.C.S. (Edin.)

Surgeon, King George Hospital, Vizagapatam (S. India)

MECKEL'S diverticulum, which is due to the persistence of a portion of the vitelline duct or yolk stalk, may, or may not, cause any abdominal symptoms. The incidence of Meckel's diverticulum varies according to institutions. Johns Hopkins Hospital reported 15 cases out of 2,600 autopsies, while Mitchell of Chicago reported 39 cases out of 1,635 autopsies. Out of 1,500 abdomens opened by the author, four cases of Meckel's diverticulum were found of which two were found accidentally while operating for duodenal ulcers. On section, these diverticula did not show any evidence of gastric mucosa. One of the other two cases was one of strangulated hernia of 11 days' duration

(Continued from previous page)

✓ (2) That diastolic murmurs in cases of severe anaemia are occasionally met with. The murmur is usually a late diastolic murmur best heard on the left side of the sternum at the fourth intercostal space about the nipple line. This diastolic murmur is not organic, but its cause has not been elucidated.

✓ (3) That the pulmonary second sound is accentuated in a fair number of cases of anaemia.

Acknowledgments

I am greatly indebted to Captain R. D. Alexander, formerly Professor of Medicine, King George's Medical College, Lucknow, who very kindly directed me in this work, also to Dr. R. Lal, radiologist to King George's Hospital, for his kindly affording the facilities of his department.

I have further to thank Colonel H. Stott, I.M.S., formerly Professor of Pathology and Dean of the Faculty of Medicine, for his kindly providing me with a research laboratory, and to the members of the visiting staff of King George's Hospital for permitting me to use their cases.

where the Meckel's diverticulum along with the loop of the bowel was found to be gangrenous, and in the other case perforation of the diverticulum causing peritonitis demanded an immediate laparotomy. In Meckel's diverticulum, the mucous membrane usually resembles that of the intestine where it is situated. The presence of gastric mucosa was first described by Deetz in 1907 and Denecke reported the first ulcer in Meckel's diverticulum in 1902. Schaetz in a study of 30 diverticula found 50 per cent contained abnormal elements, such as pancreatic tissue and gastric mucosa. Huebschmann found ulcers in the Meckel's diverticulum to be like jejunal ulcers. Schaaff found that the fluid content of the diverticulum with gastric mucosa contained greater acidity and this observation was confirmed by Lindau and Wulff (1931). Cobb in 1936 collected 100 cases of Meckel's diverticulum of which 66 showed positive evidence of presence of gastric mucosa. The clinical symptoms of Meckel's diverticula containing gastric mucosa with ulcer formation generally included pain, or intestinal haemorrhage and in some the patients sought admission for perforation.

The following case illustrates a case of acute abdomen due to perforation of Meckel's diverticulum with no previous history of pain, colic or intestinal haemorrhage. It was very sudden and ended in recovery.

A Hindu male, aged 35 years, was admitted in 1936 for the treatment of severe pain in the lower part of the abdomen, of nearly 22 hours' duration. He stated he had no colic or pain at any time. He enjoyed good health prior to this occurrence. It started suddenly as a colic after a heavy meal with subsequent pain referred to the umbilical region. With this colic and pain he walked a distance of nearly two miles. After reaching home, he developed nausea and vomited three times, bringing out undigested food. He was given an enema twice without any result. On admission his general condition was found to be good, temperature 99°F., pulse 96 per minute with good volume and tension, and respirations 22 per minute.

Local condition.—Abdomen in the lower part moved freely with respiration. Abdominal wall was not rigid but was tender in the umbilical region. Bubbling and gurgling sounds were heard. Urine was found to contain plenty of acetone but no sugar. Blood sugar was within normal limits. He was treated as a case of appendicitis and watched. Seven hours after admission, the abdomen became distended with increase in pulse rate causing great discomfort. Perforation of appendix with peritonitis was suspected and an operation was decided upon and done.

Under spinal anaesthesia, abdomen was opened through a right para-median para-umbilical incision. On opening the abdomen free fluid was found in the peritoneal cavity with flakes of lymph. Suction was used to drain this fluid out. The coils of small intestines were found distended. An appendix-like organ was found fixed to the anterior abdominal wall underneath the umbilicus which on exploration proved to be a Meckel's diverticulum. There was a small mesentery attached to it. A loop of small bowel was kinked over the proximal part of the attachment of the diverticulum to the small intestine. On freeing the intestine, exploration of the diverticulum revealed a perforation in its mesenteric border about its middle. The diverticulum was excised after crushing it at the root, as in an appendix operation, the stump was

Fig. C is a photograph of the specimen removed.

Pathological report

Histo-pathological examination showed a catarrh of the mucous membrane and in places papillomatous hypertrophy of the villi. The submucous area was found to be oedematous and the vessels were found engorged. No inflammatory cell infiltration was found. The section shows the presence of gastric mucosa of the pyloric end. No pancreatic tissue was seen (plate XVIII, fig. B).

The patient has been followed for four years and is keeping fit with no after effects after the acute perforation.

Points of interest

(1) A small appendix-like Meckel's diverticulum which simulated clinically an acute appendicitis with perforation is described. The operation was performed 29 hours after the onset of acute symptoms, with good results. Four years after operation the patient reports normal good health.

(2) The histo-pathological section showed gastric mucosa in Meckel's diverticulum and this was probably the cause of an acute perforation.

(From the Department of Pathology and Bacteriology, Medical College, Calcutta)

ALTHOUGH multicentric growths are reported from time to time, their occurrence is rare and the subject is still of great interest. In the year 1869, Biliothi reported the first case of multiple tumours. Lately, Kirshbaum and Shively (1938) gave an excellent review of the earlier recorded cases and reported 25 additional cases of multiple primary malignant tumours, collected from over ten thousand consecutive autopsies. Thomas (1940) reported a case of dual cancer of the stomach. Lamson (1940) reported 2 cases of multiple primary carcinoma. The incidence of such neoplastic tumours has an important bearing on the theory of the mode of origin of new growths. The workers who advocated the 'cell-rest' theory of carcinoma utilized the occurrence of multiple primary tumours for their support. Others who postulated some constitutional disturbance, or a generalized lowering of resistance, as essential for the formation of a neoplasm, quoted the concurrent growth of two tumours as evidence of such a change (Kettle, 1925). Multiple primary neoplastic disease has also been brought into the controversy regarding the question of immunity in tumour formation. The occurrence of one tumour is regarded as affording immunity against further primary growths.

We have come across 2 cases of multiple primary epidermoid carcinoma, which, in the light of the aforesaid, we consider to be a fact worth recording.

Case 1.—E. S., male, aged 60 years, a retired seafaring man, was admitted into the hospital on 9th January, 1933, with a provisional diagnosis of rodent ulcer of the face.

History.—Six years ago after a short febrile attack, a small abrasion-like area for which he could not give any cause appeared on the right side of his forehead. The area was covered with dry skin. It was picked off but after a few weeks the dry skin reappeared. A few weeks later another small area like the previous one, appeared on the right side of the lower jaw. He

used to take off the dry skin from those patches but they reappeared. This sort of thing continued for about two years. In the meantime, another area similar in nature appeared behind and below the left ear. He took x-ray treatment for those patches in England. As a result of the x-ray treatment both the areas on the forehead and the jaw disappeared, but the patch on the forehead reappeared after a month. About two months before his admission a large fungating ulcer appeared on the left side just in front of the left ear.

Family history showed no incidences of malignant diseases. The patient smoked about twenty cigarettes a day and was a moderate drinker.

On examination.—Small pigmented areas were found all over the body, most marked on the upper part of the body and extremities. On the right side of the forehead there was a swelling, the top of which was ulcerated. The ulcer measured about $1\frac{1}{2}$ inches by 1 inch in size. The adjacent area surrounding the swelling showed slight flattened bossing. From the base of the ulcer slight serous discharge was found to occur. The tumour was fixed to the deep structures (figure 1). On the left zygoma, an ulcer of the size of a rupee was seen. It was seen to be raised above the surrounding skin. The base of the ulcer was composed of granulation tissue and there was pus and serous discharge from the ulcer (figure 2). No glandular enlargement could be seen. No other abnormal findings were elicited, on physical examination. Blood examination showed a moderate degree of anaemia. Urine and stool were found to be normal. Blood-Wassermann reaction negative. Scrapings from the ulcerated areas were examined by the dark-ground method with negative result. On several occasions blood was examined for microfilaria, but all the examinations were negative. Röntgenological examination revealed several small deficiencies in the right frontal bone. The condition of specific osteoporosis was suggested on radiological grounds. A piece of tissue was cut from the edge of the ulcer of the forehead, which on histological examination showed the typical picture of epidermoid carcinoma (figure 3). The other ulcer on the left zygoma was also similarly examined and the same picture was obtained. He obtained his discharge from the hospital and was subsequently re-admitted on 8th November, 1934, with the above conditions in a much aggravated form. Further histological examination of the ulcers showed the structures of an epidermoid carcinoma. In these sections cell nests were absent and the cells were more embryonic in nature with marked differentiation (figures 4 and 5).

The patient went downhill and expired from the effects of cachexia on 6th June, 1935, without any further detailed history with regard to the presence of metastases elsewhere being elicited.

Case 2.—S., aged 45 years, cultivator by occupation, inhabitant of Muzaffarpur district, came with the complaint of a number of lumps with ulcers on his body.

On examination.—A tumour the size of a small coconut with a diameter of 4 inches at the top was seen just below the left axilla, occupying the space between the anterior axillary fold and the mid-axillary line. The top of the tumour was found to be ulcerated. The tumour was hard to the touch and was movable from the surrounding structures. The movement of the hand was not impaired. An ulcerated area (figure 6) was seen on the lateral aspect of the middle of the left leg. It was 2 inches in diameter and was found to be situated on an area raised from the general surface of the skin (figure 5). A third tumour, 2 inches in diameter, was found on the back in the middle line, at the level of the 2nd and 3rd lumbar vertebrae (figure 6); it was ulcerated. The tumour in the axillary region was of 5 months' duration. A month after the appearance of this tumour, the ulcerated area on the leg appeared which was soon followed by the ulcer on the back. Besides these there were a number of small ulcerated areas on the back and arms (figure 7). There was no involvement of the regional lymph glands. The patient had been an albino since his birth. There were many melanotic areas on the depigmented skin and at

several places there were areas of keratosis. From the nature of the ulcerated tumours, a malignant process was suspected and pieces from all the three areas were cut and examined histologically. All the three showed the typical appearance of an epidermoid carcinoma (figure 8). The patient refused hospital treatment and left for home. His subsequent history could not be obtained.

Comment: There are several points which are to be considered before one can conclude the primary nature of a multiple neoplastic condition. There are divergent opinions as to the criteria of the above. Lamson (1940) quoted Goetze's suggestion of what should be the criteria to establish the primary nature in the case of multiple carcinoma; according to Goetze the tumour must have the macroscopic and microscopic appearance of usual tumours of the organs involved, and exclusion of metastasis must be certain. Bilioth laid down that, (1) each tumour must have a different histological appearance; (2) the tumours must have different sites of location; and (3) each tumour must produce its own metastasis. Again Wooley's (1903) opinion was that the multiple primary tumours (1) may affect the same tissue and produce identical tumours or growths of different types; (2) may affect both of a pair of organs but that need not necessarily be of the same histological type, e.g., both breasts; (3) may affect different regions of the same system, not necessarily of the same histologic type, i.e., the genital tract; (4) different systems may be affected by different types of new growths. If Goetze's contentions are accepted the two cases reported above are found to fulfil the conditions. The microscopic appearances of these (as seen in figures 3, 4 and 5) are quite characteristic of epidermoid carcinoma. Malignant epithelial tumours of the skin are never known to produce metastases in another part of the skin. Moreover, in both the above cases, the appearance of the second focus of tumour formation was almost simultaneous with the first one. In the first case, the second growth appeared after a few weeks, and, in the second case, the second patch showed itself after a month. Our two cases fulfil Bilioth's second condition, but here Bilioth's first condition cannot be applied, because in our cases the nature of the tumour and the tissue were the same. None of the cases showed any lymphatic glandular involvement when they came first under our observation, although multiple new growths were conspicuous. Hence, taking all the above points into consideration, it seems reasonable to conclude that both cases can be taken as instances of multiple primary growths occurring in the skin. In Kirshbaum and Shivley's (1938) series, they reported 25 cases of multiple primary carcinoma involving most of the organs, but not in a single case was the skin found to be involved. As to the aetiological factors, we could get no indication as to the

Fig. 1. Case 1.—Photograph showing the site and nature of the tumour.

Fig. 2. Case 1.—Photograph showing the second site of the tumour. The scar tissue formed after the x-ray treatment below the left ear could be seen.

Fig. 3. Case 1.—Photomicrograph of a piece of tissue from the growth of the forehead. The picture is typical of an epidermoid carcinoma with marked cell nest formation. $\times 150$.

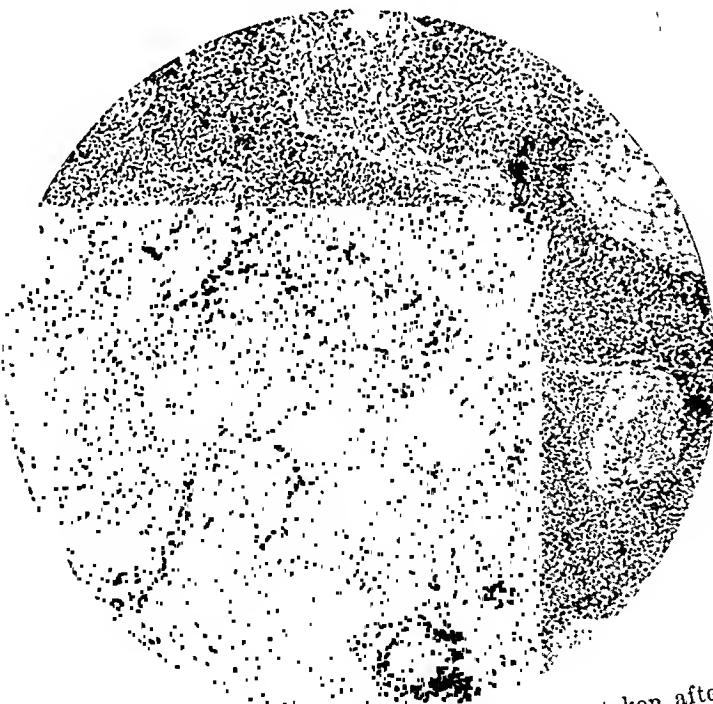

Fig. 4. Case 1.—Photomicrograph of a piece taken after 8th November, 1934, from the forehead. An epidermoid carcinomatous condition is evident but cell nests were absent and cells were more embryonic than seen in figure 3. $\times 150$.

Fig. 5. Case 1.—The same as the above under higher magnification to show the marked differentiated condition of the squamous cells. $\times 420$.

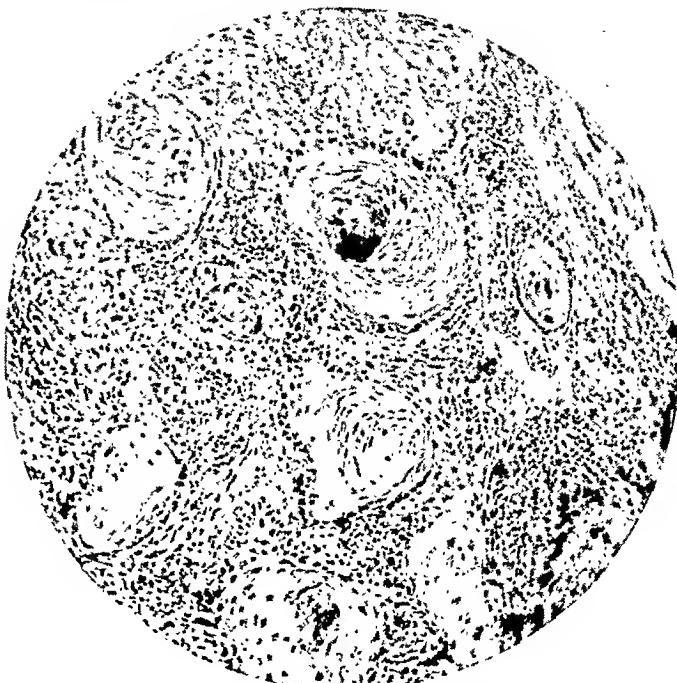

Fig. 8. Case 2.—Photomicrograph of a piece of tissue removed from the axillary tumour. Epidermoid carcinomatous condition of the tumour is clear. Cells are well differentiated. $\times 70$.

Fig. 6. Case 2.—Photograph of the patient showing both the tumour areas.

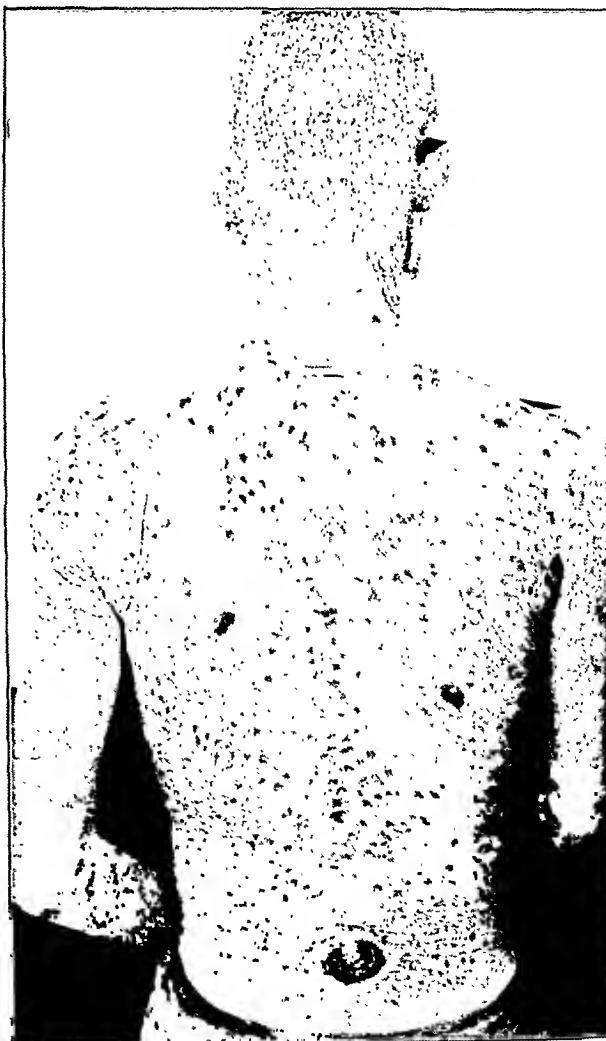

Fig. 7. Case 2.—Photograph of the same patient showing the third site of the tumour. Note the general pigmented condition of the skin with numerous melanotic areas scattered all over. Two small black coloured ulcerated areas one at either side of the middle of the back are also seen.

Fig. 7.

THE ARNETH COUNT IN THE TROPICS

By DHARMENDRA, M.B., B.S., D.B. (Lond.)

School of Tropical Medicine, Calcutta

The Arneth count.—The neutrophilic polymorphonuclear leucocyte is derived from a mononuclear cell (myelocyte) with a single round nucleus. The myelocyte passes through an intermediate stage with a single indented nucleus (metamyelocyte). It is evident therefore that the cell with a simple round nucleus is younger than that with an indented nucleus and this form is younger than the true polymorphonuclear cell. Arneth (1904), following this line of thought, argued that a polymorphonuclear cell with only one lobe was younger than one with two lobes and so on. The work of Colbert (1924); Ponder (1924 and 1926), Charipper (1928) and Hunt and Weiskotten (1930) has produced experimental evidence in favour of Arneth's theory regarding the age of the polymorphonuclear leucocyte and conformation of the nucleus.

Arneth divided polymorphonuclear cells into five main classes, the division being based on the number of the nuclear lobules. He counted one hundred polymorphonuclear cells and arranged them in his five classes like this:

I	II	III	IV	V
5	35	41	17	2

Cells in the different classes were further subdivided according to the morphology of the nucleus. Arneth stated that the percentage of cells in the various classes varied only within normal limits in health, but changed in infectious conditions, the change usually being in the direction of an increase in the percentage of classes I and II and a decrease in classes III, IV and V; this he spoke of technically as a 'shift to the left'.

(Continued from previous page)

possibility of chronic irritation as the predisposing cause in either of the cases. It seems reasonable that in both the cases the epidermis had the natural genetic tendency to proliferate in an atypical way. It is unfortunate that we were not able to study the cases more closely, especially with reference to any metastases that may have been present.

Lastly, our thanks are due to the Surgeon Superintendent, Presidency General Hospital, Calcutta, for the record of the first case.

The polynuclear count.—Cooke (1914) simplified and modified the Arneth count by doing away with the subdivisions in the classes and by giving a criterion of nuclear lobulation—'If there is any band of nuclear tissue except a chromatin filament connecting the different parts of a nucleus, the nucleus cannot for the purpose of Arneth count be said to be divided'. When the count is done according to this criterion Cooke and Ponder (1927) call it the 'polynuclear count'.

The weighted mean of the count.—In Arneth's count the result is expressed in five sets of figures, which is rather cumbersome, and it was desirable to replace such an expression by a single figure. Many ways of doing this have been suggested. The best method appears to be to express the count in terms of weighted mean as suggested by Ponder and Flinn (1926). The cells of each group are multiplied by the number of the group (group I by 1, group II by 2 and so on), the results added, and the total divided by the number of cells counted; this gives the weighted mean.

Normals.—Cooke and Ponder (1927) examined ninety healthy individuals carefully selected to exclude the presence of any focus of infection and obtained the following average :—

I	II	III	IV	V
10	25	47	16	2

The average weighted mean of their series is 2.74 and they are of opinion that the weighted mean of the count in a healthy individual should not be less than 2.4.

Kennedy (1933) examined ninety healthy students not so rigidly selected; the average weighted mean of his series is 2.628 and the standard deviation 0.19. The nearest count corresponding to this mean was:—

I	II	III	IV	V
13	30	43	10	4

Local variations of the count.—There is some evidence to show that the average polynuclear count varies according to locality. Abels (1934) examined one hundred healthy individuals in New York; he obtained an average weighted mean of 2.3 which is lower than the mean of Cooke and Ponder in England (2.74) and of Kennedy in Scotland (2.628). MacLeod (1935) made polynuclear counts on blood films obtained from widely scattered localities. He concludes that his figures indicate that definite differences exist between the means of various localities.

Variations of the count in the tropics.—Marked variations in the counts from the standards laid down in Britain have been reported in healthy individuals in tropical and subtropical countries (tables I and II). Chamberlain and Vedder (1911) found a marked 'shift to the left' in Filipinos and a slight shift in the same

direction in Americans living in the Philippines. Breinl and Priestley (1914, 1915, and 1916) found a marked 'shift to the left' in healthy white school children in tropical Queensland, in

native adults and children in New Guinea, and in native children in northern Australia. Macfie (1915) found a slight 'shift to the left' in natives of West Africa and in healthy

Europeans living there. Banerji (1924) found a 'shift to the left' in healthy Bengalees. Kennedy (1935) found a marked 'shift to the left' in the polynuclear counts of natives of Iraq, the weighted mean being 1.98. Kennedy and Mackay (1935 and 1936) found a marked 'shift to the left' in the polynuclear counts of British airmen and officers stationed near Baghdad, the average weighted mean being 1.94. Pai (1935 and 1936) found a marked 'shift to the left' in the polynuclear counts of healthy Chinese and of British residents in Moukden. Shaw (1936) found that the polynuclear counts of healthy Egyptians and of British subjects domiciled in Egypt showed a significant 'shift to the left'. The average weighted mean in Egyptians was 2.128 and that in British subjects in Egypt was 2.077. Shanklin (1936) found a marked 'shift to the left' in the polynuclear counts of the Alouites, the average weighted mean being 1.48.

Present work.—Fifty healthy Indians, all males, were examined in the beginning of June 1937. The age in the majority of cases varied between 20 and 40, only in five cases was it above 40. All the specimens were collected within five days and were obtained between 10 a.m. and 12 p.m. The maximum shade temperature during these days varied between 93.6° and 97.4°F. The subjects comprised doctors, technicians and laboratory assistants at the Calcutta School of Tropical Medicine. No individual who had had a cold or other minor illness during the past one month or had any degree of pyorrhœa was included in the series.

The technique.—Smears were made with the blood obtained from a finger prick on scrupulously clean slides. The films were dried in air, fixed in methyl alcohol, and stained with haematoxylin and eosin. The staining is done as follows:—The fixed smear is stained with Delafield's haematoxylin solution for 3 to 5 minutes. The slide is washed well in water and as a counter-stain a 0.5 per cent watery solution of eosin is applied for a minute or so. The slide is again washed, dried and examined. One hundred cells were counted in each slide and Cooke's criterion about nuclear lobulation was strictly adhered to, the nuclear parts joined by more than a thread being considered as one. Free nuclei and cells with distorted nuclei were rejected.

Results.—The results of these examinations are presented in table III. The last column of the table gives the weighted means of the counts calculated by the method of Ponder and Flinn. These means vary between 1.80 and 2.37, the average being 2.014 with a standard deviation of 0.132. The highest number of observations occurred between 1.90 and 1.99. A comparison of our findings with the findings of other work (table II) brings out the following points:—

(1) Our average weighted mean of the count is significantly lower than the average mean for England, Scotland and Egypt. The difference from the Egypt figures not being marked.

(2) It does not differ significantly from the average weighted mean for Iraqis and Chinese.

(3) It is significantly higher than the average weighted mean for British in Iraq and China and for the Alouites. Only in the case of Alouites is the difference very marked.

The observations therefore show that compared with the standard in Britain there is a marked left-handed shift of the Arneth count in Calcutta, as in other tropical countries where such studies have been made. The extent of the shift may vary in the different countries.

Possible causes of the variation in the count.—A left-handed shift of the count can be produced either by an over-stimulation of the bone-marrow, whereby younger cells are added in greater numbers, or by an accelerated removal of the polymorphonuclear cells from the circulation, whereby the cells are removed before they attain maturity. If only one of the factors operate the result will be to produce an unsteady state of the count as the steady state of the polynuclear count is the result of a balance between the rate of production of the polymorphonuclear cells and the rate of their removal from the circulation. The left-handed shift found in the tropics is thus suggestive of both bone-marrow stimulation and accelerated removal of the polymorphonuclears from the circulation.

Nothing is known about the causes that shorten the life of a polymorphonuclear cell in the circulation. As regards the other factor it is known that thyroid feeding, benzol injections, α -rays and ultra-violet exposures, microbial infections, etc., stimulate the bone-marrow and bring about a left-handed shift in the Arneth count.

Since microbial infection was the first known cause of a marked left-handed shift in the Arneth count, it was natural that at first there was a tendency to attribute the left-handed shift observed in apparently healthy individuals in the tropics to active or latent infections of a minor degree, e.g., oral sepsis, chronic intestinal infections, malaria, etc. Macfie (1915) found a well-marked shift to the left of the Arneth count in patients with malaria. This led him to believe that the left-handed shift found in healthy people in the Philippines (Chamberlain and Vedder), tropical Australia (Breinl and Priestley), and West Africa (Macfie) was due to the fact that these apparently healthy individuals were suffering from an inapparent infection with malarial parasite. Breinl and Priestley did not subscribe to this view *in toto*, as they obtained marked left-handed shift in the Arneth counts of children in North Australia in whom malaria could be excluded. Kennedy (1935) at first thought that the left-handed shift encountered in the natives of Iraq might possibly be accounted for by widespread diseases not severe enough to make the patient feel unwell. His later work with Mackay, however, showed that the climatic conditions appeared

to be the determining factor. Kennedy and Mackay (1935 and 1936) found that the British airmen living in Iraq showed nearly the same amount of left-handed shift in the polynuclear

tion is very high; the admission to the Royal Air Force is made after a rigorous medical examination and all the subjects had good health records.

count as did the natives of Iraq. The question of pathological stimuli could be excluded in this population as the health standard of the popula-

Next to infection comes the consideration of the racial factor. Whether this left-handed shift in the count in the tropics as compared

with the standards in England has anything to do with racial differences? The earlier work of Chamberlain and Vedder, of Breinl and Priestley and of Macfie and the recent work of Kennedy and Mackay, of Pai and of Shaw gives a reply to this question in the negative.

The possibility of the differences in the counts being due to the differences in the diet does not seem to be a probable one, as the diet of British residents in China, Iraq and Egypt approximates very closely to that in England.

The fact that the count of British residents in China, Iraq and Egypt conforms to that of the inhabitants of the respective countries indicates that the difference is environmental in origin. The studies on the changes in the count produced by change of residence support this view. Pai (1935) reported a change in the counts with change of residence in two Chinese. In China, the counts were of the Chinese type, there being a marked left-handed shift, but a residence in England changed the counts to the English type. Shaw (1936) reports similar changes. Two British subjects who had been in Egypt for eight months had a count of the Egyptian type. The counts assumed the British type on their return to Europe and conformed to that type throughout their residence in that country. When they again returned to Egypt the counts once more assumed the Egyptian type.

What are the environmental factors that are common to the tropical countries in which the count has been studied? It has been suggested by Chamberlain and Vedder, Breinl and Priestley, Pai, Kennedy and Mackay that climate may be responsible for the differences observed. Kennedy and Mackay consider that ultra-violet radiation was probably an important factor. Kennedy and Thompson (1929) found that by an exposure to ultra-violet rays the Arneth count in rabbits was deflected to the left. Kennedy (Kennedy and Mackay, 1935) found that exposure to the intense dry heat of a Turkish bath caused a significant left-handed shift. Both heat and ultra-violet radiation are thus capable of effecting a left-handed shift and are, no doubt, a common environmental factor in tropics, but it appears that these factors as such are not the determining factors. Pai (1935) found that the polynuclear counts in healthy Chinese in summer showed a less marked left-handed shift than those in the winter. Again Pai's results for Chinese (average weighted mean 2.05) during the cold and dry winter in China do not differ significantly from Kennedy's results for Iraqis (average weighted mean 1.994) examined in Iraq during the months of June and July when the maximum shade temperature varied from 98° to 116°F. Shaw's figures for British subjects in Egypt (average weighted mean 2.077) examined during winter when the maximum shade temperature varied from 65° to 81°F., although significantly different from

Kennedy and Mackay's figures for British subjects in Iraq (average weighted mean 1.937) examined in May and June when the maximum shade temperature varied between 100° and 115°F. do not show that marked difference which one would expect to find if tropical heat were the sole factor in bringing about a change in the Arneth count. As regards the ultra-violet radiation no work has been done to correlate the degree of the left-handed shift in the count with the amount of exposure of the subject to such radiation.

It would thus appear that not much is known about the environmental factor or factors which are responsible for the left-handed shift in the polynuclear counts in the tropics and the way in which they produce this change. Danzer (1930) found that injections of extracts of different tissues of haemolysed red cells and of leucocytes, and the destruction and absorption of tissues *in vivo* in rabbits was followed by a deflection of the Arneth count to the left. He suggested that the continual and normal breakdown of the tissues in the body was sufficient to provide a stimulus for the continuous and normal output of polymorphonuclear cells from the bone-marrow. Thus it is probable that the rate of destruction of leucocytes and their removal from the circulation, along with other factors, exercises a control on the production of these cells in the bone-marrow. It might be that accelerated removal of the polymorphonuclears from the circulation is primarily responsible for the left-handed shift and the stimulation of the bone-marrow is a secondary factor. If it were shown that the length of life of a polymorphonuclear cell is shortened in tropics, a step forward would be taken in explaining the left-handed shift found in these countries. The next thing would then be to search for the factors in tropical climates that shorten the life of the polymorphonuclears.

Summary

1. The Arneth counts in fifty healthy Indians are reported.
2. The average weighted mean is 2.014 with a standard deviation of 0.132.
3. This average mean is significantly lower than the normal standards laid down in Britain. On the other hand, it is similar to the findings reported from other tropical countries, e.g., Iraq, China and Egypt.

THE ARNETH COUNT IN NORMAL INDIANS

By C. R. DAS GUPTA, M.B. (Cal.), D.T.M.

School of Tropical Medicine, Calcutta

Subjects.—In all, 50 men were examined. Any man who was performing his usual work and did not give a history of a recent illness was taken as normal.

Of the 50 people examined, 30 were workers from the School, *viz.*, doctors, chemists and laboratory assistants, and the remaining 20 were doctors from the D. T. M. class of the School.

The majority of the subjects were Bengalis, only 6 out of 50 were from outside the province of Bengal; of these 4 were from the Punjab and one each from United Provinces and Rajputana.

Their ages varied from 26 to 50 years, but the majority were under 40 years of age.

Technique.—Very thin smears were made on rouge-polished slides; the slides were dried immediately and stained with May-Grünwald and Giemsa stains (Napier and Das Gupta, 1940).

In counting the nuclear lobes, Cooke's criterion of differentiating the lobes was strictly followed and in the case of any doubt about the lobes in cells of class V, IV, and III, they were always put into the next lower class (Napier and Das Gupta, 1941).

In every case nuclear lobes of 100 neutrophilic cells were counted.

Discussion.—It will be seen from table I that in most cases there is predominance of cells of class I, over 40 per cent of cells of this class being present in as many as 21 cases, and along with this there is paucity of cells of classes IV and V; in only five instances were cells of class V seen in a total of 50 cases. Consequently the weighted mean is very low in most cases; in only 10 cases is the weighted mean above 2.0, and in no cases is it above 2.3. The average 'weighted mean' of the whole series is only 1.84, for the 44 Bengalis 1.82, and for the 6 non-Bengalis 1.96, whereas Cooke and Ponder's (1927) average weighted mean for normals is 2.75. Dharmendra (1941), working among the same class of people as ours, found an average weighted mean of 2.014.

The slightly higher figure obtained by Dharmendra is probably due to the mode of staining. For, while we used the May-Grünwald and Giemsa stains with very satisfactory results, Dharmendra used the hematoxylin stain, with the result possibly that many of the bi-lobed eosinophils could not be differentiated from the neutrophils and were consequently classed as cells of class II. The percentage of eosinophils in the average Indian being quite high, it may be assumed that there was an undue increase of cells of class II and consequent raising of the 'weighted mean'. Another reason for the slightly higher value obtained by Dharmendra may be his slightly more rigorous selection of the cases.

Napier, Neal-Edwards and Das Gupta (1941) working among normal Indian women found the same preponderance of young cells and a low 'weighted mean'; the average 'weighted mean' of the whole series being 1.77.

A low 'weighted mean' was also found by almost all observers examining the blood of the people in the tropics, a comprehensive list of which is given by Dharmendra in his article in the present number.

Though in the selection of the cases no rigorous method was employed, as was done by Cooke and Ponder, it will be seen from table II that there was not a single case with a weighted mean above 2.30. It is impossible to believe that of the 50 apparently healthy people examined, not even a single person could be said to be perfectly normal on the basis of the Arneth count, if Cooke and Ponder's criterion of normality be adopted in the case of the Indians. The difference between the Indian and European figures is probably a racial one, for it will be seen from table I that though the weighted mean is slightly higher in the case of 6 non-Bengalis, there is not much difference between the counts in the Bengalis and non-Bengalis. But on the other hand, whilst examining the blood of a few normal Europeans

living in Calcutta, we obtained figures almost the same as those of Cooke and Ponder though Kennedy and Mackay found almost an identical 'weighted mean' in the Iraqis and in the British airman stationed in Iraq (table III).

It is very difficult to say whether this predominance of the young cells and the consequent lowering of the 'weighted mean' in Indians and in the people of the tropics is

a defence mechanism for the protection of the people from the widespread infection to which they are subjected or whether this is due to the actual presence of a low-grade infection, in these Indians. But, whatever be the cause, in interpreting the result of an Arneth count in an Indian, the low figures obtained among normal Indians should be remembered and the results must always be compared with the

A NOTE ON FEVERS OF THE TYPHUS GROUP IN ASSAM

By L. S. F. WOODHEAD
CAPTAIN, I.M.S.

Indian Research Fund Association
and

SUB-ASSISTANT SURGEON U. C. DUTTA, L.M.F.,
L.T.M., A.M.S.

(From the Pasteur Institute, Shillong)

WHILE carrying out routine Widal tests at the Pasteur Institute Laboratory, Shillong, we met from time to time with specimens from patients in Assam whose history suggested enteric fever, but whose serum gave Widal reactions not in the least indicative of that disease, even when repeated two or three times at weekly intervals.

Whilst this, of course, is a common enough experience in any laboratory, it seemed unlikely that failure to produce agglutinins against the enteric group of organisms could entirely account for all the cases of this nature, and in considering other possibilities we noted that the Wilson-Weil-Felix test was rarely, if ever, requested; in fact on only one occasion between 1930 and 1939 was this test asked for. It seemed worth while therefore trying to find out whether some of these cases of 'P. U. O.' might in fact be cases of typhus fever. With this end in view the present investigation was undertaken.

During the course of the investigation, from May 1940 up to date, 203 tests were carried out and the Wilson-Weil-Felix test was considered definitely diagnostic of typhus fever in 17 cases. Of these 17, 8 fell under the head of scrub typhus, 6 probably murine and 3 tick. In none was the Widal in any way suggestive of the enteric group of fevers.

From the geographical point of view the cases can be classified as follows :—

Upper Assam .. 2	(murine)
Lower ,,, 7	(5 scrub, 2 tick)
Hill Districts .. 7	(3 scrub, 1 tick, 3 murine)
Surma Valley .. 1	(murine)

For the purpose of this preliminary investigation the diagnosis of typhus fever is based on a positive Wilson-Weil-Felix test (our criteria being standard agglutination with *B. proteus* OXK at 1/150 or over and with strain OX19 at 1/125 or over), the Widal not suggestive of the enteric group, and the short history sent with the sera.

The highest standard agglutinations (SA) found so far are OXK 1/3,500 and OX19 1/275, the upper limit of agglutination therefore going to dilutions of about 1/6,000 and 1/500, respectively.

The following are examples of typical cases of different races with different grades and severity of disease.

Case 1.—Adult Indian male, from the plains. Disease began with malaise, headache and pain in back and limbs. Two days later temperature rose to 102°F. and had risen to 104°F. by the 4th day with daily rise and fall of 2 degrees. He was then toxemic and looked seriously ill; he was drowsy, delirious at night, and his tongue was coated and dry, and bowels constipated. Bronchial symptoms were present and myocardial weakness developed during the attack. No rash was detected. Temperature fell by lysis to normal on the 14th day. Blood taken on 10th day.

Wilson-Weil-Felix test

OXK	..	SA at 1/550.
OX2	..	SA at 1/17.
OX19	..	Negative.

Case 2.—A young adult Indian female from hills. Toxic with marked delirium and period of coma. Eyes congested, pneumonic symptoms on the 7th day and patient died on 11th day. Temperature fluctuated between 102°F. and 103°F. Blood taken on 10th day.

Wilson-Weil-Felix test

OXK	..	SA at 1/55.
OX2	..	SA at 1/27.
OX19	..	SA at 1/275.

Case 3.—An adult European male, had continuous fever for 18 days which fell by lysis. Headache, some bronchial symptoms, but not very ill. No rash.

Wilson-Weil-Felix test

	OXK	OX2	OX19
SA	SA	SA	
1. Twelfth day ..	1/400	1/40	1/85
2. One week later ..	1/3,500	1/40	1/85
3. Three months later	1/135	1/27	1/55

Case 4.—A young Indian girl, attack began with influenza-like symptoms followed by bronchitis. Blood-stained sputum. No abdominal symptoms. Spleen enlarged 3 fingers. Tongue coated. Temperature swinging in character, fell by lysis in the sixth week. After about 3 days temperature began to show an evening rise (up to 102°F. one evening) lasting about 14 days. No return of bronchial symptoms. No rash was seen.

Wilson-Weil-Felix test

	OXK	OX2	OX19
SA	SA	SA	
About 28th day of disease ..	1/800	1/27	1/27

	OXK	OX2	OX19
One month later ..	1/275	1/27	1/27

In the absence of any records of typhus fever in Assam, the possibility that this group of diseases might occur and be responsible for a certain number of undiagnosed continued fevers has apparently been lost sight of. The recorded distribution of the typhus group of fevers in India, Burma and Malaya, however, would suggest that Assam is unlikely to be exempt and the findings recorded here would seem to confirm this.

Our thanks are due to Lieut.-Colonel L. A. P. Anderson, I.M.S., Director of the Pasteur Institute, Shillong, for his suggestions and advice during this investigation and for his permission to publish this note.

PATHOGENESIS OF BRONCHIECTASIS

By R. VISWANATHAN, B.A., M.D., M.R.C.P., T.D.D.
Lecturer in Tuberculosis, Andhra Medical College,
Vizagapatam

Case report.—A well-nourished individual, aged 40, was admitted into the tuberculosis ward of the King George Hospital, Vizagapatam, with a history of cough with expectoration, irregular fever, and slight dyspnoea on exertion, of four months' duration. Clinical examination revealed diminished movements, hyper-resonance and diminished air entry over the right side of the chest; with a few moist sounds at the base. Radiography revealed a tumour-like mass near the right hilar region. The lung fields were clear. Fifteen days after admission he developed high fever, and severe cough. X-ray showed at that time a dense patch of opacity at the right base near the cardio-hepatic angle. Atelectasis of the lower lobe or a part thereof was diagnosed. A week later the fever subsided, but the opacity at the base persisted. Lipiodol bronchography revealed well-marked bronchiectasis in the atelectatic portion of the lung. The opacity disappeared in the subsequent radiograph, taken after a month, showing that the inflammation and collapse of the lower lobe had cleared off. There was no evidence of bronchial dilatation either, at that stage.

The case has the following interesting points which afford a clue to the pathogenesis of bronchiectasis :—

- (1) Partial obstruction to the bronchus produced emphysema of the affected lung.
- (2) Defective air entry with possible inflammation produced atelectasis.
- (3) Bronchial dilatation was produced in the atelectatic lobe.
- (4) Dilatation of the bronchioles disappeared when the lobe re-expanded.

Case report 2.—Excessive drinking produced a state of temporary mental depression in a naval officer who jumped overboard with the object of committing suicide; but he was rescued by his friends in a few minutes. In those few minutes of partially suspended respiration he had aspirated some sea water into his lungs. When he was admitted into the hospital he had a temperature of 100°F. and a rapid pulse. He was coughing out a good amount of rusty sputum. Physical examination revealed plenty of moist sounds without any definite impairment of resonance. A radiograph showed scattered, irregular, fairly dense opacities distributed throughout both the lungs. His symptoms disappeared the next day. A radiograph two days later showed complete disappearance of all the opacities. A diagnosis of multiple lobular atelectasis was made.

The interesting point in this case is that even salt water in the smaller bronchioles can produce obstruction and consequent atelectasis, particularly when there is defective respiration.

Fleischner (1940) has reported three cases with benign tumour of the bronchus with obstructive emphysema resulting, in one, and atelectasis with bronchiectasis in the other two. While the ball-valve action of a tumour of the bronchus produced emphysema without bronchial dilatation, complete obstruction by the tumour produced atelectasis and bronchiectasis.

Holinger (1938) and Anspach (1934) have emphasized the importance of broncho-stenosis and consequent atelectasis of the lung tissue in the production of bronchiectasis. Lander and Davidson (1938) demonstrated that bronchial

dilatation occurs as soon as the lung becomes atelectatic. Adams and Escudero (1938) and Weinberg (1937) succeeded in producing atelectasis and bronchiectasis by bronchial obstruction.

That it is not the obstruction of a main bronchus but the atelectasis of the pulmonary parenchyma which is the causative factor in bronchiectasis is evidenced by the occurrence of bronchial dilatation in non-obstructive atelectasis as well. Findlay and Graham (1931) have emphasized the significance of the interesting condition seen in the roentgenograms of dilated bronchi filled with lipiodol. While in a normal lung lipiodol penetrates into the smallest ramifications of the bronchioles, producing the picture of the 'leafy tree', in bronchiectasis the picture is that of a leafless tree, owing to the smaller bronchioles being obstructed.

A study of the history of our knowledge of pathology of bronchiectasis reveals certain very interesting facts. Rokitanski in 1842 recognizing the occlusion of bronchioles distal to bronchiectasis, emphasized that collapse, contraction, and ultimate obliteration of the surrounding pulmonary parenchyma is the primary lesion and bronchial distension secondary to it. Corrigan in 1838 stated that consolidation and contraction of lung tissue precedes the distension of bronchi. Raymond in 1835 observed the occlusion of bronchial branches distal to bronchiectasis. Though these findings have been confirmed and recorded by many other pathologists in subsequent years, they were not given due consideration, nor were their importance in the elucidation of the pathogenesis of bronchiectasis realized, until very recently.

Thus, an overwhelming mass of evidence has accumulated to indicate the co-existence of bronchiectasis and atelectasis. But no serious attempt has been made to explain the mechanism by which atelectasis produces bronchiectasis. Before enunciating the theory which, in my opinion, is the most probable, it will not be out of place to give a brief summary of the causes of bronchiectasis enumerated in existing textbooks.

Bronchitis, whooping cough, measles, influenza, pleurisy, pneumonia, tuberculosis, inhalation of dust, etc., are some of the causes mentioned. The causative factors are grouped as intrinsic and extrinsic. Bronchitis is supposed to reduce the solidity and resilience of the bronchial wall which yields easily to the intra-bronchial pressure. Fibrosis of the lung and consequent contraction of the surrounding lung parenchyma are mentioned as among the extrinsic agents producing bronchiectasis. Warner (1935) considers that the primary fault is a non-specific infection of the bronchial wall causing destruction, particularly of the muscles and elastic tissues present. The weakened bronchioles then become permanently dilated as a result of the force causing physiological

dilatation of the bronchi. Smith (1930) is of opinion that bronchiectasis is the result of a specific infection with fuso-spirochaetal organisms. Considerable support is lent to the infection theory by the frequent history of previous broncho-pneumonic attacks in these patients and also by the frequent co-existence of bronchiectasis and sinus infections. No doubt infection plays a part in the pathogenesis, but that it by itself cannot produce bronchial dilatation without the simultaneous presence of some other factors is shown by the fact that the great majority of people suffering from acute and chronic respiratory diseases do not develop bronchiectasis. Besides, Adams has shown that destruction of bronchial walls by thermal and chemical irritants is followed by stenosis and not by dilatation.

There are others like Peter Kerley (1934) who consider that all cases of bronchiectasis are congenital in origin. There are certain facts in support of this theory : (1) bronchiectasis has been discovered in some foetal lungs; (2) the existence of bronchial dilatation in children and in adults without any clinical manifestation or previous history of respiratory infection suggests that it might have existed from birth; (3) the writer (1936) found the disease in two brothers without previous history of lung trouble and without definite clinical manifestation of the disease itself. Due to developmental error, bronchial dilatation exists from birth or congenitally weakened walls get subsequently dilated as a result of exaggerated physiological force or some extraneous mechanical stress. It is not possible to say that all cases are congenital in origin. Besides, the theory is not complete in that no attempt is made to explain the mechanism by which actual dilatation is produced.

The writer (1936) in a previous communication has stated that two main factors are required for the production of bronchiectasis, namely, localized weakening of the bronchial walls and a mechanical force to produce dilatation. He does not agree with Fleischner (1940) in considering that the existence of a dilating force alone without previous weakening of the bronchial walls will produce permanent bronchial dilatation. No doubt temporary dilatation of the bronchial walls is produced in certain conditions like active massive collapse of the lung, but weakness of the bronchial wall is necessary for permanent dilatation.

The most important question that is to be answered is the mechanics of the dilating force. Many consider the violent expiratory phase of coughing an important cause of dilatation of the bronchi, but though the intra-bronchial pressure increases greatly during the time the glottis is closed, just before the expiratory blast of air, the force causing it is applied to the external surface of the lungs by the abdominal muscles contracting and pushing the diaphragm

upwards and also by the chest wall. The pressure inside and outside the bronchial wall is therefore the same and there is no dilating effect.

The more plausible view accepted by Hedblom (1931), Wall and Hoyle (1933), Warner (1935) and others is the inspiration theory; in this theory the mechanical force which comes into play during the inspiratory phase of respiration is considered to be the dilating factor. During the height of deep inspiration, the intra-bronchial pressure, i.e., inside the bronchus, is from 10 to 20 mm. of water more than the intra-pleural pressure, which means that atmospheric air exerts that much intra-bronchial pressure. Ingals (1905) and Jackson (1917) have observed through the bronchoscope that the bronchial tubes are dilated during inspiration and that they contract down again during expiration. Ellis (1936) has experimentally recorded the same changes in the calibre of bronchi by means of a special instrument.

No doubt the increased difference between the pressures inside and outside the bronchus during inspiration must naturally form the dilating force, but there must be more factors contributing to a further increase of this difference in pressures which alone can produce bronchial pressure. What is the factor or factors that augment the normally existing inspiratory dilating force? The proper answer to this question will afford the satisfactory explanation for the pathogenesis of bronchial dilatation.

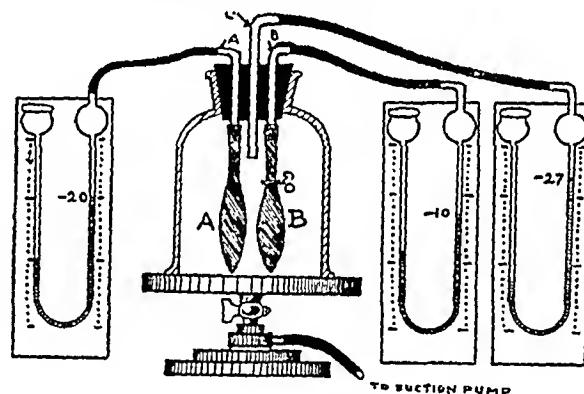

The mechanics of respiration are an interesting study. The forces that come into play are dynamic and not static. There is periodicity, as well as waxing and waning of these forces during the different phases of respiration. Let us consider the variations in pressure inside and outside a bronchus during respiration. During expiration owing to the contractions of the chest the intra-pulmonary pressure is increased and becomes more than the intra-bronchial pressure and air is squeezed into the bronchus through which it escapes outside. During inspiration the chest expands and the intra-pulmonary pressure becomes less than that inside the bronchus; consequently air rushes into the alveolar spaces through the bronchus. The air is as it were aspirated into the lung through the bronchial tube. Hence, when there is free passage for the air into the alveoli there is a relative fall in the intra-bronchial pressure during the inspiratory phase. No doubt the pressure inside the bronchus during inspiration is greater than in the alveoli. Otherwise, there will not be any flow of air from the bronchus into the alveoli. If supposing there is obstruction to one of the bronchioles with consequent prevention of air from getting into the corresponding alveoli, there will not be any movement of air at all just above the obstruction inside the bronchiole, and consequently the fall in the pressure inside that

bronchiole will be much less. In fact, it may even be the same as the atmospheric pressure, whereas the pressure inside the alveoli, supplied by that particular bronchiole which is actually embedded in them, will be practically the same as the pressure in the other parts of the lung, so long as those alveoli contain air. This means that the difference in pressure inside and outside the bronchiole will be greater when the bronchiole is obstructed than when it is not obstructed.

This can be proved to be true by the following simple experiment:—

Two rubber balloons of the same thickness and size are attached to two glass tubings and suspended inside a bell-jar through a rubber cork. The glass tubes are connected to manometers. The bell-jar is placed over the receiving plate of an exhaust pump. Another glass tube is introduced through the cork and connected to a third manometer. (Ordinary Pearson model pneumothorax apparatus manometers were used for this experiment.) A half turn of the wheel of the exhaust pump is made and the excursions of the water column inside the three manometers were simultaneously noted. While the pressures in A and B are found to be equal

BELL-JAR EXPERIMENT PRESSURES AFTER TYING B AT THE NECK

the pressure indicated by the manometer connected to C (i.e., the pressure outside the rubber bags and inside the bell-jar) is much less. B is then tied by a string tightly at its neck. When the experiment is repeated now, it is found that the pressure recorded in B is greater than that in A. The following are the readings recorded in one of the experiments:—

	Pressure inside A	Pressure inside B	Pressure inside C (bell-jar)
(1)	..	-20	-20
(2) With B tied at the neck	-20	-10	-27

During the process of exhausting, the difference in pressure inside and outside the bag acts as the dilating force on the walls of the bag. In the first experiment the dilating force in B is 7 while in the second experiment with B tied at the neck so that no air is allowed to get into the actual bag itself, the dilating force acting on the wall of the tube above the obstruction is 17. The changes in pressure will be practically the same in the case of bronchus and alveoli. In the experiment the narrow tube-like portion of the bag represents the bronchus while the bag-like portion represents the expanding alveolar bed.

There are other factors also which further augment the dilating force by producing more changes in the intra-bronchial and inter-alveolar pressures. When obstruction to a bronchiole is complete, there occurs collapse of the corresponding lobule. Hence the bronchiole instead of being surrounded by spongy cushion-like alveolar tissue gets, as it were, embedded inside stiff, unyielding, atelectatic tissue. During inspiratory dilatation of the chest the distension of the lung is mainly taken over by the yielding parenchyma. Only a small pull is transmitted normally to the bronchial wall. If a bronchus is surrounded by atelectatic lung and the atelectatic tissue fills the space between the bronchus and the chest wall (to assume an extreme case) the pull of the expanding chest is transmitted directly to the bronchial wall as the shock-absorbing action of normal spongy lung tissue is absent.

We have now seen how obstruction to a bronchiole alone might produce bronchial dilatation proximal to obstruction by increasing the difference in the intra- and extra-bronchial pressures. We have also seen how atelectasis of lung tissue resulting from obstruction to the bronchioles augments the dilating force by removing the cushion effect of normal lung tissue. We have yet to see how obstruction can be produced in the smaller bronchioles.

When obstruction to a main bronchus occurs the normal flow of air current is absent. Hence the normal physiological secretions get stagnated in the smaller bronchioles and cause obstruction. According to Fleischner, even under normal conditions when the removal of the physiological secretion is incomplete on account of faulty breathing, secretion may be retained and may temporarily plug the bronchioles. In the second case reported, owing to temporary suspension of respiration due to drowning, the aspirated water was enough to produce lobular atelectasis. Any condition, inflammatory or otherwise, which diminishes respiratory efficiency like acute and chronic infections of the respiratory tract, limited excursion of the diaphragm, pleuritic pain or reflex inhibition of respiration, reduces the cleansing effect of coughing and breathing. The result is accumulation of secretions in the bronchioles and consequent obstruction and atelectasis.

Conclusion. By the proper evaluation of the facts of history of pathology of bronchiectasis, experimental and clinical evidences, and the arguments put forward, we can arrive at the following conclusions regarding the pathogenesis of bronchiectasis :—

Augmentation of the inspiratory dilating force alone may produce temporary dilatation of the bronchioles, but for producing permanent bronchial dilatation two factors are required, namely, weakness of bronchial wall, either congenital or acquired, through inflammation,

(Continued at foot of next column)

TRICHOPHYTON CRATERIFORME IN INDIA

By N. C. DEY, B.Sc., M.B. (Cal.)

and

P. A. MAPLESTONE, D.S.O., D.Sc., M.B., B.S., D.T.M.
(From the Medical Mycology Inquiry under the Indian Research Fund Association, School of Tropical Medicine, Calcutta)

TINEA tonsurans or ringworm of the scalp was first described by Malmsten in 1845. The causative fungus, which was not cultivated at that time, was called *Trichophyton tonsurans*. The endothrix character of the parasite was determined by Sabouraud in 1894 and it was named *Trichophyton megalosporon endothrix* Sabouraud, 1894. On culture the fungus forms crater-like colonies and Bodin called it *Trichophyton crateriforme* (Sabouraud, 1894), Bodin, 1902.

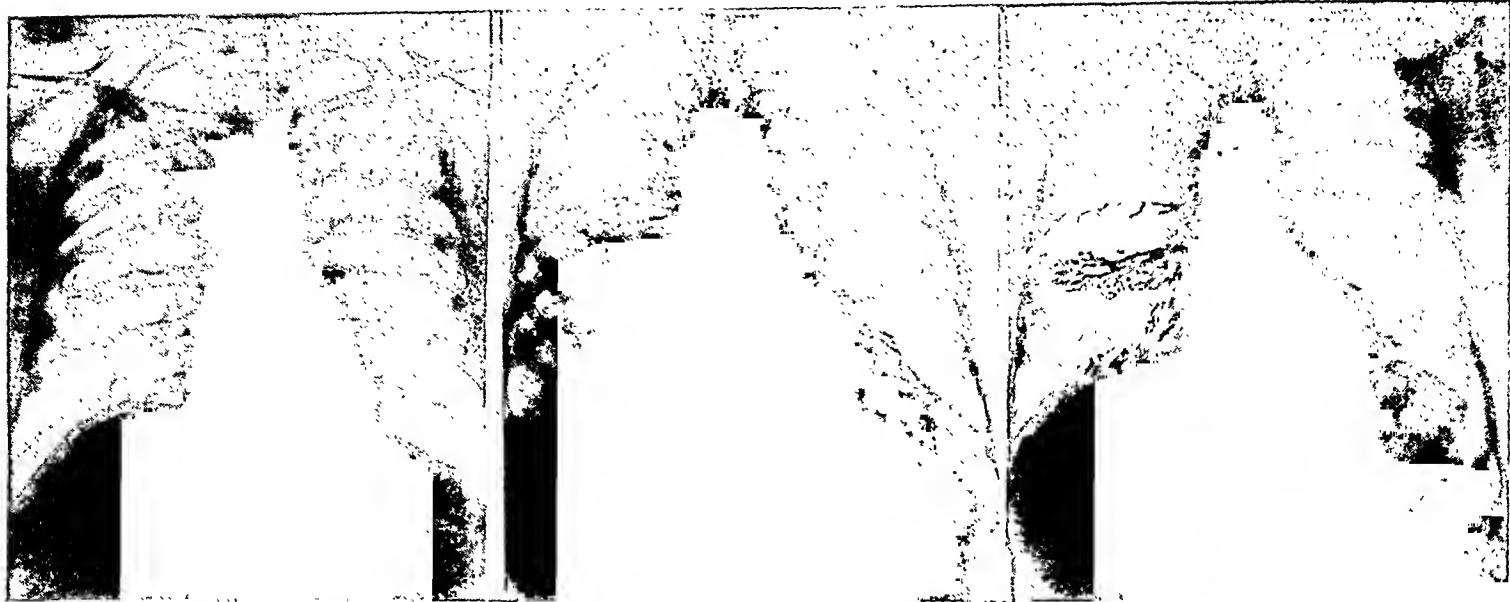

(Continued from previous column)

and the presence of a dilating force. The dilating force is the inspiratory pull on the bronchial walls which is abnormally increased through (1) obstruction to the bronchioles and (2) atelectasis of the lung tissue. Atelectasis is caused by obstruction; and obstruction is caused by collection of secretions in the bronchioles resulting from disturbance of the self-cleansing capacity of the lung by general or local impairment of pulmonary ventilation. Respiratory inefficiency may in its turn be due directly to acute or chronic infections, or indirectly to individual variations in anatomy, and type of breathing, reflex inhibition, or previous infections leaving behind fibrosis or adhesions.

Descriptions of illustrations

Fig. 1.—Multiple patches of 'black dot' ringworm of the scalp caused by *T. crateriforme*.

Fig. 2.—Hair showing mycelia and spores in chains. Mag. $\times 360$ approx.

Fig. 3.—Cultures on Sabouraud's medium

- (a) Primary culture from the hair—three weeks old.
- (b) Subcultures in tubes—two weeks old.
- (c) Subculture in a flask—four weeks old.

Fig. 4.—Microcultures on Sabouraud's medium

- (a) Primary growth from the hair showing clusters of aleurospores. Mag. $\times 64$ approx.
- (b) Simple aleurospores—either sessile or with short stocks.
- (c) Aleurospores forming clusters. Mag. $\times 360$ approx.

The genus *Trichophyton* was subdivided by Sabouraud into endothrix, ectothrix and endo-ectothrix (neo-endothrix) according to whether the fungus attacks the interior, the exterior or both the interior and exterior of the hair.

The characteristic features of an endothrix trichophyton are that it attacks the interior of the hair and grows inside it although in the primary stage, the infection must take place on the outer coating of the hair. This infection is mostly of human origin and spreads from one person to another by direct contact. It is usually confined to the scalp, and children are the worst sufferers. The ectothrix and endo-ectothrix trichophytons, on the other hand, are mostly of animal origin and infection is usually acquired from domestic pets. These fungi attack the secondary sex hairs, commonly the beard area, causing inflammation of the hair follicles.

Trichophyton crateriforme causing ringworm of the hair has not been reported from India before. The infection is quite common in Europe where according to Sabouraud it is responsible for 59 per cent (122 out of 207 cases) and Colcott Fox recorded 38 per cent of endothrix infections in England as due to this species.

Out of 169 cases of ringworm of the scalp which have been fully investigated in Calcutta by us, 72 were found to be caused by endothrix trichophyton infection and except the seven cases reported in this paper, the remaining 65 were infected with *Trichophyton violaceum*.

These seven cases of ringworm of the scalp came from a boarding school in Calcutta. The subjects were all Anglo-Indian girls between the ages of 7 and 13 years. In all the patients but one, in whom there was a circular patch on one side of the face, the lesions were confined to the scalp. The lesions of the scalp consisted of multiple small patches of different sizes and shapes. The hairs in these patches were few in number and on careful examination were found broken leaving stumps projecting about 4 to 5 mm. above the surface of the scalp. These stumps were pointing in different directions and were covered with a thick layer of greasy scales. The end of the stumps were sticking out from the scales and gave the appearance of 'black dot' ringworm (figure 1). When the scales were removed, the hairs were found lying coiled up underneath them and when pulled out they were bent like the letters S or Z or twisted spirally.

Differential diagnosis.—Clinically, it has been observed that in children, endothrix infections produce multiple bald patches on the scalp. The main characteristic features of *T. crateriforme* infection are the presence of greasy scales heaped up round the hair follicles under which the infected hairs are twisted in various ways and the hairs break a few millimetres above the surface of the scalp, whereas in cases of *T. acuminatum* and *T. violaceum* infection the hairs usually break at the root. In *T. violaceum*

there may be scaliness and hypertrophy of the hair follicles accompanied by inflammatory reaction of the surrounding skin. This fungus also infects hair follicles on other parts of the body—glabrous skin, and nails—more frequently than other endothrix species.

Microscopic examination.—Under the microscope the following characteristics were noticed. The fungus affected the interior of the hair. The mycelial filaments measured 4 to 5μ in diameter and the old ones divide into spores with square cut ends (figure 2). These spores differ from those of other endothrix trichophytons, namely *T. acuminatum* and *T. violaceum*, which are usually oval in shape.

Cultural appearance.—For the primary culture Sabouraud's proof medium was used but Merck's maltose was substituted for crude maltose.

In the primary culture the growth appeared on the 4th or 5th day at room temperature. In early cultures the surface of the growth was white and velvety with a knob-like prominence in the centre giving the appearance of a powder puff, as described by Sabouraud. Later on a depression often appeared at the centre of the knob, resembling a crater (figures 3a, b and c). The surface, which at first was white and velvety, later became brownish or yellowish-brown and powdery. The growth was somewhat hard, cartilaginous in texture and did not easily break. Subcultures in different laboratory media had the same characters as the primary growth.

Pleomorphism was not observed in any case.

Morphology.—Sabouraud's proof medium was used throughout the experiment. Morphology was studied from hanging drop preparations in welled slides made from infected hairs (figure 4a) and from subcultures, aleurospores were the only end-organs noticed, they varied from 5 to 7μ in length and 2.2 to 2.8μ in breadth. These were either simple, sessile or with short stalks, situated at the side or at the terminal part of a growing hypha, or they were compound, forming clusters or thyses as they are called (figures 4b and c). Intercalary chlamydospores were also found. In some instances the terminal parts of the hyphae were club-shaped.

Culture of *T. crateriforme* has a powdery surface and a central crater. This crater formation is so characteristic that the species has been named after it. *T. acuminatum* has a powdery growth but its centre is raised and acuminate. The growth of *T. violaceum* is very different from the above two species; because it is raised, faviform and coloured different shades of violet. *Trichophyton sutureum* also produces endothrix lesion of the hair and resembles *T. crateriforme* in almost every respect except that on culture the growth takes up a delicate yellow colour.

Biochemical reactions

- (a) Sugar—no fermentation on ordinary laboratory sugars.
- (b) Proteolysis—no proteolysis in Löffler's medium.
- (c) Milk—the milk protein (casein) was proteolyzed giving a translucent appearance to the milk.
- (d) Haemolysis—no haemolysis in blood sugar.

Animal inoculations

The abdominal skin of guinea-pigs, rabbits and mice were inoculated with an emulsion of the culture after scarifying the part. Typical lesions were produced at the site of the inoculation and fungus was isolated from them. The animals recovered spontaneously in about a month.

Summary

1. The occurrence of *Trichophyton crateriforme* infection is reported for the first time in India.

2. The morphology and cultural characters of the fungus have been described.

A NOTE ON COMPLEMENT FIXATION IN HYDATID DISEASE AND ASSOCIATED CONSIDERATIONS

By S. D. S. GREVAL

LIEUTENANT-COLONEL, I.M.S.

Imperial Serologist

S. N. CHANDRA

CAPTAIN (late I.M.S.)

First Assistant

and

B. C. DAS, B.Sc.

Chemist

(*Imperial Serologist's Laboratory, School of Tropical Medicine, Calcutta*)

THE intention is to (i) draw clinicians' attention to a newly described serological technique for the laboratory diagnosis of hydatid disease, (ii) give the positive findings obtained with sera received from widely separated localities in India, during the last 11 months, (iii) make observations on the utility of the reaction in the diagnosis and in estimating the progress of cases not treated surgically, and (iv) comment on the infestation in India.

A NEWLY DEVELOPED TECHNIQUE

The technique has been described in detail by the writers elsewhere (Greval, Chandra and Das, 1941). Its essential features are three:

(i) The antigen is selected, pooled, phenolized and preserved in a refrigerator: it keeps for at least one year and provides a constant product which gives repeatable and, therefore, comparable reactions.

(ii) The dose of the antigen is linked to the haemolytic system: it is not anticomplementary when used with 1 M. H. D. of complement and is not haemolytic even when multiplied by three.

(iii) The reaction is linked to the Wassermann reaction and is put up only when a complement of optimal reaction and titre for the latter reaction is available (Greval, Chandra and Das, 1940). A Wassermann reaction is done on the serum at the same time.

The antigen is the hydatid fluid from freshly slaughtered sheep as recommended by previous workers (Fairley, quoted by Dew, 1928; McIntosh, 1931).

The serum is tested in dilutions of 1 in 10, 1 in 50, 1 in 100 and 1 in 200 routinely, and in other dilutions afterwards, if so indicated. The complement is used in a constant dose of 2 M. H. D.

The sensitiveness and specificity of the reaction are of a high order. Only a reaction

giving full inhibition of lysis (no trace of lysis) is read positive.

The sera are collected and despatched as for the Wassermann reaction. Incidentally, the standardized preserved antigen is also available for intradermal tests.

POSITIVE FINDINGS DURING THE LAST 11 MONTHS FROM 20TH JUNE, 1940

One serum was found positive in Calcutta (titre 1 in 100, just; diagnosis confirmed surgically and microscopically; Indian patient). Later, at the senior writer's request to surgeons-general, inspectors general of civil hospitals and directors of research institutes, in India and Burma, four positive sera were obtained from Madras (titre 1 in 10; diagnosis doubtful; Indian patient), Salem (in Madras Presidency; titre 1 in 50; diagnosis confirmed surgically and microscopically; Indian patient), Coonoor (titre 1 in 40; not diagnosed surgically; medical diagnosis of fits due to cysts; Indian patient), and Dera Ghazi Khan (in the Punjab; titre 1 in 25; diagnosis confirmed surgically and microscopically; Indian patient), respectively.

During the same period, out of five other sera received for the test, two were doubtful and three negative.

During this period a surgically and microscopically positive Indian case has been reported from Lahore (Khanna, 1941). Serological reaction was not done.

The only previous serologically positive case at Calcutta appears to have been one published in connection with a suspected case of tuberculosis (Ukil and Ganguli, 1937). Details of procedure are not given.

UTILITY OF THE REACTION

The utility of the reaction in diagnosis is obvious in view of its sensitiveness, specificity and comparableness. Will the reaction indicate retrogression of the disease as a result of treatments other than surgery? Such treatments are x-ray (Tyzzer, 1933) and medicinal treatment of systems other than European allopathy and of homoeopathy, which are always on trial in India.

The hydatid cyst in the sheep is *Cysticercus granulosus*. The usual hydatid cyst in man is the same. For the detection of the unusual *Cysticercus cellulosae* in man the fluid from the corresponding hydatid cysts in the pig would be a better reagent. These cysts, however, are not so readily procurable. It is not known to the writers how far a group reaction with the fluid from the hydatid cysts in the sheep succeeds in detecting the unusual *Cysticercus cellulosae* cysts in man: such a reaction has been obtained in some proved cases but not in others (Dixon and Smithers, 1935). The reaction of sera from patients that are hosts of tapeworms is also unknown.

INFESTATION WITH *Cysticercus* IN INDIA

Infestation in sheep in Calcutta is common. A dozen fluids can be obtained sometimes on one day from the municipal slaughter house. Infestation in man is apparently rare. This is held to be true of the whole of India and also of Egypt and China (Dew, *loc. cit.*). But the infestation though reported infrequently is widespread in India. Probably the disease is often missed. Such is the opinion of previous workers also (Mahadevan and Menon, 1933; Sami, 1938). The cases now reported were contacted soon after circularization. The interest which appears to have waned already may wax again as a result of this note and bring to light more cases.

Infestation in one series of dogs with the adult worm was found to be only 2 per cent in 100 dogs examined in Calcutta (Maplestone, 1933). It was, however, held 'very probable that *granulosus* infection is fairly common in dogs in the country districts in India'. In another and recent series the infestation has been found to be 18 per cent (Maplestone and Bhaduri, 1940).

Does nature terminate the infestation in most cases in man in India? The reported absence of eosinophilia in old cases of hydatid (Mahadevan and Menon, *loc. cit.*) may point to a loss of activity or even vitality of the *cysticercus*.

The total number of cases reported in India since 1933 by the writers quoted in the note, including the number under report, is forty-six.

TAKING BLOOD FOR TRANSFUSION : FURTHER IMPROVISATIONS

By S. D. S. GREVAL
LIEUTENANT-COLONEL, I.M.S.

Imperial Serologist

S. N. CHANDRA
CAPTAIN (late I.M.S.)

First Assistant

and

D. N. CHATTERJI

Research Worker, Indian Research Fund Association
(Imperial Serologist's Laboratory, Calcutta)

In two previous communications (Greval and Chandra, 1940; Greval, Chandra and Roy Chowdhury, 1940) use of Potain's aspirator, with or without the pump, has been advocated for taking blood for transfusion in a closed system. The procedure is so controlled that air-borne contamination either does not enter or enters in a quantity which is effectively overcome by the fresh living blood. In 102 bottles of blood collected consecutively for storage between 22nd November, 1939, and 22nd April, 1941, (date of starting storage and date of writing this note, respectively) not a single bottle was found contaminated on inspection (by sight and smell). Between the same dates no accidents resulted from 75 consecutive transfusions given with stored blood.

The special stopper of the aspirator has lately become difficult to obtain or repair. The writers have in its place employed two separate metal tubes, bent at right angles with a gentle curve to provide a horizontal and a vertical limb. The ends of the horizontal limbs fit adapters of the rubber tubes of Potain's aspirator. The vertical limbs pass through a rubber stopper which fits a bottle. One of these tubes, receiving a male adapter, acts as an inlet and the other, going into a female adapter, acts as an outlet. The inlet ends at a lower level than the outlet. Instead of the taps of Potain's aspirator, two Hoffmann's clips (burette clips for pressure tubing, operated by turning screws) are placed on the rubber tubes.

When the rubber stopper and the metal tubes are sterilized both the horizontal limbs point in the same direction to economize space. The rubber tubes are sterilized with the clips in position. The clips can be attached later when they are hinged.

The clips make two precautions necessary : (i) the load on the rubber tubes must be supported or else the adapters are likely to get dislocated, and (ii) how many turns of the screw will open or close the tubes must be determined beforehand.

The outlet can be fitted with a two-way tap and the bottle exhausted with a record syringe if the pump of Potain's aspirator is not available. Even without a two-way tap the bottle can be exhausted sufficiently by removing

(Concluded at foot of next page)

BACT. ALKALESCENS IN INFECTION OF THE URINARY TRACT AND BACTERIO-PHAGE THERAPY

By C. L. PASRICHA
MAJOR, I.M.S.

Professor of Bacteriology and Pathology
and

A. J. H. DEMONTE, I.M.B.

(From the Department of Bacteriology and Pathology,
School of Tropical Medicine, Calcutta)

ANDREWES (1918) in a paper on the differentiation of true dysentery bacilli from allied organisms described and named three species or groups of species of bacilli which though strongly resembling the true dysentery bacilli were not considered by him as causal agents of dysentery; one of these was *Bacterium alkalescens*.

Andrewes described it as a Gram-negative non-motile bacillus which produced acid but no gas in glucose, maltose, mannitol and dulcitol. Lactose and saccharose are not fermented. Indole was formed by all strains examined by him and litmus milk became markedly alkaline after a week or ten days. The organism was not agglutinated by specific Shiga or Flexner-Y serum within the ordinary time limits of 4 to 5 hours at 55°C., but when the tubes were left at this temperature for 20 to 24 hours agglutination with Flexner serum occurred with some

(Continued from previous page)

syringefuls of air and closing the tube while removing and re-applying the syringe by means of an adapter. The water aspirator pump, fixed to a water tap, may be used. Suction by mouth at the distal end of the outlet produces enough exhaustion of the bottle. Care is necessary in making a second attempt when saliva may be drawn into the bottle.

The General Scientific Engineering Co., 4/1, Harish Mukherji Road, Calcutta, supply two metal tubes and four adapters, complete set for a bottle, for Rs. 10. The metal is silver-plated brass.

Even glass tubes can be used in the place of the metal tubes. They are, however, inconvenient to fit into rubber tubes and of course are liable to break.

Incidentally, the writers now use routinely a 3 per cent solution of sodium citrate instead of 2.5 per cent. As before, one-tenth volume of the ultimate content of the bottle is taken (e.g., 40 c.cm. for 400 c.cm.). The concentration in the citrated blood is 0.3 per cent instead of 0.25 per cent.

strains but always well below the titre of the serum. In no case was it agglutinated by the serum of the patient from whom it was isolated. Andrewes concluded that *Bact. alkalescens* 'can be rejected as having no connexion with dysentery'.

Many of the subsequent authors regard *Bact. alkalescens* as non-pathogenic. Park and Williams (1934) write of it as 'apparently non-pathogenic and of importance only because of the possibility of confusing it with the pathogenic varieties'. Gay (1935) states that it is 'distinctly non-pathogenic', and Havens (1935) as an organism 'whose pathogenicity has not yet been established'. Topley and Wilson (1936) write 'whether this organism is capable of giving rise to real dysentery is doubtful. Since, however, it has been isolated from the blood stream of a woman with puerperal fever (Smith and Fraser, 1928) and has been found in an institutional outbreak of food-poisoning (Welch and Mickle, 1934) its occasional pathogenicity for man must probably be accepted'. Bergey (1939) in the latest edition of the *Manual of Determinative Bacteriology* describes it as 'not pathogenic'.

Smith and Fraser (1928) were the first to assign a definite pathogenic rôle to *Bact. alkalescens*. They described a case of continued fever due to this organism. Since then there has been an increasing number of reported instances where *Bact. alkalescens* has caused disease in man. This evidence has been collected, reviewed and well summarized by Nabarro and Edward (1939) who also record a series of seventeen of their own cases where *Bact. alkalescens* was isolated from the faeces. In these it was associated with disease nearly always involving the intestinal tract. These authors conclude that infection with *Bact. alkalescens* is primarily intestinal giving rise to a mild form of acute dysentery or chronic colitis and that lesions produced elsewhere are to be regarded as complications. These workers give thirteen references in which *Bact. alkalescens* is reported to have caused pyelitis or other infection of the urinary tract. In these cases *Bact. alkalescens* was recovered in pure culture from the urine and in several, agglutinins in significant titre were demonstrated in the serum. In India, Boyd (1932) found *Bact. alkalescens* five times, three times in Poona and twice in Bangalore. Of its pathogenicity he states 'all five strains were recovered from the stools of normal individuals. There is, therefore, no suggestion of pathogenicity, a finding which accords with the opinion formed by Andrewes'.

From this brief survey of the literature it is obvious that there is no unanimity of opinion regarding the pathogenicity of *Bact. alkalescens*. It is for this reason that a brief account is given of a patient from whom this organism was isolated in pure culture several times from the urine and in whom there was sufficient evidence to regard it as the causative agent. There were

in addition certain interesting features following bacteriophage therapy; and reference to these is included.

The patient, a Scot, aged 52 years, who had seen some 25 years of service in India had been suffering from symptoms typical of cystitis for about a month. There was no history of intestinal disturbance or of any previous urinary trouble. Except for a slight but definite enlargement of the prostate (probably physiological), nothing abnormal was found on physical examination. The urine was turbid and contained a large number of pus cells and on culture *Bact. alkalescens* was isolated in pure culture. During the first month of observation 51 samples of urine were examined and the organism was isolated from 45 of the samples. It was also isolated from each of the three samples of stools examined.

All strains gave identical biochemical reactions. They produced acid but no gas in glucose, maltose, mannitol and dulcitol. There was no change in lactose, saccharose and salicin. Indole was produced and litmus milk turned alkaline. Representative strains were tested with the patient's serum (blood drawn about five weeks after the onset of symptoms) and were agglutinated up to 1 in 500 dilution. This organism agglutinated with a polyvalent Flexner serum but only to 1/10th of the titre of the serum. A serum was raised against the strain isolated from the first specimen of urine and this serum agglutinated to titre (1 in 10,000) the strains isolated later.

An active and potent alkalescens phage was prepared. It caused complete clearing of a young broth culture in about one hour and the lysis was maintained for about 72 hours when a faint turbidity appeared. This bacteriophage was given to the patient in doses of 2 c.cm. in 2 ounces of water three times a day for a month. Bacteriophage active against *Bact. alkalescens* was not present in samples of stool and urine examined before the administration of alkalescens phage, but was recovered from the stool a day after and from urine two days after the administration of the phage by mouth. *Bact. alkalescens* was not found in any of the eight samples of stools examined during and after phage treatment.

The effect of bacteriophage therapy on the organisms in the urine was interesting. The first effect was to render the urine less turbid and fewer organisms were recovered and these were obviously phage-infected. The colonies on the plate were variously notched and some showed minute areas of phage clearings. This was followed by some days when the urine contained potent alkalescens phage and gave no growth of any organisms or when, in spite of the presence of active phage, a few isolated colonies were obtained. After about a week however of such findings the urine became markedly turbid and gave a heavy growth of *Bact. alkalescens*.

Bacteriophage was present in the urine intermittently; it would be found regularly for two days (two samples examined each day), be absent for two or three days, and then be found again. An attempt was made to correlate this with the reaction of the urine, but no such correlation could be made.

A study was made of the strains of *Bact. alkalescens* isolated from the urine before and after the administration of alkalescens phage and their lysability by (1) the phage administered, (2) the phage recovered from the stool and (3) the urine, and (4) the phage contaminating the organism isolated after phage therapy. The strains (urine and stool) isolated before the administration of alkalescens phage were lysable by (1), (2), (3) and (4). The strains of *Bact. alkalescens* recovered from the urine after the administration of phage orally and when the phage had appeared in the urine were lysed by (1) and (2), the original phage, and by the phage recovered from the stool. These strains were resistant to the phage races (3) and (4), those found in the urine and those contaminating the organisms. These results show that the phage given to the patient contained more than one type and that only one type of alkalescens phage was able to get through to the urine or survive in the urine.

The alkalescens phage was given daily for a month without producing any effect either on the clinical symptoms or on the condition of the urine, which continued to contain pus cells and the organisms in large numbers. An autogenous vaccine was prepared with the strain originally isolated. The response to vaccine therapy was striking and the urine was clear and free from organisms 17 days after the commencement of vaccine therapy. The clinical condition improved considerably and the patient was completely cured.

Summary

1. Attention is drawn to the evidence implicating *Bact. alkalescens* as a pathogen of man.
2. A case is recorded in which *Bact. alkalescens* caused cystitis. This organism was isolated in pure culture from the urine on several occasions during the course of the disease and disappeared when the symptoms subsided. It was isolated also from samples of stool. Agglutinins for *Bact. alkalescens* were present in the patient's serum.
3. Alkalescens phage was given by mouth for a month. This led to the rapid disappearance of the organism from the stools, but had only a transient effect on the ordinary infection. Only one type of alkalescens phage was found in the urine, whereas the bacteriophage given by mouth contained two distinct types.
4. Bacteriophage therapy having failed to control the infection, autogenous vaccine was used with satisfactory results.

BACTERIOPHAGES IN SOIL

By C. L. PASRICHA

MAJOR, I.M.S.

Professor of Bacteriology and Pathology

and

B. M. PAUL

(From the Department of Bacteriology and Pathology,
School of Tropical Medicine, Calcutta)

DURING the course of certain experiments designed to demonstrate 'antagonistic bacteria' for intestinal pathogenic bacteria of man, the interesting observation was made, that many samples of garden and field soil contain bacteriophages active against these organisms.

A 1 in 100 suspension in saline of soil when added in 1 c.cm. amounts to melted agar containing a thick suspension of one of the test bacteria and poured, after incubation, showed a number of bacteriophage colonies. *Bacterium typhosum*, *Bact. flexneri*, *Bact. shigæ* and *Vibrio cholerae* were used as the test organisms, and from twelve of the sixteen samples of soils examined bacteriophages active against some or all the four test organisms were isolated. In some plates as many as 120 bacteriophage colonies were present. The most frequently occurring bacteriophages were the dysentery-phages and next in order typhoidphages and cholera-phages. These bacteriophages were present in samples of soil taken at different levels (down to 3 feet) below the surface.

These findings demonstrate how widely bacteriophages are distributed in nature.

NOTES ON COMMON SKIN DISEASES

III. RINGWORM OF THE SCALP : FAVUS

By N. C. DEY, B.Sc., M.B. (Cal.)

(From the Medical Mycology Inquiry, under the Indian Research Fund Association, School of Tropical Medicine, Calcutta)

FAVUS is so distinct from other ringworms that we decided to treat it separately. It is a highly contagious disease and affects adults and children alike; it spreads by extension from the scalp to the body. In India, the disease is endemic in Kashmir, the Punjab, the North-West Frontier Province, and Rajputana, but does not usually occur in the eastern and southern parts of India. It is commonly found amongst the poor and is not a problem of the boarding schools.

The causative organism is a fungus of the genus *Achorion* and, of the various species, both *Achorion schönleinii* and *A. actoni* have been reported from India.

Clinically, the disease has certain distinctive features. It begins as small yellow sulphur-coloured cup-shaped discs around the hair follicles. The concavity of the cup is upwards and the convexity is towards the surface of the scalp. When a disc is removed, it leaves an oozing ulcerated area on the scalp; the base of the ulcer is red and oozes a sero-purulent discharge. The yellow discs, or 'scutula' as they are called, gradually increase in size and coalesce with the adjacent ones. In an advanced case, the whole scalp appears to be covered with a thick yellow-coloured mud plaster. The lesions spread from the scalp to the body and form the same type of scutula among the lanugo hairs. A fully-developed case of favus presents no difficulty in the diagnosis and the patients emit a peculiar smell from the lesions like that of mouse urine.

If one of the discs or scutula is removed with a pair of forceps, some amount of force is required to pull it off and the hairs at the centre of the scutula come out with them from the root.

When a scutulum is dissolved with 40 per cent liquor potassii and examined under the microscope, it is found to consist of a network of mycelial threads in which are embedded epithelial debris and pus cells. In the hairs, the mycelia are arranged along the long axis and hence the hairs split longitudinally and do not break.

Prophylaxis.—The disease is highly contagious and complete segregation of the patient is necessary. Hats, turbans or any other head dress must be burnt and tight-fitting cotton caps given to wear until the patients are completely cured.

Treatment.—Epilation of the infected hair manually, or by x-rays, and then treatment of the scalp with mild antiseptics are essential features of the treatment. In favus, unless

fairly advanced, epilation is easy as the hairs, not being brittle, come out with scutula when these are removed.

A good method of removing the scutulum is to soak the scalp overnight with the following:

R Phenol 15 minimis
Mercuric oleate 10 grains
Olive oil $\frac{1}{2}$ ounce
Vaseline $\frac{1}{2}$ ounce

In the morning, wash the scalp with spirit soap shampoo (soft soap 1 oz., spiritus rectificatus 2 oz.) and water. During the washing, remove the scutula with the hair, as much as possible. After the shampoo wipe the part dry, apply

dilute ammoniated mercury ointment, 1 per cent to 2 per cent, to the ulcerated parts and repeat this process for 3 or 4 successive days until the scalp is fairly clear. In the case of an acute inflammatory condition, warm compress with 1/200 phenol, changed every 3 hours, will be of great benefit. When the inflammatory condition subsides, the scalp is fairly clean, and the ulcers have healed, in mild cases without any inflammation, Whitfield's ointment or thymol iodine paint may be applied.

In refractory cases, there need not be any hesitation in advising the patient x-ray treatment by an expert radiologist. The chances of baldness resulting from the disease are much greater than from faulty x-ray treatment.

A Mirror of Hospital Practice

A CASE OF CAVERNOUS SINUS THROMBOSIS COMPLICATING MENINGO-COCCAL MENINGITIS WITH RECOVERY

By C. J. HASSETT

CAPTAIN, I.M.S.

Agency Surgeon, North Waziristan

RASHA DIN, aged 19 years, was admitted into hospital on 13th October, 1940, with a history of headache for the past three days. Twelve hours prior to admission he had noticed that his left eye began to bulge and that the lids became swollen and oedematous with constant lacrimation; up to this he had been in excellent health, the temperature was 100°F. and the pulse rate 84 per minute.

Physical examination.—He was conscious but somewhat apathetic. There was exophthalmos of the left eye (see figure), the upper and lower lids were swollen and oedematous; the conjunctiva was chemosed; movements of the eye-ball were absent and the pupil failed to react to light. There was absence of vision;

Photograph taken on second day of admission.

ophthalmoscopic examination revealed choked disc and retinal haemorrhages. The right eye was normal; the throat, teeth and sinuses were normal; there were no signs of sepsis on the face; the other cranial nerves

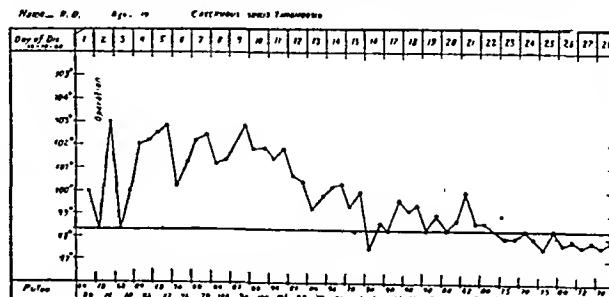

were normal; the knee and ankle jerks were exaggerated; the plantar reflexes were normal; there was no clonus; the abdominal reflexes were brisk; Kernig's sign was negative; there was no rigidity of the neck muscles; there was no impairment of sensation. The spine and cranium showed no abnormality. The visceral reflexes were normal. There was no rash. Examination of other systems was negative.

Laboratory findings.—13th October. Blood: malarial parasites—negative, red cells 4,550,000 per c.cm., leucocytes 25,312 per c.cm. Differential count—polymorphonuclears 85 per cent, lymphocytes 12 per cent, large mononuclears 3 per cent. Culture—sterile.

Cerebrospinal fluid: 1,109 cells per c.cm., meningo-cocci positive. Nonne-Apelt test positive. Urine and stools normal.

14th October. The right eye now showed exophthalmos though not so severe as in the left eye. There was some chemosis of the conjunctiva, movements were restricted, vision was normal. Ophthalmoscopic examination revealed no abnormality. General examination revealed a positive Kernig's sign and rigidity of the neck muscles.

Treatment.—Lumbar puncture was performed on the day of admission when 30 c.cm. of purulent fluid were removed. He was put on sulphapyridine, 2 grammes four hourly by mouth, and 2.5 grammes by intramuscular injection. In all a total of 67 grammes was given. As

remarked the right eye showed involvement. The left eye was more proptosed and swollen and showed signs of irido-cyclitis. The discharge was now purulent; normal saline washes were given to the right eye and liquid paraffin drops were instilled. Owing to the onset of suppuration in the left eye and with a view to preserving the vision in the right eye, it was decided to enucleate it. This was done under ether anaesthesia on the second day after admission. After the removal of the eye, the patient stated that he felt more comfortable and there was no further protrusion of the right

eye-ball. Recession began to take place though slowly. It was complete in two months; at present there is slight hypertrophy of the lower tarsal conjunctiva; movements and vision are now normal. A daily check was also kept on the white cell count to avoid the possible toxic effects of the sulphapyridine. Lumbar puncture was carried out daily for six days, when it was discontinued as there was no further indications for its employment.

During his illness he developed a mild parotitis on the left side which cleared up with an intravenous injection of calcium gluconate, and he was given chewing gum to promote the flow of saliva. The temperature chart of the case is given.

Discussion.—Such a complication of meningococcal meningitis appears to be very rare. It is not an uncommon complication of septic processes on the face, suppuration in the sphenoidal air cells, inflammation of the jaw or teeth sockets. In the well-known textbooks of medicine such a complication of meningococcal meningitis is not mentioned nor have I been able to trace such a complication in the literature at my disposal. When the case was first seen, discussion arose as to whether the thrombosis was the primary cause of the meningitis following on a possible source of sepsis in the orbit, or whether the meningitis was primary and the thrombosis of the cavernous sinus secondary. This was settled by the lumbar puncture and the demonstration of meningococci in the fluid.

A MOBILE APPENDICAL ABSCESS

By R. D. MACRAE, F.R.C.S.E.
CAPTAIN, I.M.S.

Agency Surgeon, Gilgit, via Kashmir

A YOUNG Mohammedan male was admitted with a history of recurring mild attacks of pain in the right iliac fossa. There had been nausea but no vomiting. After an unusually distinct attack of the pain had come and gone, he sought advice, and an explanation of his symptoms. He walked to the out-patient department.

Examination revealed a furred tongue, a slightly increased leucocyte count, and a tender mass in the right iliac fossa about the size of an egg. The mass was so mobile that it could be depressed towards the pelvic brim, when it could no longer be felt. It moved vertically more easily than laterally. There was no rigidity, no cutaneous hyperesthesia, no tenderness elsewhere in the abdomen or per rectum, and the psoas test was negative. The temperature was 99°F.

Diagnosis was indefinite, and cystic tumour, or abscess of the appendix, torsion of the omentum, and torsion or partial strangulation of a Meckel's diverticulum were suggested.

The abdomen was opened under spinal anaesthesia by a paramedian incision. The proximal inch of the appendix appeared normal; the rest was hidden in a round, cystic mass of tissue composed of the lower edge of the great omentum. There were only string-like adhesions to the ileum. The mass was delivered into the wound, the adhesions separated, the omentum clamped, divided, and ligated, and then appendectomy completed in the usual way.

The specimen was incised and showed a perforated appendix, surrounded by omentum, which everywhere formed the wall of an abscess containing homogeneous, odourless pus. Recovery was uneventful.

It is surmised that an appendical mucocoele became infected by organisms of low virulence, and complete omental adhesion formed before perforation occurred.

A CASE OF CEREBRAL MALARIA WITH RARE COMPLICATIONS AND COMPLETE RECOVERY

By R. M. LLOYD STILL
MAJOR, I.M.S.

Medical Officer, Burma Frontier Force Hospital, Myitkyina

and

RAI SAHIB T. N. LAL, I.M.P.
Burma Frontier Force Hospital, Myitkyina

On 12th November, 1940, at 7-30 a.m., a Punjabi Mohammedan woman, aged 18 years, was admitted into Family Line Hospital, Burma Frontier Force, Myitkyina, with fever and in a semi-conscious condition.

History.—The patient was reported to have had fever with rigor at 3 p.m. on the previous day.

Temperature on admission 102°F. Pulse—rapid but regular and strong. Respiration—28 per minute.

Examination.—Though the temperature was not very high, patient was rapidly becoming unconscious.

Lungs—clear. Heart—nothing abnormal detected. Liver—not enlarged. Spleen—not enlarged. Urine—catheter specimen revealed nothing abnormal.

Nervous system.—Knee jerks—present but sluggish. Kernig's and Babinski's signs absent. There was no rigidity of the neck. Pupils were equal and reacted both to light and accommodation.

Examination of blood for malaria parasites showed malignant tertian rings and marked mononucleosis.

Patient was given an intravenous injection of quinine gr. x and placed on usual treatment for malaria. At 8 p.m. the same day temperature went up to 104°F. and she became deeply comatose. Pulse was very rapid and weak. She was given four-hourly injections of gr. 1/100 digitalin. Intramuscular injection gr. x of quinine was also given at night.

13th. Temperature fell to 102.2°F. Pulse—110 per minute, weak but regular.

Lumbar puncture was done and cerebrospinal fluid was clear and not under pressure. Blood for Kahn test was negative.

In the evening the patient regained consciousness partially, and began to take notice of her surroundings but was unable to speak. Quinine was given orally and also another intramuscular injection.

14th. In the morning the temperature was 100.8°F. Patient was fully conscious but aphasia was still present. Patient showed by signs that she had headache and also expressed her wishes by signs. She was not incontinent. Another injection of quinine was given and also quinine mixture orally.

15th. Temperature dropped to 99.4°F. Patient was fully conscious, but aphasia was still present. Pulse was regular and of good tension and general condition much improved. On 17th, however, she developed hemiplegia of the right side of the body. Temperature was normal and aphasia was still present. From 17th onwards temperature remained normal. Treatment for hemiplegia with massage, iodides, etc., and also for malaria was carried out and the patient regained the use of her leg on 1st December. On 5th December, she could speak a few syllables though the speech was slurred. She regained the use of her arm on the 10th. From then onwards she improved steadily and was discharged as cured on 22nd December, 1940.

Notes.—(1) This case is reported as it had some unusual and interesting features. Although hemiplegia and aphasia are reported as rare complications of cerebral malaria the two together are very unusual, especially as the aphasia occurred 3 days before the hemiplegia.

(2) There was not a heavy infection of malignant tertian or other forms of malaria parasite as one would expect in such a case and the temperature was not unusually high on admission.

(3) Complete recovery in a relatively short space of time.

A CASE OF PYAEMIA TREATED WITH SULPHATHIAZOLE

By J. W. D. GOODALL, M.B., M.R.C.P. (Edin.)
MAJOR, I.M.S.

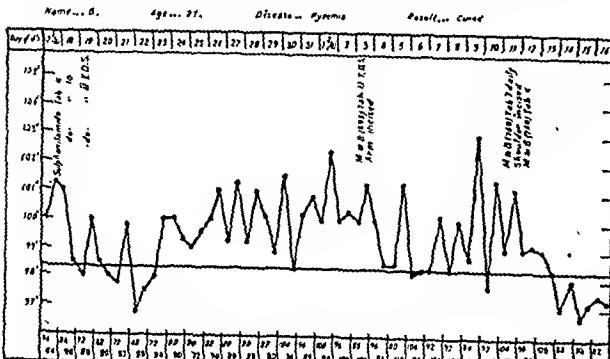

UNTIL recently sulphathiazole (M. & B. 760) has not been readily obtainable in the Indian market. In Great Britain and the U. S. A. it has been employed against streptococcal and staphylococcal infections with some success.

Paterson and Walker (1940) cured a case of osteomyelitis and pericarditis with this drug. The experimental work of Wagle, Sokhey, Dikshit, and Ganapathy (1941) in the use of sulphathiazole against plague, and of Rao and Ganapathi (1941) in its use against *B. typhosus* show that it has some effect against these organisms. These latter workers, as a result of experiments on mice (1940), believe that sulphathiazole is distinctly superior to sulphanilamide and sulphapyridine in streptococcal infection and is as good as sulphapyridine in pneumococcal infection.

The following case which was diagnosed as pyaemia probably of staphylococcal origin and treated by sulphathiazole (M. & B. 760) may be of interest.

Captain B., aged 27 years, was admitted into hospital on 17th January, 1941, complaining of pain and swelling of his nose. He stated that three days previously he had picked a black-head on his nose and squeezed it. It became very painful so he called in the doctor next day who gave him tablets of sulphanilamide to take (2 t.d.s.). The following day he was given eight tablets but as he was slightly worse and the swelling and redness of his nose had increased he was admitted into hospital.

Previous illnesses.—He stated that in May of last year he developed blood-poisoning from septic heels after a route march. Also he had suffered from an undiagnosed fever when on leave in England in 1939.

Examination.—The patient was found to have a temperature of 101°F. and a raised pulse rate. The nose was red and inflamed and the area of inflammation extended on to the left cheek. The skin was unbroken. On general examination nothing of significance was noticed, except that he had a pigeon chest.

SA

Investigations.—The white blood count was 8,200 per c.mm. and the red blood count 4½ millions per c.mm. The Wassermann was negative. Urine and stools normal.

Treatment.—The sulphanilamide tablets were continued in hospital for three days in a dosage of 10, 6, and 4 daily.

Progress.—The sulphanilamide did not have any appreciable effect on the course of the disease and was stopped on the fourth day in hospital. His condition became worse, but by fomenting his nose some thick discharge came away at the end of a week.

On the eighteenth day of hospital treatment a swelling of his right upper arm which had given him pain for four days was opened under local anaesthesia and thick chocolate-coloured pus was drained out. The arm was fomented, his bowels were regulated with liquid paraffin and he was given Ostomalt. In addition he was treated with sulphapyridine (M. & B. 693) for the next seven days, giving two tablets three times a day. This also had no appreciable effect on the course of the disease.

Aster 26 days in hospital he was given sulphathiazole (M. & B. 760) starting with four tablets the first day and 2 t.d.s. for the next five days. Another painful swelling had meanwhile appeared over the right shoulder and this was opened and drained of chocolate-coloured pus, as in the case of the arm. On the third day after starting sulphathiazole the patient's temperature became normal and remained normal. His general condition also improved remarkably and he made an uninterrupted recovery.

Summary

A case of pyaemia successfully treated with sulphathiazole (M. & B. 760) is described. The blood culture was sterile, but it is thought that the causal organism was probably a staphylococcus. Sulphanilamide and sulphapyridine were employed but did not have any appreciable effect. Sulphathiazole combined with surgical drainage resulted in cure.

BLACKWATER FEVER IN THE HILLS

By JAGADISH C. BHATTACHARJEE, L.M.P.
Darjeeling Himalayan Railway Hospital, Tindharia,
Darjeeling

BLACKWATER fever is pre-eminently a disease of the plains, where malaria is endemic, but recently a case has been encountered at Tindharia, an industrial town on the Himalayas, 2,800 feet above sea level, where indigenous cases of malaria are very seldom met with.

A Nepali boy, *ast.* 10, was admitted as an in-patient on 11th February, 1941, for treatment of a sprained elbow. He was otherwise healthy and had no other complaint till 16th February, when he was found to have suddenly passed about 6 ounces of dark urine in the early morning. The temperature was found to be 100°F. and it rose to 100.5°F. towards the afternoon. Spleen or liver was not enlarged. He complained of pain in the loins and nausea, but could retain food and drugs by the mouth. Passage of urine was free,

coffee colour, and about 40 ounces were passed in the first 24 hours. It contained haemoglobin in solution. Examination of blood films showed *Plasmodium vivax* rings and gametocytes.

The patient had no history of fever, at least recently, and he had not taken quinine as he was under our observation in the hospital for about a week.

He was given alkaline mixtures, glucose and soda drinks, and quinocrine tablets (May and Baker)—two tablets of 0.1 gm. divided into three doses. He was also given an intravenous injection of 25 c.c.m. of 25 per cent glucose solution with 5 c.c.m. of 10 per cent calcium gluconate solution. Injection of glucose solution was repeated in the evening.

17th February.—Temperature between 98.4°F. and 100°F. Urine—about 25 ounces in 24 hours. Patient developed jaundice, hiccup and vomiting and could hardly retain anything by the mouth. Treatment same as before supplemented by rectal saline with glucose. An attempt was made to administer fresh decoction of leaves of *Vitex peduncularis* but the patient could not retain it because of frequent vomiting.

18th February.—Temperature between 98.4°F. and 99°F. Urine less than 20 ounces; colour red but intensity lessened. Vomiting and jaundice increased. Liver became tender and slightly enlarged. Treatment same.

19th February.—Temperature normal throughout the day. Urine comparatively clear but amount still diminished. Nausea still persistent. Treatment same.

20th February.—Urine brown. No fever. Quinocrine only one tablet given. Blood films were examined but no parasites were found. Patient became anaemic.

Recovery was uneventful and he was discharged cured on 23rd February, 1941.

Points of interest

(1) Occurrence of blackwater fever at an altitude of 2,800 feet where malaria is a rarity especially at this season of the year.

(2) Sudden appearance of haemoglobinuria with slight rise of temperature in a subject, who had no history of recent fever nor quinine intake, but whose blood contained malaria parasites.

(3) Quick response to ordinary routine treatment plus quinocrine (May and Baker), which acted on gametocytes as well.

I am grateful to Dr. S. K. Biswas, Head of the Medical Department, Darjeeling Himalayan Railway, for his interest and suggestions in the treatment of the case.

[Note.]—The important point is surely not where the patient first showed symptoms of blackwater fever, but where he acquired the infection that caused the blackwater. The writer gives no history of the previous movements of the patient. It is unusual to get blackwater fever with a benign tertian infection; it is however very difficult to be certain that the infection was not a mixed one.—EDITOR, I. M. G.J.

OMENTAL LIPOMA

By HUKAM CHANDRA, M.B., B.S., P.C.M.S.
Assistant Surgcon, in-charge Civil Hospital, Jhang
(Punjab)

K. B., aged 31 years, female, consulted me in the early half of October 1940 for the following complaints:—

(1) Amenorrhœa—duration two years.
(2) Progressive enlargement of abdomen—duration ten months.

She had been examined several times by native *dais* who had diagnosed pregnancy as the cause of abdominal enlargement. She had also experienced the usual symptoms of pregnancy, such as nausea, vomiting and foetal movements but because the expected delivery

did not come about and appeared to have been delayed much beyond the usual period of gestation, the patient and her relations felt anxious about it and fearing grave abnormality consulted a lady doctor who discovered the absence of pregnancy altogether, but gave no opinion as to the cause of enlargement of the abdomen.

Previous history.—Married at the age of 13; commenced menstruating a year later. Suffered from more or less continuous fever for six months—probably of enteric origin—two years after marriage; recovery from this illness was followed by good deal of increase in weight. Menstrual history normal for fifteen years during which period she never conceived. Two years ago menses stopped abruptly and the patient was believed to have become pregnant but nothing happened to support this belief. Fourteen months after this the abdomen began to enlarge and the symptoms of pregnancy appeared in due course.

Physical examination.—Patient rather obese. Abdomen enlarged to the size of full-term pregnancy. Palpation revealed a tumour, semi-fluctuant in consistence, rounded and lobulated in outline, freely movable and most prominent on the right side below the umbilicus, but no foetal parts or movements could be felt and auscultation of the abdomen was also negative. Breasts were fully developed and contained milk which could easily be squeezed out of the nipples. Examination *per vaginam* negative except some fullness in the posterior vaginal fornix. Bowels regular and digestion good. Nothing abnormal about the heart, lungs or other organs. There was nothing to support the hypothesis of pregnancy and a provisional diagnosis of right ovarian cyst was made.

Operation was advised but the relatives of the patient insisted upon more definite exclusion of the possible existence of pregnancy. X-ray examination was suggested and done; the skigram showed no evidence of pregnancy.

The patient was admitted into the civil hospital, Mailsi, on 8th November, 1940, and operated upon on the following day. The abdomen was opened under chloroform anaesthesia by a median incision below the umbilicus. Immediately on cutting the peritoneum a fatty tumour presented in the wound. Closer examination revealed this to be a lipoma encapsulated by the great omentum; it was decided to remove the tumour which consisted of two main lobes connected by a neck of fatty tissue. The whole mass was shelled out and bleeding points secured and ligatured. The margins of the cavity left in the omentum were brought together and sutured with fine silk. Examination of the uterus and ovaries showed nothing abnormal, and there were no adhesions between the omentum and coils of intestines. The abdomen was closed in the usual manner.

There were no apparent post-operative complications and the wound healed by first intention. Skin stitches were removed on the ninth day after operation when a soft fluctuant area was felt underneath the otherwise healed-up wound. A haematoma was suspected and confirmed by making a small opening through the lower part of the wound. About 3 ounces of fluid blood were mopped out, when the incision made through the peritoneum and muscular aponeurosis was seen to have healed up. Obviously the source of blood was from minute vessels in the subcutaneous fat which was present in abundance. The cavity left by the haematoma filled up slowly by granulation and the patient was discharged cured on 15th January, 1941.

Comments.—The occurrence of lipomata of any size (the one in the present case weighed 26 ounces) in the omentum is very unusual and I failed to find any reference to such cases in the literature on the subject available to me. Fatty herniae of the linea alba and subserous lipomata are, in my opinion, entirely different from the one described above. The appearance of the usual symptoms of pregnancy, though

significant in this case, is not uncommon under similar conditions.

My grateful thanks are due to Captain D. D. Kapur, civil surgeon, Multan, for his permission to publish this report.

ITCHING IN SYPHILITIC SKIN ERUPTIONS

By SOHAN SINGH, M.B., B.S., P.C.M.S.
Second Physician to the Medical out and in-Patients,
Irwin Hospital, New Delhi

and

R. K. SEN, M.B., B.S.
House Physician

THAT there is no itching in syphilitic skin eruptions is so well known that the mere presence of this symptom is thought to be enough to exclude syphilis in diagnosis. The case in point was interesting for this; he had a skin rash which was very itchy, and the diagnosis ultimately turned out to be secondary syphilitic skin rash.

Case report.—A male, aged 20, was admitted to the Irwin Hospital on the 8th January, 1941, with the complaint of itching all over the body. The trouble started a few days back and was more-or-less generalized from the very beginning. There was no history of contact with a case of scabies, nor of syphilis. Patient has no history of having taken any drug like arsenic, etc.

Examination.—There was a skin rash distributed all over the body—limbs, trunk and face. It was most marked over the left arm where the skin between the

Photograph of the case of syphilitic rash showing the vesicular eruption with a black top.

individual lesions was also somewhat inflamed. The lesions were also present in between the fingers and toes. The volar aspect of the wrists was not involved. Evidence of itching was present in the form of scratches.

The individual lesions were small discrete vesicles with a pointed top which in many instances simulated very closely the black-topped lesions of scabies.

There was no evidence of a syphilitic sore on the penis but the epitrochlear nodes were markedly enlarged. There was no pyrexia, and the heart, lungs and abdomen showed no abnormality.

Laboratory findings.—Scraping was taken for *Sarcopias scabiei* but was negative.

Blood: haemoglobin 60 per cent, leucocytes 6,875 per c.mm., polymorphonuclears 60 per cent, lymphocytes 24 per cent, eosinophils 11 per cent, large mononuclears 5 per cent. Kahn's test was three plus. Urine analysis revealed no abnormality.

Discussion.—Resemblance to scabies was marked from the type of lesions, their presence in the creases between the fingers and toes, and the presence of marked itching. But the presence of the lesions on the face and their absence on the volar aspect of the wrists was strongly against this diagnosis. A negative scraping excludes this disease altogether.

Before the result of Kahn's test was known, itching was strongly against the diagnosis of secondary syphilitic rash. In fact, during the time we were waiting for the blood examination, we had actually put the patient on treatment with sulphur ointment. This gave no relief. The itching persisted but the vesicles were rubbed down during the application of the ointment and the lesions became more macular.

After the blood report was available, the patient was given three weekly injections of neosalvarsan each dose being 0.45 gm., as only these doses were available. The itching improved considerably after the first injection, and so also the rash; until now, after the third injection, there is no itching and the skin lesions have also disappeared. In some places, especially the thighs, there is some pigmentation left. The patient is now getting bi-weekly injections of bismostab.

The blood examination and the result of treatment leaves no doubt as to the cause of the skin eruption. It was syphilitic. The interesting point was the itching which led to difficulty in diagnosis and mistake in treatment. We have felt inclined to report this case because of this. An odd case of syphilis may have itching as demonstrated by this example and we should be open-minded on this question, because sticking blindly to the orthodox view that syphilitic lesions do not itch might lead to an error like this. Itching should be regarded as a point against the diagnosis of syphilitic skin lesions but when other data point to this disease itching alone should not exclude it.

Acknowledgment.—Our thanks are due to Lieut.-Colonel M. M. Cruickshank, I.M.S., chief medical officer, Delhi, for his kind permission to report this case.

A CASE OF LEUCOPENIA WITHIN TWENTY-FOUR HOURS OF THE INITIAL ADMINISTRATION OF PARASULPHANILYL-AMINOPYRIDINE

By A. T. M. GLEN

CAPTAIN, R.A.M.C.

Combe Regis, Mussorie

THERE have been in recent times many discussions about the toxicity of the various drugs of the sulphonamide group. Little, however, is

known as to the aetiological factors causing the leucopenia, which occasionally follows administration of these dyes; but it is fairly well substantiated that leucopenia follows large doses rather than small.

The writer encountered an interesting case treated with small doses of para-sulphanilyl-aminopyridine in which leucopenia ensued within 48 hours of the initial dose of the dye.

On 4th August, 1940, 'J. O.', a healthy male European of 28 years, awakened with severe abdominal pain and backache. There was no history of frequency of micturition, but a definite history of nausea, vomiting and constipation. In this state he was admitted to hospital and after abdominal and urinary examinations were carried out a diagnosis of pyelitis was made.

Urinary examination

Specific gravity	1018
Albumen	Trace
Sugar	Not present
Deposit	A few pus and red blood cells were present.

White blood cell examination

Total white blood cells	9,000
Polymorphonuclears	87 per cent.
Lymphocytes	6 "
Large mononuclears	6 "
Eosinophils	1 "

During the day of the 4th August 6 grammes of 2-sulphanilyl-aminopyridine were administered, and the temperature which had been 100°F. settled to normal on the morning of 5th August.

On 5th August the patient felt much better and did not complain of any of the symptoms associated with the toxicity of the sulphonamide group—cyanosis, dyspnoea, nausea, vomiting or palpitation.

The total white blood cells were 9,000, but a differential count was not made.

The urine when centrifuged showed as many as 4 to 6 pus cells and 2 to 3 red cells to a field; calcium oxalate crystals were also present. Six grammes of para-sulphanilyl-aminopyridine were administered orally during the 24 hours.

On 6th August 2 grammes of the dye were administered before the total white cell count was discovered to be 4,800 with the following differential count:—

Polymorphonuclears	53 per cent.
Lymphocytes	42 "
Large mononuclears	4 "
Eosinophils	1 "

The urine on centrifugalization only contained very few pus cells, no red blood cells and some amorphous phosphate.

In view of the leucopenia the para-sulphanilyl-aminopyridine was immediately discontinued, although the patient showed no signs of toxicity. On 8th August the patient developed a urethritis, the pus from which, on direct smear, showed Gram-negative intracellular diplococci. The total white cell count had risen to 7,600, with the following differential count:—

Polymorphonuclears	66 per cent.
Lymphocytes	26 "
Large mononuclears	5 "
Eosinophils	1 "

The gonorrhœa was treated with para-sulphanilyl-aminopyridine; 3½ grammes were administered on the 8th August.

On morning of the 9th August 2 grammes were given and the total white cell count was 4,600, whilst the differential count was:

Polymorphonuclears	43 per cent.
Lymphocytes	54 "
Large mononuclears	3 "

In spite of the haematological signs of toxicity there were no abnormal symptoms or signs of general toxicity.

The dye was immediately discontinued for a second time and the gonorrhœa treated by other means.

On 11th of August the patient still showed no manifestations of toxicity, other than a total white count of 4,000; no treatment was given for the leucopenia and on 13th August the white cells had risen to 7,600.

The patient was discharged from hospital on 26th August, with the condition relieved.

Summary

1. It is observed that on two occasions a leucopenia followed the oral administration of small doses of para-sulphanilyl-aminopyridine without the patient complaining of any abnormality and without the clinician observing any signs of toxicity.

2. Damage to the cells of the bone marrow by this group of drugs will cause permanent blood disease, and this damage can only be detected by frequent and regular white cell counts.

3. Fourteen grammes of the dye had been administered when the leucopenia was first detected, whilst only 5½ grammes were required to produce the second leucopenia.

4. In both cases immediate discontinuance of the drug resulted in a rapid return to the normal count.

A THORACOPAGUS MONSTER

By B. R. RANGANATHA RAO, L.M.P.

Sub-Assistant Surgeon, Mysore Medical Service, Kumsi

A PHOTOGRAPH of a thoracopagus monster recently given birth to by a 4th para.

One noteworthy point is that the patient's mother and sister delivered 'short-lived' twins in their 4th pregnancies.

Indian Medical Gazette

JULY

HOURS OF WORK

THE attitude of individuals towards work varies considerably; some view work as the main disadvantage of life, others as the only thing that makes it bearable; some would never do a hands-turn of work if they could help it, others will work all day while there is work to be found and their energy lasts. Whilst in any country both extreme classes, and all the intermediate grades, are usually represented, national and racial characteristics determine which end of the scale is most heavily represented in any one country. These characteristics are developed, mainly though not entirely, by the influences of environment, over a long period. Basically, man only works to obtain food; if nature is kind and he only has to scratch the ground and throw down a handful of seed to obtain an abundant crop, his idea of the working day is that it should not last more than a couple of hours, and the female of the species who is engaged on domestic work for a greater part of the day does not gain the male's respect but rather his contempt. Where nature is less kind and man has the elements to contend with, his working day tends to be much longer. Climatic conditions also play an important part in the determination of these characteristics; the hot climate of our first example not only makes long hours unnecessary, but it makes man disinclined to work, especially in the heat of the day, and this disinclination has a sound physiological basis. Conversely, in the cold north, man not only has to work harder to produce his food requirements, which are incidentally greater, and to protect himself from the cold by making clothes and building houses, but also his inclination to work is greater because work keeps him warm.

India is a large country and can produce climatic conditions parallel to those of almost any part of the world, so that generalizations regarding the peoples of India are dangerous; nevertheless we will risk the statement that as a whole the natives of India, though they do not share that restless inclination to work hard or play hard that is the characteristic of those of northern Europe and America, they have no deep-rooted objection to hard work. This is obvious from the amount of labour that is recruited in India for surrounding countries.

When the British came to India they brought with them a number of their own habits, and with characteristic British obstinacy they stuck to them even though many were unsuited to the climate in which they were then living. These included the wearing of heavy and unsuitable

clothing, eating heavy meals and drinking heavy wines particularly in the middle of the day, and unsuitable hours of work; these habits were undoubtedly an important factor in determining the very high death rate that occurred in the British army and amongst British civilians in this country. The latter is reflected on the tombstones in many old Christian cemeteries in this country, for example, in the now-famous Park Street cemetery in Calcutta in which a high percentage of the deaths are amongst men and women between the ages of 20 and 30. Of these habits the only one that they imposed upon Indians who worked for and with them were their habits regarding hours of work.

Wisdom has prevailed and the British in India have given up many of these unsuitable habits; the European to-day certainly works harder and longer than did his predecessor of a hundred years ago, but he has many compensatory amenities that make this longer day possible; he has however adopted, in many places, especially in the mofussil, a more suitable distribution of the hours of work. In the army, for example, during peace-time, work starts at dawn and stops in the middle of the day. A similar plan is adopted in many hot up-country non-military stations where the community is a compact one and nobody lives very far from his work. Under such conditions it is possible to arrange a good day's work in the early morning and evening, leaving the middle of the day for rest. But even under these conditions there is an objection to this plan, especially where the sedentary worker is concerned; for besides the foreign customs to which we have referred, the British have also brought with them an adage about 'all work and no play making Jack a dull boy', and the habit of playing games is one that has been readily adopted by Indians. If the coolest part of the day is to be taken up by work what time will remain for games? Certainly not the middle of the day, for if that is unsuitable for work it is more unsuitable for games. And when does the sedentary worker get his exercise?

For many years there has been a periodically recurring agitation for a revision of the hours of work in the large Indian cities. This agitation is nearly always started by a new-comer, either a new arrival in India who has perhaps been influenced by Noel Coward's satire 'Mad dogs and Englishmen go out in the midday sun', or someone who has previously had little experience of town life and has appreciated the advantages of earlier hours of work in his up-country experience, but it seldom results in more than the publication of a few letters in the papers or a short-lived local experiment. Now why is this? Surely, it is more than ever necessary in a big town where the buildings hold the heat and shut off the air currents that work should cease in the middle of the day. Is it just stupid conservatism, and refusal to modify

the habits of generations (though not of centuries, it should be remembered) that opposes any change, or is there reason in the opposition? Conservatism is undoubtedly an important factor, but there is very considerable reason on the side of the majority who have always opposed any drastic change. The reasons against a change will depend of course upon what the change is. We will revert to this later.

'Hours of work' has again come into the news, metaphorically: actually very little about it has appeared in the public press. On this occasion, there are special reasons for the revival of this agitation—the war and the 'black-out'. It is important that as many people as possible should reach their homes before darkness falls, and this can only be ensured by advancing the hours of commencing and finishing work.

Some suggestions

The Director of Public Health (DPH), Bengal, has subscribed to the controversy, and in a pamphlet entitled *Time of work* has made some astonishing suggestions. The hours of work that he has proposed are from 6.30 to 11.30 a.m. with a return between 4 and 6 p.m. to do 'urgent work'. He has not made it very clear what constitutes 'urgent work'. Whether, for example, it means work that has arisen during the day. If this is the interpretation then presumably the office worker will have to return at 4 p.m. daily to see if there is any 'urgent work'. Or does it refer to work that has already lain on his table for a month and can be put off no longer? If the latter, who decides whether the work must be considered 'urgent'? No, we are afraid that the DPH is not facing facts quite squarely; he is either suggesting that the working day in Bengal should be reduced to five hours—a suggestion that it is very difficult to take seriously—, or that the office worker should return in the evening to finish his day's work. He cannot have it both ways.

However, none of the arguments in favour of his suggestion visualizes a return to work in the afternoon, and we are not surprised at this, for, in a city where a large percentage of the clerks live an hour to two hours' journey from their place of work, it would mean that, during the midday break, 11.30 a.m. to 4 p.m., they would have to remain in or near their offices, or spend the hottest part of the day rushing home, taking a hurried meal, and rushing back again, which, to borrow from the physiology of the DPH, would mean that their blood rushed to their limbs, then to their stomachs, and back to their limbs again, so that there would be little left for their brains when they did get back to work in the evening. As far as Calcutta is concerned this is a totally unpracticable suggestion, from that of health and from every other point of view.

The two points that the DPH makes in favour of earlier hours are with reference to

temperature and humidity; he argues, quite rightly, that high relative humidity is almost as detrimental as high temperature. He then develops his argument by pointing out that the temperature is lower in the morning—this is of course quite true—but he adds that humidity is also lowest in the mornings, a statement that is in direct opposition to experience at the meteorological office in Alipore, and is so surprising, coming as it does from the Director of Public Health of a large province, that, lest we have misinterpreted his words, we will quote them in full:—'If we cannot attain the optimum of 60 per cent, we should at least try to be as near it as is possible, and on the average, it is likely to be much less in the mornings'. Again he says, 'the temperature and, usually also the relative humidity are low in the morning'.

Chart 1 was drawn from figures which originally came from the meteorological office,

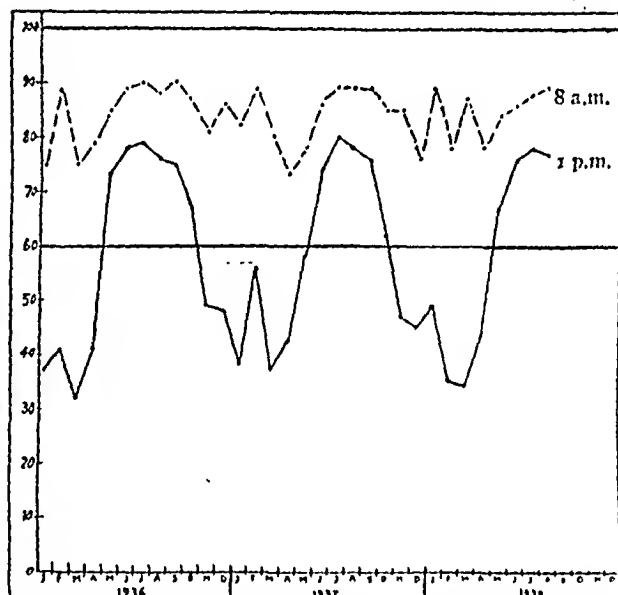

Chart 1 showing the monthly mean relative humidity at 8 a.m. (broken line) and at 1 p.m. (continuous line), during three consecutive years.

Alipore, and which happened to be at hand. They show that in no single month was the average relative humidity at 8 o'clock in the morning less than 10 per cent higher than the corresponding humidity at 1 o'clock in the afternoon, and that for many months in the year it was 40 per cent lower in the middle of the day than in the early morning.

Charts 2, 3 and 4 are from data very kindly supplied by the Director of the Meteorological Survey—at a few hours' notice on a telephonic request; they show the normal average dry bulb temperature, wet bulb temperature and relative humidity, respectively, throughout the day, for three representative months of the year. The five-hour day of the DPH and the present secretariat hours are shaded. The relative humidity chart scarcely adds support to the

JULY, 1941]

claim that his hours would mean work under conditions closer to the ideal humidity of 60 per cent; in fact exactly the contrary is obvious. We do not claim that these charts refute his case for earlier hours; we only point out that, when he picked relative humidity to support his argument, he was backing a loser. Judging the case from these three charts alone, the balance is in favour of the early hours in the hot-weather months (represented here by March), there is little to be said either way as regards the monsoon months (represented by August), and in the cold-weather months the temperature at 7 a.m. (the DPH's modification for the cold weather is 7 a.m. to 12 noon) is a long way below the ideal, which according to the DPH is 75°F., and is in fact uncomfortably cold.

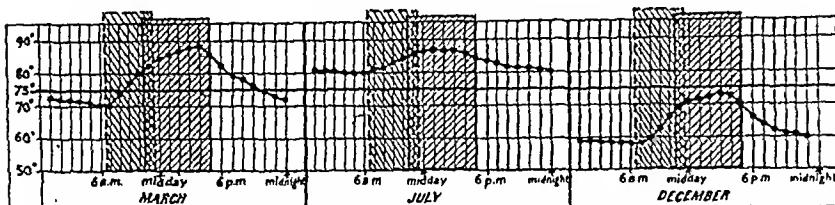

Chart 2 showing the normal diurnal range of dry bulb temperatures.

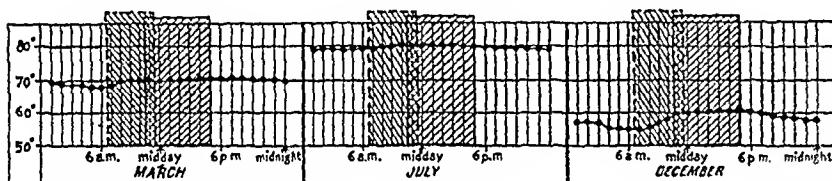

Chart 3 showing the normal diurnal range of wet bulb temperatures.

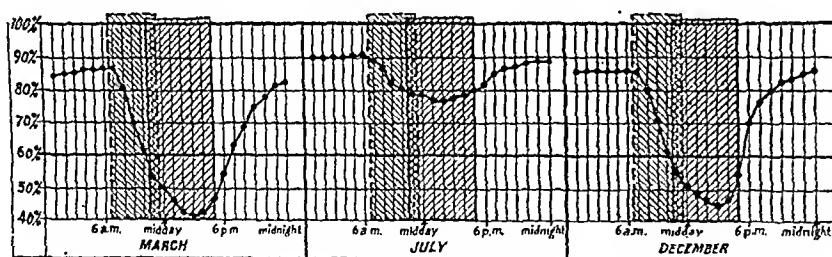

Chart 4 showing the normal diurnal range of humidities.

In heat loss, an essential part of temperature regulation, there are four important factors, namely, the temperature of the air, the humidity of the air, the movement of the air, and insulation. The importance of these factors is in the order in which they are given, but none can be ignored. There is no logical formula by which maximum comfort, and therefore optimum conditions for work, can be calculated; all the data on the subject that have been collected are based on practical trial, and are therefore subject to the fallacy of the personal factor. The data, though very considerable, have mostly been collected in America and must therefore be applied here with reserve.

To express the effect of three climatic factors, temperature, humidity and air movement on the

body sensations, a term 'effective temperature index' has been introduced. The unit of expression is an arbitrary one, but, as it is usually calculated from Fahrenheit temperatures, it is usually given in terms of Fahrenheit degrees.

This 'effective temperature' is a very much better expression of the effect of the climatic conditions on the human body than either the dry bulb or the wet bulb temperature, and in fact in our present state of knowledge it is the best standard for judging this effect that we have. The charts that are available for calculating effective temperature were prepared in America and are based on certain standard conditions, with regard to clothing in particular, that are not quite paralleled in this country. For

example, the summer clothing in general use in America is light, but not as light as we use here. Again, there is the difference between the European style of clothing and the Indian style, as well as the individual and seasonal differences, and altogether this factor is so complex that it is impossible to give it any accurate mathematical expression. As we noted above, this matter of insulation, which is the effect clothing has, is the least important of the factors affecting loss of heat; it is thus better to ignore it, and to assume that the person concerned will adapt his form of clothing to the prevailing climate.

The next point to be considered is, what is the optimum effective temperature? Or perhaps it is more important to know what is the 'comfort zone', above which one is too hot and below which too cold? Even on this simple matter, we have not yet collected figures in India, though the subject is being studied. Naturally this

will vary according to what one is doing, but most figures are based on the individual being seated at a table writing, or doing light work. The personal factor will also come in, but this is eliminated in the calculations by taking a large number of observations. The observations that have been made on the racial factor are interesting and often paradoxical. For example, it was found in a large office in China that the Cantonese clerks had a lower comfort zone than the Europeans. On the whole, both the racial and the acclimatization factors are surprisingly unimportant.

Even in American cities, the optimum effective temperature has been shown to vary between 66°F. and 72°F., with the 'comfort zone' extending about five degrees above and below the

optimum figure; in India, we can tentatively place the optimum at the highest of these figures, with the comfort zone from 67°F. to 77°F. effective temperature.

Chart 5 shows the effective temperatures throughout the day during the three representative months that we have taken, and the hottest month, May. The arbitrary comfort zone is marked out, also, the five-hour day suggested by the DPH and the present secretariat day.

Now to return to the question of hours of work, if we are going to base it entirely on the favourability of climatic conditions we must be prepared to change our hours frequently. The present (secretariat) hours are obviously almost ideal for the cold-weather months, as the lower edge of the comfort zone is reached about 11 o'clock and conditions remain within this zone until about 4-30 p.m. Whereas if one followed the suggestion of the DPH one would not be comfortably warm until it was nearly time to leave office.

In March the converse is the case and conditions during the present office hours are wholly outside the comfort zone; the best hours are from midnight to 7 a.m. but up to 11 o'clock the conditions are still within the comfort zone. In July the whole day is well outside the comfort zone and there is only $4\frac{1}{2}$ degrees between the best and the worst hours. Similarly in May, the hottest month of the year, the conditions during the whole 24 hours are well above the comfort zone, but the difference between the best and worst hours is not very great.

Let us consider March first. Obviously it would be totally impracticable for the clerk to work from 12 midnight to 6-30 a.m., or even to start work at dawn, but is it possible for him to start at 6-30 a.m. as the DPH has suggested? In the vast majority of cases we believe it is not practicable. He has a long day's work in front of him and he must take some food before he starts. Even if he has someone to cook his food for him (and many have not only to cook but to buy their own food), he can scarcely get up, wash, dress, and take his food in reasonable comfort and decency in less than an hour and a half; if then he has an hour's journey to his office—this is putting it at a low figure—he will have to get up at 4 o'clock. So we must put the earliest reasonable hour for starting work at 7-30 a.m.; even this will be a considerable hardship to many. To put in the full $6\frac{1}{2}$ hours, he must work until 2 p.m., and if emergency

work arises he may have to put in another two hours (this very often happens in commercial offices, even if it is rare in government departments), which would mean his working through the worst hours of the day.

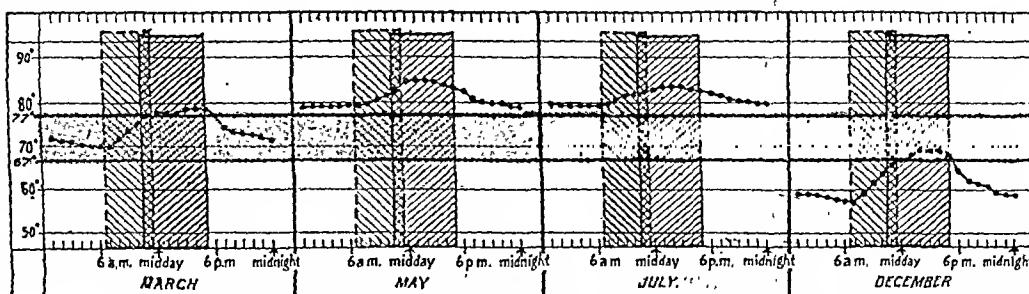

Chart 5 showing the normal diurnal range of effective temperatures.

Very much the same argument can be applied to the later hot months, for example, May; there would admittedly be a slight advantage from the point of view of effective temperature in starting work at 7-30 a.m., but one could not avoid the worst hours of the day. Even during these early hours the temperature is well above the comfort zone, and the difference between the best and the worst is not very great, and in the monsoon months this difference is reduced still further.

It is therefore only in the intermediate period between the hot and the cold weathers that there would be any real advantage in making any drastic change in the working hours; for the hottest months and the monsoon months we must face the fact that Bengal is a hot country in which one may expect the temperature to be outside the comfort zone for the 24 hours of the day, so that we cannot avoid the heat however we juggle with our working hours. The slight advantages to comfort during working hours that might be gained by a drastic change would be outweighed by the dislocation of the established custom that would reflect on the health and happiness of the vast majority of workers.

We do not mean to suggest that some change is not advisable. If the office hours could be advanced by an hour, or even two hours where they are now very late, it would, we believe, be to the advantage of the worker, and therefore of his work. The slightly earlier start would not entail any hardship when habits had been adjusted, the earlier closing hours would give the worker who lives near his work more time for games and exercise, and allow those who live some distance away to get home in the daylight.

This adjustment could best be made by altering the clock. We could scarcely call it 'summer-time', or 'war-time', and even 'black-out time' might be misleading. We leave the choice of name to some more fertile imagination, but meanwhile we suggest putting forward our clocks by at least an hour.

HÆMATOLOGICAL TECHNIQUE

PART XII*

By L. EVERARD NAPIER, F.R.C.P. (Lond.)
and

C. R. DAS GUPTA, M.B. (Cal.), D.T.M.

(From the School of Tropical Medicine, Calcutta)

The investigation of a case and the reporting of results

THE question that we are frequently asked is, what do you consider the minimum examinations that should be carried out in a case of anaemia? We should be forced to reply that, with the exception of those in part X, which apply particularly in haemorrhagic diseases, at least all the examinations that have been described in this series should be made for the proper investigation of a patient.

In actual practice, nearly all the blood examinations can be carried out from a single specimen of blood and do not take a good technician more than an hour, if the Price-Jones curve is excluded. A certain amount of time can be saved by omitting the Arneth count, the fragility test, and the enumeration of thrombocytes, and there are many circumstances in which these tests will give little information of practical value. This leaves the haemoglobin estimation, the total red and white cell counts, the reticulocyte count, cell volume percentage estimation (haematocrit) and sedimentation rate, van den Bergh's reaction, and white cell differential count, to be done as a minimum routine procedure in every case.

The findings will indicate whether these examinations should be supplemented. Sternal puncture gives very valuable additional information, but it must not be considered as a short cut to diagnosis for it will seldom be of any value without a complete blood count, and further the identification of the various cells is very skilled work that necessitates considerable experience.

There will be occasions when electric current is not available and in these circumstances it will not be possible to estimate the cell volume percentage satisfactorily. Although the mean corpuscular haemoglobin (MCH) usually runs more-or-less parallel with the mean corpuscular volume (MCV), it will be advisable to make

some measurement of the red cells, and, as in our experience clinical halometers are very inaccurate, the mean cell diameter should be measured by the modification of Price-Jones method that we have described.

The inclusion of the erythrocyte sedimentation rate (ESR) in the minimum procedures might be questioned, but, if a Wintrobe's tube is used for cell-volume estimations, the ESR requires no additional apparatus and entails no extra labour, except the taking of a reading at the end of an hour, and the information it gives is often useful.

Gastric analysis is important when the question of pernicious anaemia arises and in some cases of microcytic anaemia of doubtful aetiology, but we would not give it a high place in the order of importance, in the investigation of cases of anaemia in this country.

For the complete investigation of the aetiological factors many other examinations will have to be carried out, e.g., the urine for albumin, blood, and ova; the stools for protozoa, helminths, and pathogenic bacteria, for fat content, and for the presence of occult blood; and the blood for 'blood grouping', the Wassermann reaction, cholesterol, albumin/globulin ratio, etc.

Controlling progress.—Circumstances will usually dictate how often blood examinations should be carried out during treatment, but there are certain points which we will consider here.

In the first place, when a seriously-ill patient is admitted into hospital, he is often suffering from some degree of haemo-concentration, and a second examination made a few days after admission shows a marked drop in haemoglobin percentage, whereas the patient's condition may have improved considerably. If allowance is not made for this fact, the effect of the first treatment that is given may be misjudged, and we have always adopted the practice of making a second examination before prescribing specific treatment (except in urgent cases where an immediate blood transfusion is indicated).

Further, there are many nutritional anaemias in India in which there is a steady improvement directly the patient is put to bed and given a good diet. Allowance must also be made for this fact, if the value of any special form of treatment is being estimated and, in such circumstances, at least two weeks of rest and diet should be allowed before the specific treatment is started.

We make a practice of repeating the blood examination, including haemoglobin percentage, red cell count, reticulocytes, cell volume percentage, van den Bergh's reaction, and ESR, and examination of the film for abnormal cells, once a week, or earlier if a setback is suspected or if the treatment is to be changed. In special cases other examinations, such as the platelet and leucocyte counts, are also repeated.

When any specific form of treatment is given a reticulocyte count is done daily from the 4th until about the 12th day, or, in a case where

* It was not the original intention to publish another article in this series. These notes were written as the final chapter of *Hæmatological Technique*, the booklet referred to in our editorial note in the May number. On reconsideration, we have decided that it will make this series more complete, if we reprint these notes and the forms here.

Hæmatological Technique is now on sale, and may be obtained from Messrs. Thacker, Spink and Co. (1933), Ltd., Esplanade, East, Calcutta.

there is a reticulocyte crisis, until the reticulocyte percentage has fallen to its previous level.

The printed forms that we use in the School are shown below. There is quite possibly room for improvement in these forms, and we have modified them from time to time, but we find that, without being cumbersome, they are sufficient for our purpose.

Form 1 is the ordinary report form which is sent to the ward and attached to the notes (size 8½ by 6½ inches).

CASES OF POISONING AND SUSPECTED POISONING

LECTURE GIVEN TO THE LAHORE BRANCH OF THE BRITISH MEDICAL ASSOCIATION

By D. R. THOMAS, O.B.E.
LIEUTENANT-COLONEL, I.M.S.

[Reprinted from the Report of the Chemical Examiner to Government, Punjab, for the year 1940]

Cases of poisoning and suspected poisoning

Dr. ROCHE LYNCH, the Senior Analyst to the Home Office, in a paper on this same subject wrote as follows:—

'One of the most harassing predicaments of medical practice is the occurrence of some incident which leads to the suspicion that someone is the victim of foul play either by the addition of poisonous substances to food or medicine, or more rarely in India by interference

with the treatment.' The average medical practitioner is a very peaceful individual who is generally so fully absorbed in his daily work that he hates to be involved in any incident where he may be called upon to give evidence in a law court and to submit himself to cross-examination. Medical men generally make bad witnesses, the reason may be that medical 'science' is the antithesis of dogmatism, so much so, that it is not always easy to give direct replies to questions put by the counsel. This creates a poor impression in court and the doctor is looked upon as an unsatisfactory witness. It is always better when you cannot answer a question to admit it and say so.

Many cases of suspected poisoning are totally incapable of proof and suspicion, indeed, turn out to be entirely unjustified. This is especially true of suspected cases of poisoning in our Indian villages where false rumours spread quickly. Nevertheless, many practitioners of long standing can recall occasional cases where subsequent events have not served to abolish their doubts.

Poisoning, both suicidal and homicidal in India, is very common when contrasted with the frequency with which it occurs in the countries of the West, and it must be remembered that in India the criminals are not always brought to justice. The intimate relations of the medical man with the family household place him in an unrivalled position for close observation of suspected cases, and he is sometimes able to avert tragedy. In our purdah quarters, the lady doctor can play a similar rôle.

Early Hindu history of poisoning

It should be of interest to us in India to know that the early Sanskrit medical writings contained in the *Ayurveda*, dated about 900 B.C., and the commentaries thereon (*Shastras*) of Charaka and Sushruta, dated about 600 B.C., indicate an extensive knowledge of poisons among the Hindus of that early period. The *Ayurveda* contained a division treating of the administration of antidotes for poisons, and the bites of venomous serpents, insects, etc. The *Shastras* of Charaka and Sushruta contain sections devoted to poisons and their antidotes in which the action of vegetable, animal, and mineral poisons are described, including a lucid account of alcoholic intoxication and the following is quoted to show that criminal poisoning was then guarded against:—

'It is necessary for the practitioner to have a knowledge of the symptoms of the different poisons and their antidotes. As the enemies of the Rajah, bad women and ungrateful servants, sometimes mix poison with food on this account the cook should be of good family, virtuous, faithful, and not covetous, nor subject to anger, pride or laziness.'

The practitioner should have like qualities, with an intimate knowledge of poisons, and should examine the food to be eaten by a Rajah in the cook-house. This place should be large, airy, light and surrounded with faithful servants, and no one should be allowed to enter; unless he is first examined.

A person who gives poison may be recognized. He does not answer questions, or they are evasive answers; he speaks nonsense, rubs the great toe along the ground, and shivers; his face is discoloured, he rubs the roots of the hair with his fingers, and he tries by every means to leave the house. (Are these the present-day physical signs of a guilty conscience?) The food which is suspected should be first given to certain animals and if they die, it is to be avoided'.

What is a poison?

A poison is any substance which, when taken or given, is capable of seriously affecting health, or of destroying life. From the forensic standpoint it is, however, the intention to murder or harm which constitutes the crime, consequently the administration of substances not usually regarded as poisons may be poisons from the legal point of view if they are administered with evil intention.

How does poisoning occur?

- (1) Administration for homicidal purposes.
- (2) Self-administration for suicidal purposes.
- (3) Self-administration for a special purpose, e.g., abortion.
- (4) Accidental administration, e.g., wrong treatment, bad dispensing or an excessive dose amongst drug addicts.

What is the motive for poisoning?

The motive for poisoning in the Punjab is very tersely described in the three Persian words—*Zar*, *Zan* and *Zamin*, which being translated means money, woman and land. The motive is therefore quarrels over money, the irrigation and possession of land, or the possession of a woman. These motives may be some of the reasons why cases of homicidal poisoning are higher in the rural districts than in the towns. Still it must not be implied that there are more criminals of this type in the country districts, but

rather that a criminal is more likely to be found out since his private affairs are known in greater detail by his neighbours. In other words, the poisoner stands a greater chance of successfully evading detection in town than in the country. Again, the Indian poisoner lacks the craftiness often displayed by his confrère in the West; he commits his crime without premeditation and occasionally very crudely. Another point to be noted is that far more males commit crime than females, but the percentage of females using poison in India is greater than males.

The detection of poison in exhumed bodies, where medical treatment had been carried out before death, shows the difficulties and responsibilities of the medical practitioner. This practice of cremation in India amongst certain communities leaves a definite loophole whereby the poisoner can escape detection and it must be recognized that such successful poisoners frequently have more than one victim to their credit. How often have the police removed a corpse from the funeral pyre before it was completely burnt and a poison was detected in the unburnt portion of the human organs? How often has the body been so completely incinerated that it was not possible to detect poison in spite of the fact that the history pointed conclusively to some poison having been administered and having caused death?

How to investigate a suspected case

Poisoning in India is so common that every practitioner at some period must have attended a case. When he finds the victim is moribund and dying, the obligations of the medical practitioner in this country are simplified as he can call in the government medical officer who carries out the post-mortem examination and informs the police. If, however, the patient is only suspected to be a case of poisoning, the procedure is not so simple, particularly if he is a private patient who does not wish to be admitted to a hospital. The question is then what to do, how to do it and how to find out if your patient is being poisoned without arousing unnecessary suspicion. Most of the common poisons are excreted in the urine, therefore, if you take a morning and evening specimen for analysis, you may be able to confirm your suspicions without having to confide in others. Arsenic, mercury and most of the heavy metals are excreted rapidly by the kidneys. Certain other poisons, particularly opium, may be detected by their clinical signs such as the pin-point pupil, the cold clammy skin, stertorous breathing and possibly the smell of opium in the breath. When you are satisfied that your patient is the victim of poisoning do all you can to avert a tragedy and do not hesitate to call in another doctor to share the responsibility.

Your most likely poison in the Punjab will be opium and I am sure that you must have all seen such cases either in hospital or in your practice. Hardly a week passes without a case of opium poisoning being hurried into the Mayo Hospital for treatment.

Statistics of opium poisoning

Advantage was taken of the publication of the 1931 census report to work out the prevalence of opium poisoning for that year in the Punjab. In my annual report for that year opium was stated to account for roughly 45 per cent of all cases of poisoning. The conclusions reached from the statistical examination may be summarized briefly as follows:—

- (1) That the number of cases amongst males is three times that amongst females.
- (2) That this proportion is evenly distributed through all the major communities.
- (3) That the number of cases relative to population amongst Muslims, Hindus, Sikhs and Christians is roughly in the ratio of 1, 2, 4, 8. The native Christians have the highest ratio of cases to population and the Muslims the lowest.
- (4) That fatal cases number more than three times non-fatal cases. This indicates that opium as a poison is fairly reliable.

- (5) That suicidal opium cases occur amongst males more than three times more frequently than amongst females. This is an interesting fact, as suicides amongst females in India exceed that amongst males. Women in India resort to drowning or hanging in preference to poisoning.
- (6) That the most popular age for both sexes to commit suicide by taking opium is between 15 and 25 years.
- (7) The opium suicides amongst Sikhs are twice as frequent as amongst Hindus and four times as frequent as amongst Muslims.
- (8) That accidental poisoning in opium addicts is also more common amongst males than amongst females and proportionally higher in Sikhs than Hindus.
- (9) That cases of homicide by opium poisoning are extremely rare and only happen in very young infants, particularly illegitimate children.

Some years ago a police officer wrote to ask why opium which is so plentiful in the bazaars is not used for murder. I replied that opium for the person who wishes to pass beyond the portals of a world that has become unbearable but who would preferably take that journey by the least disagreeable route, presented so many advantages in its freedom from physical suffering, the ease with which it is obtained and its certainty in its effects as a poison that it had come to be known in the East as the favourite means of suicidal poisoning.

There are, however, many reasons why opium can never be popular as a poison for homicidal purposes:—

- (1) The bulk required, which is approximately 30 grains. This is the size of a small walnut. Addicts would require probably three times this dose or more.
- (2) Its bitterness, its smell and its dark brown colour are so well known in India that it would be recognized.
- (3) The time before unconsciousness sets in; the person can give warning and have himself treated.
- (4) Treatment is so simple and satisfactory. The stomach is washed out with a weak Condy's fluid solution and artificial respiration and stimulants applied if necessary.
- (5) There are so many more certain and popular poisons in India. It would be just as unnatural for an Indian to give opium to another for homicidal purposes as it would be for a European to give alcohol to one of his own race for the same object.
- (6) Poison as a liquid or a powder is more easily disguised than a sticky mass like opium.

All attempts at murder would not prove successful and those cases where recovery took place, would be brought to light and a charge of attempted murder would be framed. There are no such cases on record in the Punjab.

Acute poisoning with potassium permanganate

A youth, aged 17, in order to commit suicide, swallowed the mercury from a thermometer and then a tablespoonful of permanganate of potash with some water. On account of the burning and pain in his mouth and throat he drank quickly some glasses of water and immediately vomited and lost consciousness. On examination, he was deeply comatose, and the mouth and throat were pale violet in colour, with superficial abrasions. The pulse was slow and the breathing of the Cheyne-Stokes' type. The stomach was washed out and caffeine and lobelin administered. Some minutes later, the heart and respiration became normal, but the youth remained unconscious until the next morning. The day after, he was quite well.

Poisoning by potassium permanganate is of interest to us in India because this is the antidote generally given in cases of suspected opium poisoning and poisoning by opium is very common, as it is the favourite poison of the suicide. Whenever a stomach-washing is sent for analysis for the detection of opium and the washing contains potassium permanganate in

solution, the presence of opium cannot be detected, as the tests for opium are destroyed by the action of the potassium permanganate. However, this is not the point I want to bring out, it is far more important to save the patient's life than it is to be able to detect the presence of opium in the washings. The solution of potassium permanganate given as the antidote should be made into a weak solution, its colour should be faintly pink and the quantity used as a stomach wash is far more important than the actual strength of the solution. Repeated washing by means of the stomach tube of a weak solution has proved to be the most successful treatment in all such cases. In fatal cases we have received viscera in which the condition of the mucous membranes of the stomach conclusively proves that a very strong solution of potassium permanganate has been used, in fact there have been cases which left grave doubts as to whether the treatment was not worse than the effect of the opium, and had death not resulted from the opium it might have resulted from the effects of the strong solution of potassium permanganate administered as an antidote.

Arsenical poisoning per vaginam

Many cases have been received in the Chemical Examiner's Department where the attempt to procure criminal abortion by the administration of arsenic *per vaginam* has proved fatal to the mother and the child. Arsenic seems to be readily absorbed by the mucous membrane of the vagina as it is by the mucous membrane of the stomach and the intestinal canal, and in those cases where the viscera have been submitted for analysis, the arsenic is found in the stomach, intestines, liver, kidneys as well as in the urine of the mother. The alimentary tract seems to reverse its action, i.e., the stomach in particular takes on the function of excreting the poison from the blood stream, thereby helping nature in eliminating the poison from the body by the process of vomiting and the intestinal tract endeavours to eliminate the poison by the process of purgation.

Civil surgeons should, therefore, submit all the viscera in a case of suspected arsenical poisoning *per vaginam* just as they would do in any ordinary case of acute arsenical poisoning which has been administered by the mouth.

Chronic arsenic poisoning due to well water

The water supply of a farm near Madoc, Ontario, was found to be naturally contaminated with arsenic. Several cases of chronic arsenic poisoning occurred among the inhabitants of the farm, and all were due to drinking water from the well, which was drilled to a depth of 94 feet through 'red rock' (a sandy limestone stratum) in 1922. The farmer living on this farm frequently suffered ill-health and was treated for anaemia, even yet he exhibits hyperkeratosis of the palms of the hands. In 1927 the farm was sold to a young man, who soon became ill, grew steadily worse, and in 1932 was diagnosed to be suffering from nephritis, although signs of arsenic poisoning were present. He died two months later. On the death of the farmer his brother took over the management of the farm, and after two years he, too, became ill. His sister-in-law, who had remained on the farm as his house-keeper, also complained of not feeling well, and in April 1935, she consulted a heart specialist, who diagnosed chronic arsenical poisoning. Meanwhile the brother, who had frequently complained of gastro-intestinal discomfort and pain, was referred by his physician to a surgeon, who diagnosed appendicitis, and performed appendectomy in June 1935. Following a brief period of convalescence he resumed work on the farm, and very soon his former symptoms—nausea, vomiting and abdominal pain returned. His suspicions were aroused and samples of water were sent to the Central Laboratory of the Ontario Department of Health. The report was to the effect that the water contained 7/10 grain of arsenic (expressed as arsenious oxide) per gallon. An investigation of the probable source of the arsenic showed that samples of limestone stratum, through which the well had been drilled, yielded as much as 15 parts arsenic

(as arsenious oxide) per million, or 1.05 grain per lb. A microscopical section of the limestone showed it to contain aggregates of brownish particles of an arsenate of iron. Similar particles were present in the scale from the household kettle, and the powdered scale itself contained 0.4 per cent of arsenic, as arsenious oxide. The clinical histories of the cases indicated that a period of approximately 2½ years was necessary to produce definite signs of chronic arsenical poisoning from the use of the arsenical water.

Although we in the Chemical Examiner's Department at Lahore have examined many samples of water from different parts of Northern India during the last 30 years, no sample of water has been received which contained even traces of arsenic. I believe that there are arsenic mines in Chitral but even the samples of water received from that district and examined on behalf of the military authorities for the troops, which are permanently stationed there, have never shown any traces of arsenic on analysis. It is reported that some of the waters from wells in Armenia and Georgia contain traces of arsenic and that the beautiful skins of the Armenians and Georgians, particularly the women, have been attributed to the traces of arsenic in the water supply. Arsenic is known to have a beneficial effect on the skin when taken in medicinal doses.

In arsenic poisoning demonstration of poison in body not essential to conviction of homicide

Three boys became ill with vomiting, nausea and cramp, after eating candy prepared and given to them by the defendant. A physician, although unable to diagnose their condition, prescribed a purgative and emetic to each. A few days later the illness was diagnosed by another physician as metallic poisoning, probably arsenic. One of the boys died 12 days after having developed paralysis ('drawn legs'). The defendant was convicted of murder in the first degree, and he appealed to the Supreme Court of West Virginia.

Expert medical witnesses who made an examination of the organs of the dead body testified that the inner surface of the stomach was red and irritated and covered with sticky mucus. There was no evidence of the presence of arsenic by chemical analysis. Considering the time which elapsed between the death of the boy and the taking of the poison (12 days) this might have been eliminated. The failure of the chemical analysis was not sufficient, the judge said, to exclude arsenic as the cause of death, the possibility of finding traces after the purgatives, emetic, etc., was less than if death had occurred within a few hours. Arsenic is not a strongly cumulative poison, it is temporarily deposited in the liver and other organs of the body after absorption, but it is rapidly eliminated from the system by the urine, bile and other secretions. Should the person survive for 2 or 3 weeks no trace of poison may be found after death, and it is not incumbent on the prosecution to prove that a quantity of poison sufficient to cause death was found in the body, before a jury can be allowed to find that it was the cause of death, if the evidence sufficiently establishes the fact that the poison alleged to have caused death did kill the deceased. Accordingly the court concluded that the evidence justified conviction of homicide by arsenic poisoning and affirmed the judgment of the lower court.

This is a very unusual case of poisoning by arsenic which apparently left no evidence of the presence of arsenic by chemical analysis. It seems to me impossible that traces of arsenic could not have been detected in the long bones, the hair or in the nails of the dead person. The case, however, is of interest as a conviction was obtained without finding the poison.

Blood transfusion for carbon monoxide poisoning

When carbon monoxide combines with oxyhaemoglobin a dangerous compound—carboxyhaemoglobin—forms. This is dangerous because it causes anoxemia. Haemoglobin is the normal oxygen carrier whereas carboxyhaemoglobin is not.

When the blood of a donor is introduced into the vein of a victim this new transfused blood will act

immediately as an oxygen vehicle. The essential point to remember in these poisoning cases is that the transfusion must be preceded by venesection. The object of the preliminary venesection is to cause a pilgrimage of new red blood cells from their normal habitat and point of genesis in the bone marrow into the general circulation. It is therefore safe to conclude that venesection followed by blood transfusion in cases of very severe carbon monoxide poisoning may be an effective emergency measure and prevent death. (K. C. Koch, *Munch. Med. Wochenschr.*)

The transfusing of blood for haemorrhage and shock amongst air raid casualties and severely wounded in the field is now routine treatment as far as circumstances permit. Owing to the difficulties of storing blood, work is now being carried out on dried blood plasma as a more economical and easy substitute for blood. The time may not be far off when tubes containing dried blood plasma crystals enough for a dose will be made available for all.

Illicium religiosum

The *Illicium religiosum*, sometimes called the bastard anisi, is a Japanese plant known as the *Skimmi* of Japan, the Japanese sacred anisi tree. Its fruit in India is called *Badyan khatai*, and is favoured as an adulterant of the true star-anisi fruit. The fruit of star-anisi, which is chiefly used in the manufacture of oil of anisi, consists of eight boat-shaped follicles or carpels arranged around a central axis. The carpels have an acute summit and taper to a nearly straight beak; externally they are reddish-brown and somewhat wrinkled, the inner surface is smooth and shining and encloses a single, smooth, compressed ovoid brown seed. The odour and taste is aromatic resembling anisi, and serve to distinguish them from the fruits of the Japanese star-anisi. It is not possible to differentiate between them by naked-eye appearances. Both have eight carpels. The fruit of the true star-anisi is extensively used in local medicine as a carminative and stomachic. The fruit of the Japanese variety on the other hand is very poisonous and when taken internally causes vomiting, epileptiform convulsions with dilated pupils, cyanosis and death. The poison present belongs to the group of convulsants of the picrotoxin type.

A fatal case of poisoning with this fruit was received from Jullundur and concerned a Hindu male, aged 22 years, who was given a medicine for his dyspepsia. The seeds were boiled and ingested, and two hours after taking the medicine he exhibited the symptoms of vomiting followed by convulsions. On admission into the civil hospital he had toxic spasms of the whole body, recurring about every half an hour. His eyes were very congested and he could not speak. He died 24 hours after taking his medicine. The post-mortem signs were not very distinctive, there was congestion of the brain and spinal cord and both lungs showed congestion, the heart was full of thick black blood, suggesting death to be due to asphyxia. The viscera and solid organs of the abdomen were practically normal.

The poison was detected in the stomach contents, and the intestine by means of the microscope, the husks of the seed closely resembling those of the *datura* seeds, but in addition there were very typical honey-combed cells. This examination was carried out, side by side, with the genuine poisonous fruit of the *Illicium religiosum* as a control. No definite active principle of the fruit could be isolated by chemical means.

The poison suggested by the civil surgeon was strychnine and the symptoms all resembled strychnine except that there was unconsciousness in this case.

Yellow oleander poisoning

A Hindu male aged 32 years was admitted into the Mayo Hospital in an unconscious condition and died in 25 minutes. Four hours previous to his death he was seen riding a bicycle. The police information was that he had died as a result of drinking 'Butti'—a native medicine. On admission, all the muscles of the body were in a spastic condition and the patient was getting frequent violent spasms. Dr. Quick, who saw him first,

states 'that there was some cyanosis of the lips and nails. The muscles including those of the interior and lateral abdominal walls felt almost as hard as a wooden board and his fingers were clenched'. The vessels of the brain were congested, the lungs were markedly congested, the right heart was distended whilst the other chambers were contracted, the alimentary canal and the solid organs showed venous congestion. Death appeared to be due to a cardiac poison. The poison suspected was strychnine.

On analysis, the active principle of the yellow oleander (*Thevetia*) was detected in all the viscera. This kind of poisoning is quite common in South India but such cases are rare in this part of India.

It is remarkable, however, that with poisoning by *Illicium religiosum* and yellow oleander, the symptoms observed led both the civil surgeons to suspect strychnine poisoning, death from which is described in textbooks as being sufficiently characteristic to be diagnosed from the symptoms alone.

Medical News

THE FIRST ANNUAL GENERAL MEETING OF THE PHARMACEUTICAL AND ALLIED MANUFACTURERS' AND DISTRIBUTORS' ASSOCIATION LIMITED, HELD ON WEDNESDAY, THE 30TH APRIL, 1941, IN BOMBAY

THE President, E. W. Fairbrass, F.C.S., M.P.S., submitted his address:—

'Gentlemen.—It is my pleasure this morning to address you at the First Annual General Meeting of our Association, and it is with feelings of great pleasure that I note so many have attended to-day.

The period under review is rather less than one year; nevertheless it has been a period full of hard work. You have all had the preliminary report in your hands and an opportunity to read the brief history which gives you some idea of what happened before the Association was formed, and how it became an accomplished fact. The Central Government has been pleased to place us on their list of approved associations, i.e., recognized bodies such as the Chambers of Commerce and Trade Associations in this country.

It is not necessary for me to speak at any length on the work that has been done by the Association during the period under review. You have all been furnished with the minutes of the meetings held by the managing committee and the comprehensive information given in those minutes is ample evidence of some of the work that has been done.

We may not all be satisfied with the general outcome of the endeavours that have been made to obtain what we wanted or what we thought was best for us, but there is no doubt the Association has been instrumental in keeping certain bodies alive to the fact that we, as an Association, are doing our utmost to carry out the objects for which we were formed.

In these days of war, we are all having an extremely difficult time in carrying on in business. 'Business as usual' sounds more and more ridiculous. At every step one takes these days one finds how impossible it is to adhere to it! The mere cost of staying in business, not to speak of doing business, continues on the up grade. Some of our members who were representing continental manufacturers have lost not only a large volume of business but considerable incomes. Some of them have been enterprise enough to start manufacturing in this country, and it is to be hoped that they will be successful, and that they will be able to dig their toes in deep enough to establish firmly what they have started and in due time realize their aims in having consolidated manufacturing concerns in this country.

This brings me to the subject of import trade control, and although it is difficult for some of us quite to

reasons for control, we must believe

have very sound reasons for introducing these restrictions to conserve currency. For one thing, it is an ideal method of absorbing some of the unemployed, since more and more people are needed for doing the additional work imposed by the Government regulations.

It is gratifying that there are no embargoes on the importation of our raw materials as yet. So long as we

can obtain raw materials, manufacturing in this country can be carried on, and it is pleasing to a good many of us that our principals abroad in Great Britain and America are not only seriously considering, but are even taking action in having a certain amount of manufacture done in this country.

This position is not appreciated to the extent that it might be. There is still a large proportion of the population in India who are being misled by unfair trading competition by certain manufacturers who, to say the least, are unethical in their methods of marketing merchandise in this country. It is common knowledge to a great many of us that there are no raw materials of certain types to be found in India, also that this country is not yet equipped with the necessary plant to carry on certain manufacturing processes, yet there are some manufacturers in this country who try to impress upon the medical profession and the general public that certain preparations are the produce of this country, and yet we know that they are imported from abroad in bulk and re-packed here. We also know that a number of these concerns are now endeavouring to build up their business with these re-packed materials and are definitely marketing them as substitutes for well-known foreign products. Business houses of repute in Great Britain, America and the Continent of Europe have spent lacs of rupees in this country establishing markets for their merchandise and we regret to see that several concerns in this country are trying to market their products on the goodwill of many of our principals. I am sure that none of us are afraid of good, sound, healthy competition—in fact, competition of the right kind is to be encouraged. It is a great pity, therefore, that this particular kind of unfair competition should be permitted in any way.

Many of our members have lost a considerable percentage of their staff by conscription to national service. The loss of executive and technical personnel can only be appreciated by those of you who are now trying to carry on in these difficult days with a depleted staff. It does sometimes appear that our job, which is very important, is not considered so to the extent that it might be. Why? This is probably due in some measure to the comparatively peaceful situation in which we find ourselves, so far from the actual centres where war is being waged. I do feel that at times far too many people do not seem to appreciate the fact that there is a war on and that it is extremely difficult to conduct our business in these troublesome days.

Legislation of various types gives us a tremendous amount of extra work and I am sure the Association has been instrumental in trying to solve a number of the problems such legislation brings about.

Price control.—Now just a few words about price control. I think that it is time some serious steps were taken to bring about an efficient system of controlling prices in Bombay. The honorary secretary of this Association and I had a very long interview with the controller of prices in Bombay and made various suggestions, but so far we have heard nothing. We also put up a suggestion to the surgeon-general with the Government of Bombay that a committee be formed to go thoroughly into this very important question. I

believe the surgeon-general was good enough to support this suggestion of ours and recommended it to the Government of Bombay; as far as I know, nothing further has been done in this connection up to the present time. We all know that it is possible, in certain areas, to buy practically any type of medicine that one may want, *provided* one is prepared to pay the price that is demanded. Our job these days has been made doubly difficult by those merchants who will persist in hoarding merchandise with the hope of getting colossal prices at some later date. We have to resort to cutting down orders, restricting supplies owing to the fact that we ourselves are experiencing great difficulty in obtaining replenishments of stock, and yet these merchants are permitted to continue doing business in this manner without any price control restrictions imposed on them. I feel that it is high time the Government of Bombay took a serious view of this situation and considered introducing some form of legislation which would solve this very important problem which now faces all our members.

Unfortunately we lost two members during the year but our numbers show an increase at the moment. Even with the enlistment of new members, there are still quite a number of reputable companies in this country whom we feel should be members and I would ask those of you who get the opportunity of doing a little recruiting in the interests of the Association, to do so.

It has been a very busy year; a lot of work has been done and although the future is rather obscure at the present time, I am sure that, if we cling together, a very sound future for the Association is assured.

My personal thanks are due to the honorary secretary who has put in so much time in the interests of the Association. You have only to glance over the minutes which have been sent to you regularly to see the tremendous amount of work he has done not only in connection with correspondence and meetings, but in undertaking interviews with various Government officers and other authorities. I would ask all members if they will, to continue in the future to appreciate this work and to try and make his job as easy as possible.

EXTRACTS FROM THE MINUTES OF THE MEETING OF THE UNITED PROVINCES MEDICAL COUNCIL HELD IN THE COMMITTEE ROOM OF THE OFFICE OF THE INSPECTOR-GENERAL OF CIVIL HOSPITALS, UNITED PROVINCES, AT LUCKNOW, ON SATURDAY, 29TH MARCH, 1941

THE following resolution, the consideration of which was postponed to this meeting:

'This Council recommends to the Government of India that the Indian Medical Council Act, 1933, be amended on the following lines:

'to provide for a majority of elected members on the Council'

was lost.

The consideration of letter no. 4659-G, dated the 7th March, 1941, from the Inspector-General of Civil Hospitals, United Provinces, forwarding a letter from the Medical Council of India, suggesting that necessary steps, by enactment or otherwise, be taken to ensure that qualifications granted by institutions outside British India which are included in Schedule II to the Indian Medical Council Act alone are recognized by the Provincial Medical Council, was postponed to the next meeting. In the meantime, other medical councils be addressed to find out what they were doing about this. Also the legal position be ascertained.

The Council was in agreement with the proposal of the All-India Compounders' Association (*viz.*, that it should be made obligatory on registered medical practitioners to employ only qualified dispensers and dressers) and it was resolved that it should be enforced when we are in a position to do so. In the meantime

Government be requested to provide facilities for the proper training of compounders. A copy of this decision be forwarded to the Compounders' Association.

The case against Dr. Prayag Narayan Misra, L.S.M.F. (Reg. no. 2815), of Benares was considered and the Council judged him guilty of infamous conduct in a professional respect and decided that his name may be erased from the medical register. Further, it was decided that he may be permitted to apply for restoration (with certificates which are necessary for restoration) after a period of one year.

The case against Dr. Ganesh Ram Mullick, M.B., B.S. (Reg. no. 2717), of Benares was considered and the Council judged him guilty of infamous conduct in a professional respect and decided that his name may be erased from the medical register. Further, it was decided that he may be permitted to apply for restoration (with certificates which are necessary for restoration) after a period of one year.

The report of the Standing Committee, which met on 11th and 12th January, 1941, in connection with (1) amendments to the report of the Local Self-Government Committee proposed by the President of the District Board Medical Officers' Association, (2) Rai Bahadur Captain K. N. Goyal's certificate to a firm, which has been published in a newspaper, and (3) the proposal that prosecutions under the Indian Medical Degrees Act be published in the newspapers, was considered and their recommendations were accepted.

The report of the Standing Committee, which met on 10th March, 1941, regarding the advertisement by Dr. P. L. Whig, M.B., M.R.C.P., D.P.H., etc., an applicant for registration, was accepted.

The consideration of the amendments to the United Provinces Medical Act, and the rules thereunder, formulated by the Standing Committee and as finally approved by it at its meeting held on 10th March, 1941, was postponed to the next meeting and this subject to be the first item of the agenda.

NEED FOR REORGANIZATION OF MILK TRADE

REORGANIZATION of milk marketing and the creation of a 'monopoly' marketing organization, to be responsible for the purchase of milk from rural areas, its transport, processing and distribution, and the control of quality from the stage of production to that of actual sales, is the most important recommendation of the Agricultural Marketing Adviser to the Government of India in his 'Report on the Marketing of Milk in India and Burma'.

'The deplorable state of affairs existing in the milk trade of the country,' he says, 'has been realized by many in the past, and comparison has often been rightly made with the progress achieved elsewhere in the world. . . . As a result of various circumstances peculiar to India—economic, social and religious—it may not be possible to achieve here all that has been achieved in other countries within the same space of time, but matters could certainly be considerably improved if the problem were tackled on the right lines'.

IMPORTANCE OF MILK IN DIET

He stresses the vital importance of milk to the Indian population, whose diet is deficient in first-class proteins which are easily obtained from milk. Both from the public health and the economic points of view—the annual value of India's milk production is estimated at over Rs. 175 crores—the dairy industry is of considerable importance.

Urging the need for complete control over the distribution of milk in an urban area, and thereby on the production of milk in the rural area concerned, the report says special legislation, of a provincial nature, will be necessary as, 'although there is an element of compulsion in the suggested monopolizing of the milk business, this appears to be the only way in which both producers and consumers can be protected'.

STRICTER CONTROL OVER QUALITY

The report also urges the necessity for the revision of standards of purity and for more vigilant control of the quality of milk. 'Most milk', it states, 'is distributed under filthy conditions—enough to create a dislike for milk in the minds of many consumers.... There is a strong feeling amongst consumers and progressive milk dealers that official control of the quality of market milk has been very lax. Adulterated dirty milk is gradually driving away pure and clean milk from the market. It is almost impossible to obtain pure milk in open markets, with any degree of certainty'.

The abolition of 'mixed' milk standards, which allow scope for adulteration; the rising of the standards for 'cow' and 'buffalo' milk to correspond with the natural composition of Indian milk; the recognition of toned 'Standard' milk and the re-drafting of by-laws relating to the production and sale of milk and dairy products, so that they can be properly enforced, are recommended.

ORGANIZATION OF COLLECTORS

The application of co-operative principles to the assembling and distribution of milk not having produced the desired results, the report recommends that efforts should be made to organize the collectors of village milk who handle large quantities, and not only the producers, as has been done so far.

'To improve the fluid milk trade', it is urged, 'the small and inefficient processor and distributor must be gradually eliminated. Processing and distribution in cities and towns must be entrusted to large, well-managed organizations, which can make use of every aid that science can offer and can improve the technical efficiency of their business and put on the market a high quality product.'

The cost of handling 1,000 maunds of milk a day under the proposed scheme of reorganization would necessitate the investment of approximately Rs. 4,50,000. As the scheme is a self-supporting one, the sum is likely to be recovered in less than ten years.

Current Topics

Low Back Pain

By P. C. WILLIAMS, M.D.

(Abstracted from the *Southern Medical Journal*, Vol. XXXIII, August 1940, p. 788)

THE knowledge which has been gained during the past fifteen years regarding the condition spoken of as low back pain, lumbago and sciatica if properly correlated should practically eliminate the confusion which has been associated with these conditions. The literature of the past decade has presented many theories which to those who do not specialize on this ailment may appear to be severely contradictory. It is the opinion of the author that this is not the case and that most investigators are rapidly progressing to a common conclusion.

It has been definitely shown that the lower lumbar and lumbosacral articulations are responsible for symptoms in the majority of those cases suffering with the complaints already mentioned. Attributing such symptoms primarily to infection, muscle strain or mechanical disorders of the female pelvis is far less prevalent than it was a few years ago when a pain in the lower part of the back was too often taken as an indication for an investigation of practically all parts of the body except the spine.

Changes within the lumbosacral and less frequently other lumbar intervertebral disks are undoubtedly the cause of symptoms in more than 90 per cent of those patients who present themselves with any one or all of these complaints. Trauma is the aetiological factor in bringing about the changes within the disk in most cases. The various mechanical factors, which result in degenerative changes of the annulus fibrosus and in turn the nucleus pulposus, will be designated.

ACUTE TRAUMATIC DESTRUCTION OF THE INTERVERTEBRAL DISK

An acute traumatic rupture of the disk usually occurs between the ages of 10 and 25 years and is the result of a definite injury, the mechanics of which are compressive in character. In childhood and early adult life the nucleus pulposus of the lumbosacral disk is a definite fluid-like structure capable of resiliency and intervertebral support, therefore subject to rupture. Symptoms following the acute injury are often severe, but as a rule temporary in character. Later, varying from a few weeks to several years, usually while lifting a load, the patient again suffers an attack of pain in the lower part of the back. Such attacks may occur repeatedly and eventually are associated with an accompanying pain radiating down one and occasionally both extremities to the lateral aspect of the calf and ankle, following the fifth lumbar nerve distribution.

The most constant history associated with severe recurrent attacks of pain is that of some motion which involves hyperextension of the lumbosacral spine combined with a contraction of the erector spinae muscles.

Many acute ruptures would have been avoided had the compressive force been evenly distributed on the intervertebral disk, but in the presence of a static disturbance in the mechanics, the compressive force is applied primarily to one portion of the annulus fibrosus which ruptures under the strain. For this reason many disks which would eventually have given way to a chronic uneven distribution of weight are ruptured at an earlier period in life.

CHRONIC DESTRUCTION OF THE INTERVERTEBRAL DISK

Providing an individual, who presents a mechanical alteration and thus an uneven distribution of weight on the lumbosacral disk, does not suffer an acute injury, symptoms usually do not make their appearance until some time during the fourth decade of life. Such a patient may enter around the age of 35 giving a history of an acute sudden onset of pain following an injury. X-rays will show findings characteristic of a destruction of the disk, but associated changes give evidence that the process has been going on through the years, and for this reason the injury must be considered as only the factor which initiated clinical symptoms.

The commonest cause of an uneven distribution of weight on the intervertebral disk is a lordosis of the lumbosacral spine. Due to the erect posture of man which transmits the weight of the trunk to the posterior fibres of the annulus fibrosus of the lumbosacral disk, degenerative changes caused by stress have opened avenues of escape for the nuclear content and a fibrous degeneration has taken place by the time the individual has reached the age of 40. For this reason most individuals at this age period are potentially subject to pain in the lower part of the back. The stress on the posterior fibres of the lumbosacral disk is in proportion to the acuteness of the lumbosacral angle. Severe acuteness in the individual of the constitutional type who is short of stature, well nourished and presents firmly constructed joints and a good muscle tonus is due frequently to tight muscles and fascias in the anterior and lateral aspects of the thighs. The latter prevent an elevation of the front of the pelvis. In individuals of the constitutional type who are tall, thin and present long extremities and loose joints and exaggerated lumbosacral angle appears to be due to a poor muscular tonus which causes them to assume a relaxed attitude in a position of balance while in the erect posture.

A lateral tilt of the first sacral vertebra due to a short leg or a developmental disturbance within the sacrum itself is the common cause of increased pressure on the lateral aspect of the lumbosacral disk. In maintaining the centre of gravity over the base of support it is necessary to distribute the greater part of the weight of the trunk to that side of the intervertebral disk which corresponds to the high side of the sacrum. Barring an acute rupture of the disk as a result of a compressive injury in earlier life, these patients usually present first symptoms between the ages of 25 and 35 years. The x-rays show findings characteristic of a traumatic destruction of the lumbosacral intervertebral disk.

The anomaly commonly spoken of as sacralization of the fifth lumbar vertebra is another cause of an uneven distribution of weight on the lower lumbar intervertebral disks. The fixation of this segment to the sacrum may be either unilateral or bilateral. When bilateral, the lumbosacral intervertebral disk retains a normal structure throughout life, but the articulation between the fourth and fifth vertebrae must compensate severely for the erect position, and in so doing the intervertebral disk at this site receives a severe stress on its posterior portion. If not ruptured acutely in early life, chronic trauma brings about degenerative changes of the disk and clinical symptoms usually by the age of 30. Aside from localized symptoms, pain and frequently nerve changes follow primarily the distribution of the fourth lumbar nerve on either side and sometimes both.

When the fifth lumbar vertebra is attached to the sacrum on one side only, in addition to the stress applied to the posterior portion of the fourth lumbar intervertebral disk, there is an abnormal stress taken on the free side of the lumbosacral intervertebral disk. Symptoms resulting from a settling of the free side of the fifth lumbar vertebra usually do not appear until after the age of 40. Segmental symptoms in such a case follow the distribution of the fifth lumbar nerve on the side opposite the fixation; however, for the reason already given this symptom may be combined with fourth lumbar nerve pain on either side.

The anomaly spoken of as lumbarization of the first sacral segment is also capable of disturbing the weight-bearing mechanics at the lumbosacral articulation and thus causing an uneven distribution of weight on the intervertebral disk at this site. This condition may also be unilateral or bilateral. Whether unilateral or bilateral, the posterior fibres of the annulus fibrosus of the lumbosacral disk receive an abnormal stress from an uneven distribution of weight caused by an abnormally acute lumbosacral angle which these cases present. Unless ruptured early by an acute injury degenerative changes have caused a settling of the disk, and clinical symptoms usually appear by the age of 35. Aside from localized pain, symptoms follow primarily the distribution of the fifth lumbar nerve on either side and sometimes both. When the intervertebral disk between the first and second sacral segments is well developed and the segment is entirely free on one side, abnormal stress on the free side may cause a gradual settling, resulting in clinical symptoms following the distribution of the first sacral nerve on the free side. This particular symptom usually does not occur until after the age of 45, but earlier symptoms following the distribution of the fifth lumbar nerve may have been present at an earlier date for the reason already given.

An infectious destruction of the lumbosacral intervertebral disk is occasionally seen and in early cases may be mistaken for the ordinary case which enters complaining of pain in the lower part of the back; however, the clinical course will usually differentiate it from the latter. The author has seen two cases of tuberculous destruction of the lumbosacral intervertebral disk which were treated for sciatica because of the segmental pain throughout the distribution of the fifth lumbar nerve, before the true nature of the lesion was recognized. Aside from tuberculosis the

other commonest infectious destruction of the lumbosacral and other intervertebral disks is caused by the typhoid bacillus. The acuteness of pain and the inflammatory symptoms will readily differentiate the latter from the ordinary case.

Spondylolisthesis, while not a primary disk lesion, occurs to the extent of approximately 4 per cent and therefore should always be considered in those presenting themselves complaining of pain in the lower part of the back. In the author's experience segmental symptoms have not been a common finding in these cases. Pain in the lower part of the back radiating through to the abdomen, the anterior upper thigh and the groin is a more common complaint.

Fragmentation of the facets at the lumbosacral articulation constitutes less than 1 per cent of the patients entering with the complaint already outlined. When present, symptoms usually follow the distribution of the fifth lumbar nerve on the affected side.

X-ray changes.—It is the author's opinion that the recent inclination to insert an opaque oil into the neural canal in an effort to determine disk changes has been severely abused. A ruptured intervertebral disk at the lumbosacral or lower lumbar articulations can be interpreted by facet changes providing a proper x-ray technique is employed. Repeated careful clinical examinations will afford adequate information to determine whether the prolapse of the disk itself is sufficient to be of clinical significance. When the supportive structure of the nucleus pulposus is lost there is an immediate settling of the vertebra above, which is always registered on the corresponding facets when stress is being applied. Therefore either weight-bearing or in reclining, an extended position of the low spine is essential in obtaining proper facet relationship. All studies taken for the purpose of facet readings should be stereoscopic. Best results are obtained by a rotating anode tube. The patient should be posed in such a position that superimposed bony structures are minimal.

Narrowing of the intervertebral joint space is not so important in an interpretation of x-ray studies as are the facet articulations. This is due to the fact that a settling of the disk is frequently stopped by contact of bony structures. Therefore, primary attention should be focused on the articular facets in an effort to determine whether there is an overriding of these processes. Frequently the first sacral facets lodge in the inferior vertebral notches before an appreciable narrowing of the disk is apparent. Under such conditions they become weight-bearing structures and produce a scarring of the vertebral notches of the fifth lumbar vertebra as well as a sclerosis of the superior margins of the first sacral facets themselves. In the anteroposterior study, this sclerotic change presents an irregular line at the junction of the lamina and the inferior articular facet of the fifth lumbar vertebra which may be misinterpreted as a fracture. In addition, the bony irritation in the inferior vertebral notch may result in a spur formation.

When settling of the segment above is stopped by lodging of the superior facets of the segment below the inferior facets of the above segments frequently appear atrophic when viewed by x-ray studies. This is due to the fact that the superior facets of the lower segment become weight-bearing structures and have taken over the load, thus moving the stress from the inferior facets of the above segment.

The degree of narrowing of the lumbosacral space depends primarily on the acuteness of the lumbosacral angle and the magnitude of the first sacral facets. When the lumbosacral angle is acute and the superior first sacral facets are large, the latter will lodge in the inferior vertebral notches before the narrowing of the disk has become greatly apparent or in extreme cases even before the narrowing has become appreciable.

Occasionally the spinous processes, when large, contact each other and prevent further settling of the disk.

Marginal lipping around the inferior and superior borders of the vertebral bodies adjoining the affected disk is the result of abnormal stress on bony structures

which has resulted from a loss of the resilient intervertebral disk.

THE CAUSE OF SYMPTOMS

It is the opinion of many investigators to-day that disk changes account for symptoms in most of the cases frequently referred to as sciatica and lumbago. There is yet considerable confusion as to what change results in the segmental symptoms which these patients present. It is the author's opinion that they are due primarily to resultant disturbances in the mechanics in the lower part of the spine and that to ignore these and remove a prolapsed disk will result in persistent local and segmental symptoms following such surgical procedures.

The lumbosacral intervertebral disk undoubtedly suffers more from trauma than any other disk within the spine. The reasons for this are too apparent to be enumerated in this paper. A careful study of the anatomy of this region will reveal that the prolapse of the annulus fibrosus or the nucleus will not contact the fifth nerve root, yet none can deny that most cases present segmental symptoms throughout the distribution of this segment. The nerve emerges from the canal just below the inferior vertebral notch and contacts only the lateral aspect of the lumbosacral disk.

We should bear in mind that below the cord we are dealing with a bundle of nerve segments bathed in spinal fluid and confined in an area of the spinal canal which has been enlarged by nature to accommodate mobility at this site. Because of this, slight displacement from within would not be expected to cause symptoms so severe as at a higher level. If the magnitude of the protruding disk is great enough, an irritation of the meninges would be expected. This should cause a wider-spread distribution of symptoms than most of the cases present when once they become chronic. It is probable that the extensive distribution of pain occasionally seen in those patients who have suffered their original injury is due to such an irritation; however, symptoms usually subside in these cases and the fixed segmental pain follows months or years later. The funicular portion of the nerve should be more subject to irritation than the intraspinal portion since it is not protected by spinal fluid. It is more logical to conclude that such symptoms are due to progressive changes which follow the rupture of the disk. When once the nucleus ruptures the annulus fibrosus undergoes an atrophic degeneration which results in a gradual narrowing of the intervertebral space providing stress is continued and not interfered with by the contact of certain bony structures. From anatomical studies it becomes apparent that as the disk settles there results a subluxation of the lumbosacral facets and that the first sacral facets may directly contact the funicular portion of the nerve as it emerges through the lumbosacral foramen. With such a mechanical situation hyperextensive motions of the low spine may result in an impingement of the nerve root. A careful study of the histories of these patients will reveal that recurrent attacks accompany a contraction of the erector spinae muscles at a time when the lumbosacral spine is in an extended position. Examples are lifting a load above the waist line, pivoting on a golf drive and raising a window.

In two patients who presented severe fifth lumbar segmental symptoms, a fusion was accomplished without relief of symptoms. A second operation consisting only of a removal of the lumbosacral facets on the side affected afforded complete relief.

Over a period of eight years the facets have been removed and a graft placed in thirty-two patients. All, save one who died post-operatively, obtained relief of segmental symptoms.

It is the author's opinion that in better than 95 per cent of the cases, pain is due to mechanical alterations which have resulted in a constriction of the foramina and an impingement of the nerve root rather than to the prolapse of the disk itself. During the past year there have been two cases in which symptoms were

such that they indicated pressure within the canal. Both were referred to a neural surgeon, who did a laminectomy. One revealed a nucleus pulposus which had become completely separated from the intervertebral disk and was lodged in the foramen around the nerve root. A fusion was done at the time and a relief of symptoms has resulted. The other presented a chondroma of the disk protruding posteriorly. It was removed and mechanics otherwise ignored. The patient, although considerably improved, continues to have segmental pain. Both cases presented a clinical picture which, when observed over a period of time, could not be confused with the usual case. Another patient under observation for the past year who was operated on elsewhere eighteen months ago, the operation consisting only of a removal of the prolapsed disk, continues to present pain and nerve changes throughout the distribution of the fifth lumbar nerve.

TREATMENT

All cases should be given a prolonged conservative treatment before any radical measures are considered. With a thorough conservative programme, better than 90 per cent of the cases will be relieved to the extent that they are happy to continue without surgery. This depends to a considerable extent on the occupation of the patient. Where heavy lifting is necessary it is difficult to control the mechanics of the lower spine. Conservative methods are based on reducing the lumbosacral angle and thereby lifting the weight from the posterior structures at this site. This means that the lordosis of the lower spine must be reduced to a minimum at all times, thus flexion of the hips is preferable when reclining. A slightly slumped position is desirable in sitting and in standing a straight lumbar spine is indicated. Lifting should be done without extending the low back and patients with such a lesion should always avoid bending backward. Spinal surgery should never be employed until a thorough conservative programme has overcome a fixed lumbosacral lordosis and lengthened short fascias and muscles of the anterior and lateral aspect of the thigh. The latter may require severing as described by Ober. If this is not done, pain just above the graft or at the lumbosacral joints due to a downward pull on the front of the pelvis may either persist or make its appearance following surgery of the lumbosacral spine.

One should have a thorough understanding of segmental symptoms before spinal surgery is attempted. Such surgery should consist of relieving nerve root irritation by removing the facets which correspond to the segmental distribution of pain and nerve changes and at the same time laying a lumbosacral graft. In those few cases presenting symptoms more suggestive of a spinal cord tumour due to fixed pain and nerve changes as well as spinal fluid changes, there is an indication for an opaque oil in the neural canal in order to gain a better understanding of the pathological change before surgery is undertaken. When such surgery is indicated the mechanics of the low spine should not be overlooked. A graft should be placed and facetectomy usually performed if we are to avoid post-operative symptoms.

Pyelitis

By T. H. OLIVER, M.D., F.R.C.P.

(From the *Practitioner*, Vol. CXLV, July 1940, p. 1)

PYELITIS, or inflammation of the pelvis of the kidney, presents difficulties to the clinician in two ways. In the first place, the symptoms may simulate those of other conditions, diagnosis may be difficult, and the favourable opportunity of early treatment may be lost. Secondly, even if the correct diagnosis has been made, some condition underlying and predisposing to it may be overlooked and the chance of permanent cure diminished. These cases therefore may require a most careful and systematic investigation and certain points

in the aetiology of the condition should be borne in mind:—

(a) It is much more common in women than in men; of my own cases 84 per cent were women.

(b) More than 75 per cent of cases are due to the *Bacillus coli*. Other organisms which may be responsible are the streptococcus, the proteus bacillus and the staphylococcus: this last being commonly associated with a calculus. Mixed infections, however, are not uncommon and, owing to the profuse growth of the *B. coli*, the presence of another organism may go undetected.

(c) It is usually a blood-stream infection but some determining factor may be present:—

(1) Previous damage to the kidney.

(2) An unhealthy condition of the gastro-intestinal tract.

(3) A manifestation of a lack of resistance owing to the presence of some chronic disease.

(4) An ascending infection from a cystitis—although this is not yet absolutely proved.

Clinically the disease is divided into acute and chronic, but it should be remembered that a chronic case may develop acute symptoms which may be the first manifestation of a condition previously unsuspected. The careful elucidation of apparently trivial symptoms—a slight dysuria or frequency, the occasional passage of offensive urine or mild febrile attacks, which have been regarded as influenza—may indicate an unhealthy urinary tract as the origin of a vague ill-health which may have been in existence for years and which in many cases may be traced back to a previous pregnancy. Of all the aetiological factors pregnancy is probably the commonest, and occasionally an attack of pyelitis is the first indication of the condition.

In *acute pyelitis* there may be a prodromal period of a few days during which the patient may complain of increased frequency of micturition and general malaise: usually, however, the symptoms are not sufficiently severe to warrant confinement to bed or even to the house, and the temperature is little, if at all, raised. The acute phase begins suddenly, often with a rigor, which in a severe case may be repeated, and the temperature may remain high for a week or more. Urinary symptoms are usually present and may be severe, and there is a marked increase in frequency with a scalding pain on micturition. The urine itself has an opalescent appearance and in *B. coli* infections is intensely acid and has an unpleasant fishy odour. Haematuria may occur, but it is uncommon for it to be excessive and in many cases it is entirely absent. A moderate degree of albuminuria is common.

DIAGNOSIS

The differential diagnosis may be difficult. In some cases pain in the flank or severe generalized abdominal pain with distension may occur at the onset, and the case may easily be mistaken for one of acute appendicitis. Rigors, especially if recurrent, and the higher temperature in pyelitis together with tenderness in the loin rather than over McBurney's point, with increased frequency of micturition, will in most cases enable the distinction to be made. It should be remembered, however, that appendicitis may be a predisposing cause of pyelitis and the two conditions may coexist. A retrocaecal appendicitis, in particular, may give rise to especial difficulty, and a diagnosis may be impossible until a microscopical examination of the urine has been made. Occasionally the urinary symptoms are not pronounced, there may be no localized tenderness and the continuous temperature may lead to suspicion of a typhoid infection. As sweating in pyelitis is often a prominent symptom, its presence may appear to indicate the existence of abortus fever. Probably, however, abdominal influenza is the mis-diagnosis most commonly made.

In children, headache, delirium, and vomiting may be so severe as to arouse suspicion of meningitis. Occasionally in adults cerebral symptoms are pronounced. In one case of a woman of thirty, the head retraction was so marked that a diagnosis of cerebro-spinal meningitis was made and was only disproved by

the finding of a normal cerebro-spinal fluid. In a few cases renal colic is the predominant symptom, although the presence of a stone cannot be demonstrated by x-ray. The final establishment of the diagnosis can only be made by a bacteriological examination of the urine. As in many instances the urinary symptoms are slight, pyelitis should always be borne in mind in cases in which there is an unaccountable rise of temperature, and a catheter specimen of the urine should be sent for microscopical and bacteriological examinations. Cystoscopy is not necessary in the acute phase, and is indeed highly inadvisable.

Course.—The acute phase lasts for a week to ten days, but the actual duration will depend on early diagnosis and on the efficacy of the treatment adopted. If treatment is begun early and pursued vigorously, the fever subsides in a week and the patient's general condition improves. In most cases three to six weeks' treatment is required before the urine becomes sterile, and when this has been achieved a recurrence is unlikely. The dangers are that with the subsidence of symptoms the patient may get up and abandon systematic treatment before the urine has become sterile, or a concealed focus of infection may be overlooked. As a general rule a minimum of three weeks in bed should be insisted upon.

TREATMENT

The acute phase.—Confinement to bed and ample fluids are imperative. Fruit juices in themselves tend to make the urine alkaline and the patient should be encouraged to take them freely. With the subsidence of the temperature and an improvement in the appetite, toast, rusks, or other carbohydrates may be given. I prefer not to give milk in the early stages and alcohol should always be avoided. Sweating is often a marked feature, and on this account the patient should be nursed between blankets in the early stages. The bowels should be opened by means of soap-and-water enemas. The use of purgatives is of doubtful value. Powerful intestinal irritants may do more harm than good, and I use a mild aperient—infusion of senna or one of the proprietary brands of cascara—only if the result of the enema is unsatisfactory. While the temperature is high, potassium citrate 30 grains, at three- or even two-hourly intervals until the urine becomes alkaline, is still a satisfactory form of treatment, and in many cases the urine becomes sterile with this alone. Since the introduction of the sulphonamide group of drugs, I give them in addition, in doses of 1 gm. four-hourly, and there seems to be no doubt that they enhance the chances of a complete recovery. These drugs have the advantage over mandelic acid in that they are active in an alkaline urine, and there is therefore no necessity to omit the potassium citrate. As in most cases their action is somewhat depressing, I prefer to use them only after the acute phase is subsiding and some clinical recovery has begun to take place. After the acute attacks have subsided iron is usually advisable to combat the anaemia which is almost always present to a greater or lesser extent.

CHRONIC PYELITIS

Chronic pyelitis is a common cause of vague ill-health and may continue unsuspected for many years, unless the possibility of its presence is borne in mind. For long periods there may be little or no rise of temperature and the symptoms may be attributed to debility, anaemia or neurasthenia. Headache, backache and generalized rheumatic pains are common, and there may be periodical rises of temperature with slight shivering and malaise and general aching, which are diagnosed as influenza. When a patient gives a history of repeated attacks of 'influenza', particularly if they occur when that disease is not epidemic and if there is no history of other members of the household being affected, I always suspect that the cause of the trouble may be found in the urinary tract.

Sometimes a frank attack of pyelitis, with rigors and all the symptoms previously described, is the first indication of an infection which may have been in existence for many years.

I recently saw a woman who had had an attack of pyelitis during her first pregnancy and had only had another one fifteen years later. In the interval a tendency of polyuria, slight anaemia and the occasional passage of offensive urine were the only indications that the disease had not been completely eradicated.

Although in many cases chronic pyelitis is the result of an acute attack, which has either been unrecognized or has been inadequately treated, it may come on insidiously without any obvious cause.

In a proportion of cases it is associated with disease of the urinary tract, a renal calculus or a hydronephrosis arising either from the compression of the ureter against the pelvic brim by an enlarged uterus or from a congenital abnormality of the ureter. Usually a growth of staphylococcus is an indication of a renal calculus, and recent evidence would appear to show that the organism may be the predisposing cause of the calculus formation, as cases have occurred in which staphylococci, with the same peculiarities as those cultivated from the urine, have been grown from the centre of the stone itself. Often a calculus is associated with a mixed infection of *B. coli* and staphylococci, and the latter may be overlooked owing to the profuse growth of the former.

The symptoms of calculus may be slight and its presence unsuspected until it had been revealed by x-ray. A radiological examination of the kidney should be made as a routine in all chronic cases, and a pyelogram may be required to show the presence of an unsuspected hydronephrosis, due perhaps to a congenital malformation of the ureter or to pressure on it by calcareous tuberculous glands. In men an enlarged prostate may be the cause of a cystitis and a subsequent pyelitis, which would appear to be due to an ascending infection. Occasionally renal tuberculosis may be complicated by a coexisting *B. coli* infection and the primary condition overlooked.

The next most common predisposing cause of pyelitis is an unhealthy gastro-intestinal tract—either an abnormality of function, diarrhoea or constipation, or definite organic disease. Diarrhoea would appear to be a commoner cause than constipation, and in the latter case it is probable that the chronic irritation of the intestinal mucous membrane by the purgatives taken to correct it, rather than the constipation itself, is responsible in a large number of instances. In my experience, indeed, constipation is rarely a cause of the condition unless it is due to some organic obstruction. Thus in one case, in which recurrent attacks of pyelitis had not cleared up despite systematic urinary disinfection, and in which constipation was a prominent feature, the removal of a small fibroid which had been pressing on the pelvic colon cleared up the condition completely.

In obscure cases the gall-bladder may be the infecting agent, and a Graham's test will be required. More commonly diverticulitis or a chronic appendicitis is the underlying cause and, if the latter is situated in the pelvis, it may be unrecognized for many years, as there may be little evidence of it on ordinary abdominal examination. A rectal examination should therefore never be omitted. A malignant growth of the bowel is also a not uncommon cause of pyelitis and may easily lead to errors. Twice in the last few years I have seen a case in which pyelitis was the first indication of anything seriously wrong, and in both cases it occurred before there had been any symptoms of obstruction. A full gastro-intestinal x-ray is therefore necessary in a persistent case: the possibility of uterine or ovarian disease should also be remembered and any abnormality of function investigated by a bimanual examination. Finally, pyelitis may complicate some constitutional disease. It is not uncommon in diabetes mellitus and will not yield to treatment until the diabetes has been got under control, or it may be associated with a chronic nephritis or a severe anaemia.

COMPLICATIONS

Complications are uncommon. There may be an associated cystitis which usually clears up after treatment of the pyelitis. Occasionally a *B. coli* epididymitis

may be a painful complication and may lead to a suspicion of gonorrhœal infection. More rarely, there may be a prostatitis or a urethritis. In neglected cases the presence of a considerable quantity of albumin and pus in the urine is evidence that the infection has invaded the kidney. Even then, with modern methods of treatment, the outlook is not hopeless.

In one case, that of a man of sixty, the urine was so foul and the general symptoms so severe that a nephrectomy was advised. The patient refused and his condition continued to deteriorate until the introduction of the ketogenic diet. To this he responded so well that eventually the urine became sterile and has so remained for several years.

TREATMENT OF CHRONIC PYELITIS

Before the introduction of the ketogenic diet and its derivative mandelic acid, the treatment of the chronic case was most unsatisfactory and patients were occasionally met with who had had the condition for twenty years or more. Vaccines and the drugs of the hexamine group were of some assistance, but in my experience rarely eliminated the disease. More recently the sulphonamide group of drugs has in many cases proved more effective. The ketogenic diet was introduced after the discovery that β -hydroxybutyric acid was lethal to the *B. coli*. It was most successful, but its unpleasantness has made it now of only historical interest and it has been replaced by mandelic acid or one of its compounds. This acid is a phenol derivative of β -hydroxybutyric acid, which can be taken by mouth, and is excreted as such in the urine, and has an effect similar to the acid itself. If the mandelic acid itself is used, it is essential that the urine should be acidified to pH 5.5 by giving ammonium chloride at the same time. The fluid intake is reduced to two pints daily in order to concentrate the urine, 12 gm. daily of the acid are given in divided doses (usually 45 grains), and eight 15-grain capsules of ammonium chloride are given in addition. The acidity is controlled by testing with a solution of methyl red. As many patients are nauseated by ammonium chloride, ammonium mandelate is now generally used, 50 grains four times daily being the usual dose required. Even then a few doses of ammonium chloride may be necessary to reach the required acidity. This treatment is effective, not only for the *B. coli*, but for the *Streptococcus faecalis* and to a lesser extent for *B. proteus*. A frequent practical difficulty is to reach the required acidity of the urine and to ensure a sufficient concentration of the drug. Nausea may prove troublesome in treatment, and occasionally there may be definite symptoms of toxæmia with severe urticarial rashes.

Recently the sulphonamide group of drugs has tended to replace mandelic acid. They are quite as powerful in their effect on the *B. coli* and in addition are more active against the *Streptococcus haemolyticus* and the *B. proteus*. They have also the advantage that they are more active when the urine is alkaline and so can be given in conjunction with potassium citrate. In cases of *Streptococcus faecalis* infection mandelic acid is the more powerful, but apart from this I would consider the sulphonamide group as the method of choice; and it has the great advantage that even with a damaged kidney the drug is excreted in sufficient concentration to be effective. I usually give $\frac{1}{2}$ gm. four-hourly for four to five days, which in many cases is sufficient to render the urine sterile. It is advisable, however, to repeat the course after a few days' interval, in order to make assurance doubly sure.

Toxic symptoms, apart from some cyanosis, are rarely severe, although in a few prostration or vomiting may compel discontinuance of the treatment and the substitution of mandelic acid. Sulphapyridine (M. & B. 693) is equally but, in my experience, no more effective than the earlier sulphonamide drugs and, as it is often very nauseating, I do not use it in this group of cases. Washing out of the bowel with normal saline may be

helpful, if there is evidence that it is the primary cause of the trouble, but in the majority of cases this is unnecessary.

When the treatment has ceased, the patient should be told to report periodically for the next twelve months and a catheter specimen of urine should be examined to eliminate the possibility of recurrence. If this has occurred, it is almost certain that a predisposing factor exists which has been overlooked.

CONCLUSION

With careful diagnosis and thorough treatment the prospects of a successful outcome in pyclitis are great, and the practitioner has the satisfaction of achieving a success which would have been impossible less than twenty years ago. In the pyclitis of pregnancy the success of modern treatment has been particularly effective, and termination for this reason alone is now never necessary.

Reviews

STATISTICAL METHODS FOR MEDICAL AND BIOLOGICAL STUDENTS.—By Gunnar Dahlberg, M.D., LL.D. 1940. George Allen and Unwin, Limited, London (Ruskin House, 40, Museum Street, W.C.1). Pp. 232. Illustrated. Price, 10s. 6d.

THE appearance of this book is opportune as there seems to be a growing desire on the part of medical research workers to base their conclusions on a statistical analysis of their experimental data. For the purpose of planning experiments and of drawing valid conclusions from them it is desirable that the medical worker should himself be familiar with statistical methods. This book should serve to fulfil this purpose to a large extent.

The book explains the applications of elementary statistical methods for analysing those types of data with which medical and biological workers have to deal. Although it is not free from mathematical symbols the author has struck a compromise between the mathematical demands of statistical science and the limitations of the average medical or biological student. The exposition is lucid. The examples illustrating the application of statistical methods are based on medical problems. However, certain statistical terms such as 'histogram' given on page 43, 'exponential equation' on page 48, 'standard error' and 'probability equation' on page 73, 'correlation' on page 94 and 'coefficient of correlation' on page 113 have been introduced at a stage when their meaning is not likely to be understood by the beginner.

In the first four chapters the author explains the conception of probability and the simple theorems of combination and permutation. With these simple concepts he proceeds to demonstrate how the proportion of dizygotic and monozygotic twins among twin pairs can be calculated and how the existence of certain hereditary characters among them can be studied. The remaining chapters deal with the different ways of analysing qualitative and quantitative sets of observations and with their presentation in the form of charts and diagrams. The scope includes the majority of the methods which have been generally employed in recent medico-statistical papers and the knowledge of which should therefore be considered to be an essential equipment of a medical research worker. Fully-worked-out numerical examples have been given to illustrate the application of these methods and this adds greatly to the usefulness of the book.

In a first edition some errors are likely to occur inadvertently and we may draw attention to the following—(i) figure 132 in the last line of page 21 should read 169; (ii) the probability of both twins being born alive has been shown incorrectly on page 26; (iii) in the third line from the bottom on page 83, II should replace I; (iv) the word 'tenth' should replace 'hundredth', in the fourth line from the top on page 8; (v) in the fifth line from the bottom on page 163 the limits should be from 2 sigma to $\frac{2}{3}$ sigma; (vi) in table I of appendix II for the values of 'X', after the value 1.00 the next nine values should be 1.10, 1.20, etc., and not 0.10, 0.20, etc. A similar correction is necessary throughout this table.

Certain paragraphs we feel could have perhaps been left out from this work, because they are likely to puzzle the non-mathematical reader. One of such para-

graphs is the last one on page 72 and another on page 116. For the purpose of carrying out comparisons between mean values and variations exhibited by different sets of data, the author has described methods which, though they were considered important some years ago, have now given place to statistically sounder tests. Tests on the lines of those suggested by the author on page 99 for comparing two standard deviations are not only out of date but are also inexact, and we feel it would have been better if the author had instead described the use of tests designed by Fisher which are easier to apply, and at the same time are valid for small as well as large samples.

The value of the book will be enhanced if, in the next edition, space is devoted to the description of tests which are valid for small samples, to a discussion of growth curves and life table, to certain fundamental considerations to be adopted in the designing of experiments and to an elementary exposition of the technique of the analysis of variance and covariance.

The appearance of a book of this type, written for medical men by a medical man, has long been overdue and we trust that it will now bridge the gulf that has existed between the mathematical teacher of statistics and the average medical research worker. The book bears the mark of having been written by an experienced teacher.

MATERIA MEDICA OF PHARMACEUTICAL COMBINATIONS AND SPECIALITIES.—By Dr. U. B. Narayanrao. Second Edition. 1941. Published by 'Medical Digest', Girgaum, Bombay 4. Pp. xlix plus 322. Price, Rs. 7-12; postage, As. 10

In the small space of 322 pages, the author has made an attempt to introduce short references of nearly 400 patent medicines of both indigenous and foreign origin, and has added special chapters on therapeutic index, hormone and vitamin therapies. The author has succeeded in giving much information, in a concise manner, regarding the composition, doses and indications of these specialities. The book also furnishes the name and address of the manufacturers of these patent drugs and enables the practitioner to find out substitutes if one or more of them are not available as a result of war conditions.

It is, however, to be regretted that Dr. Narayanrao has not been able to give a little more time and attention to the pharmacological side of these drugs and to investigate the relative values of various preparations, suggested for the same disease. It is obvious that a young practitioner will be puzzled in the selection of the right remedy when he has to choose one out of a dozen or so preparations, all claiming equal superiority, as is almost always the case with patent drugs.

With these limitations, the book will serve the purpose of a reference book on the patent drugs available in the market.

J. C. G.

SURGERY OF MODERN WARFARE.—Edited by Hamilton Bailey, F.R.C.S. Part III. 1941. E. and S. Livingstone, Edinburgh. Pp. 321 to 480. Illustrated. Price, 12s. 6d.; postage, 6d.

THE first few pages of this part conclude the section on wounds of blood vessels, and section V is a short

JULY, 1941]

section on injuries to nerves and tendons. Section VI is perhaps one of the most important in the whole publication; it is concerned with methods of immobilization of the limbs. In the first chapter the different methods of applying extension are discussed, by adhesive plaster, by skeletal traction, and by pulp traction. The next two chapters deal with Thomas' frames and the Thomas' splint. Boehler's methods of the treatment of fractures are well described in chapter XLVII, and the various applications of Cramer wire frames in the following chapter. The section concludes with a very excellent chapter on the modern methods of applying plaster of paris.

In the section on the treatment of wounds of the hands and feet, the important teaching of Kanavel has been given the prominence that is due to it.

Section VIII, on wounds of bones and joints, has only two chapters in this part; these are on wounds of the knee and hip joints, respectively.

The editor is to be congratulated not only on maintaining the excellent standard of this important and timely publication amongst the din of bursting bombs, but also for keeping to his time schedule under these trying conditions.

STUDIES ON THE HUMAN THYROID IN ICELAND.—

By Julius Sigurjonsson. Pp. 130, with 10 Illustrations. Obtainable from H. K. Lewis and Company, Limited, London (136, Gower Street, W.C.1). Price, 6s.

THE author has described, in this monograph, the normal features of the human thyroid in Iceland, especially with regard to the size and iodine content, the data having been collected from unselected autopsy material.

Chapters are devoted to the gross anatomy, histology, iodine content of the gland, effect of diseases, hyperplasia and the frequency of nodes.

The thyroid gland in Iceland appears to be very small as compared with the commonly accepted normal size, and its iodine content is rather high. It is interesting to note that remarkably small variation in the total iodine occurs in different localities in spite of the extremely wide variation in size of the glands.

The iodine intake is largely the determining factor in maintaining its concentration in the thyroid gland. When the total iodine, not merely the percentage, falls below a certain value, hyperplasia sets in as a compensatory reaction in order to increase the absorbing surface and thereby enable the gland to bind more iodine. Other factors may induce hyperplasia, probably by affecting the iodine requirement or utilization.

No significant variation was observed in the gland as a result of diseases of other organs or generalized diseases.

Small colloid nodes were frequently found, especially in advanced age and in females. They have been considered to be mostly due to unevenly proceeding compensatory hyperplasia.

The book contains some tables, and a list of references at the end. Anybody doing a special study of thyroid problems will find in this small book much that is interesting.

RECENT ADVANCES IN THERAPEUTICS. PART I (PART I IS COMPLETE ON 'SULPHONAMIDES').
—By J. R. Goyal, M.B., B.S. 1941. Published by the Manager, The Medical News, Burn Bastion Road, P. O. Box 81, Delhi. Pp. viii plus 88. Price, Rs. 2

SINCE prontosil initiated the era of chemotherapy almost each new member of the sulphanilamide group has been enthusiastically received. This has been largely due to the amazing results which have been obtained with each new preparation, of which sulphathiazole is the latest.

This little book, devoted entirely to sulphonamides, provides a brief account of the uses, doses, toxicity, etc., of its various derivatives. The writer has presented fairly good abstracts from the current literature. Radley Smith's view, that patients receiving sulphonamides can safely be given sulphur compounds at the same time, has been included, but we are at a loss to account for the statement recommending its administration in undulant fever, in decreasing doses for at least two months after the subsidence of fever and symptoms.

Practitioners not having had access to current journals will find this booklet useful. There are some printing mistakes which will, we hope, be corrected in the next edition.

A PEEP INTO A CORNER OF THE INNER LIFE OF ANOPHELES.—By P. C. Roy, M.B., D.P.H. 1941. Published by Messrs. S. C. Sarkar and Sons, Limited, 1-1-1C, College Square, Calcutta. Pp. 74. Price, Rs. 2-8-0

THE author of this booklet being the district health officer, Murshidabad, Bengal, for many years had ample opportunities to study the problem of anopheles and malaria in Bengal. He believes that the presence of pistia, the ubiquitous water plant of Bengal, is the main cause of increased incidence, as well as persistence of malaria in Bengal. His theory is that the anopheles larvae receive from pistia abundant supply of calcium sulphate in concentrated crystalline form and that this stimulates their growth and makes them stronger and harder. Moreover these sharp-pointed calcium crystals damage the gut of the anopheline larva. The calcium imbibed in the larval stage makes the body richer in calcium in the adult stage. The adults are much stronger and harder and live a longer life as they can stand the fight against the natural enemies better. This longevity is responsible partially for the increase in the incidence of malaria. In addition to this, the malaria parasites also grow better as they need a good deal of calcium for their growth and the parasites will pass more easily through the damaged guts than through undamaged ones.

Though the experimental proofs, in the laboratory, of the increased longevity of pistia-associated anopheles and gut-piercing are wanting, the author has tried to prove his theory by field experiment by reducing the incidence of malaria by the eradication of pistia in several villages of Murshidabad District side by side with control villages. The theory advanced by the author requires further elucidation by experimental as well as field work and corroboration by impartial observers. If this theory proves true, its application will go a long way in eradication of malaria in Bengal.

BIRTH CONTROL SIMPLIFIED—DESCRIBING EFFECTIVE AND INEXPENSIVE MODERN METHODS OF AVOIDING PREGNANCY.—By A. P. Pillay, O.B.E., M.B., B.S. Published by D. V. Taraporewala Sons and Company, Bombay (Hornby Road, Fort). Pp. ix plus 138. Illustrated. Price, Re. 1-14

CONCEPTION nowadays can be controlled with a fair degree of certainty by the use of contraceptives. The subject has been studied scientifically, and reliable methods and appliances have been introduced.

Here is a small volume on the subject specially written for the layman of this country. The author has incorporated in it all the modern contraceptive methods including some 'natural' ones. The text is sufficiently illustrated, and there is a glossary at the end of the book.

Abstracts from Reports

THE ROCKEFELLER FOUNDATION, NEW YORK: A REVIEW FOR 1940. BY RAYMOND B. FOSDICK, PRESIDENT OF THE FOUNDATION

Of the money spent during the year, 77 per cent was for work in the United States and 23 per cent for work abroad. In spite of the serious interference of the war, the Foundation's activities during 1940 involved co-operative efforts in forty-four countries in Europe, Asia, Africa and the Americas.

For an organization like The Rockefeller Foundation which over many years has tried to carry on its work regardless of flags or boundary lines, these are unhappy days. To sit by and watch the disappearance or decadence or, worse, the perversion of institutions of learning which in earlier and better years we were privileged to assist is not an easy assignment. In the decade that followed the war these institutions gave high promise in public health, in medicine, and in the natural and social sciences. The Institute of Hygiene at Warsaw, the Institute of Public Health at Prague, the Kaiser Wilhelm Gesellschaft in Berlin, the Institute of Psychiatry at Munich, the Institute of Inorganic Chemistry at Gottingen—these were a few of many organizations, in a world where thought was free, to which the Foundation gave needed assistance.

Even more difficult is it to see the brilliant men with whose work we were associated—many of them on fellowships or with grants in aid from the Foundation—now driven from the posts for which they were trained, debarred from their laboratories, some of them fugitives, some in concentration camps, many of them separated from their families or lost in foreign countries where they sought haven. To these scholars scattered in many lands, whose lives are now a sacrificial testimony to the principle of intellectual freedom, we in this protected hemisphere pay tribute of admiration and homage. Under the regulations of the United States Treasury Department, to make payments on appropriations for work in the occupied areas of Europe, Norway, Belgium, Holland, Denmark, France, Rumania—the projects which were being supported in these countries in medical research and in the natural and social sciences cannot now be assisted.

The development of the war has had the further effect of driving back several of the Foundation's outposts established in connection with its own operating programme around the world. However, Foundation personnel is still operating on the Burma Road, in India, in South China, in the Belgian Congo, in Uganda (Central Africa), in Spain and Portugal and of course in Latin America.

On the continent, as distinguished from Great Britain, the situation during the last year has rapidly deteriorated. January 1941 finds a large number of universities and institutes closed, and many others working under conditions scarcely tolerable. As German forces have moved into one country after another a definite pattern has been followed in relation to the universities and other schools. Allowed at first to continue with their work, their teaching and student activities were closely supervised by the German authorities. The supervision involved an attempt to enforce a 'cultural programme' similar to that already imposed by the Nazis on German institutions. Where this attempt was resisted, as it frequently was, the measures of repression adopted by the occupying authorities included the 'closing' of the institutions, sending faculties to concentration camps and even breaking up student demonstrations with machine guns and tanks.

The condition of university life and standards on the Continent is now little short of appalling. As a result of flight, imprisonment or disappearance the number of professors in institutions has been reduced by at least 50 per cent. Jewish professors in France were discharged as a result of the September decrees issued

from Vichy, and similar action has been taken in other countries under German domination with the exception of Denmark. Professors residing in German-occupied territory who were known to be anti-Nazi have been taken to concentration camps or have disappeared. The same is true of German refugee scholars who had found haven in countries subsequently invaded by German troops. Similarly in the three Baltic states—Lithuania, Latvia and Estonia—which were absorbed by Russia in June 1940, the process of converting the universities into Soviet institutions has proceeded rapidly. More than half the professors have been removed from their positions and many of them have been imprisoned or have disappeared. The teaching programme has been completely reorganized, particularly in the social sciences.

In such surroundings scholarship withers and only through heroic struggle keeps itself alive. When the German Minister of Justice tells the Association of University Professors that the old ideal of objectivity was nonsense and that 'to-day the German university professor must ask himself one question: does my scientific work serve the welfare of National Socialism?' he is voicing a doctrine which if broadly applied spells the end of Western scientific thought. When relativity becomes 'an example of characteristically perverse Jewish thinking', and genetics is a battleground for the 'Aryan theory', then the end of the day has come in which Claude Bernard could say: 'I give small thought to where the truth will lead me, provided that I find it'.

The necessity of protecting the careers of scholars unable to continue work in their native lands has given rise to two Foundation programmes: one a placement programme, from 1933 to 1939; the other an emergency rescue programme in 1940.

In 1940, with the invasion of Scandinavia, the Lowlands and France, and the intensification of war in England, a new kind of problem arose, necessitating a new type of programme. Many eminent scholars, some of whom the Foundation had already rescued from Central Europe between 1933 and 1939, suddenly found themselves not only unable to continue their work, but often in extreme personal peril. The situation was an emergency one. Long negotiation such as was formerly necessary to secure permanent placement was now out of the question. In order to save these men, action had to be taken at once.

During 1940, on behalf of these refugee scholars, The Rockefeller Foundation made fifty-six grants totalling \$266,350. The fifty-six scholars represent eleven nationalities, including nineteen Germans, eleven French, seven Poles, five Russians, five Austrians, three Norwegians, two Spaniards, one Belgian, one Czech, one Italian and one Swiss. Among them were physiologists, biochemists, mathematicians, psychiatrists, neurologists, economists, statisticians, historians, philosophers and philologists, all of whom had occupied distinguished places in European universities. One was a Nobel prize winner; nearly all had international reputations.

Just before he died, Lord Lothian, British Ambassador to the United States, asked The Rockefeller Foundation whether it would consider the possibility of giving a number of British medical students the opportunity to complete their training in the medical schools of the United States and Canada.

Lord Lothian's suggestion was warmly supported by leading British medical authorities, and as a result the Foundation appropriated \$100,000 to initiate the plan.

Twenty-five leading medical schools in Canada and the United States have indicated their cordial willingness to accept these new students, and some have offered to remit tuition. An officer of the Foundation is now in England working with a British committee on the details of selection and transportation. Candidates will be considered not only from the London area but from the provincial universities in England, Scotland and Wales, where extensive damage has also been done to clinical teaching services. Arrangements are being made for the local supervision of the students in America and for the acceptance by

British medical authorities of their American training, when successfully completed, as the equivalent of the British licensure. Appointments will be for not more than three years and will provide modest living expenses and tuition. The three-year period is likely to include two years of clinical training and one year of internship. The student will be expected to provide his own cost of travel. He will, of course, be required to return to Great Britain upon the termination of his scholarship. The scholarship will be administered by the authorities of the school to which he is assigned, and it is not expected that he will be enrolled as a candidate for an American degree.

Influenza.—Toward the end of 1939 a curious accident occurred in the laboratories of the International Health Division of The Rockefeller Foundation in New York. An outbreak of distemper-like disease developed among the ferrets used in the studies of influenza A. In order to prevent the spread of the infection, a vaccine was made from the organs of some of the animals which had just recovered from influenza and had come down with the distemper; and this vaccine was injected into a large number of normal ferrets. When these vaccinated ferrets were later inoculated with influenza A virus, they were found to be immune.

This phenomenon, accidentally encountered, was intensively studied during the year 1940 in the hope that it might lead eventually to the development of a satisfactory anti-influenza vaccine. In the course of the work different types of vaccine were tried, and eventually, in place of infected ferret tissues, developing chick embryos were employed. The vaccine thus produced was studied in a number of human volunteers and was found to give a sharp rise in antibodies against influenza virus in the blood of vaccinated persons. In some instances this increase was over a hundredfold, and the high antibody level resulting from the experimental vaccination persisted for a number of months. Because these results seemed much more promising than those previously obtained with any other type of vaccine, it was considered desirable to determine whether the antibody rise in the blood indicated active immunity to influenza.

Plans were therefore made to vaccinate representative groups in different parts of the country in the expectation that during the usual winter influenza season epidemics might affect some of the localities under study and thus give an answer to this crucial question.

During the midwinter an extensive outbreak occurred throughout the southern states. In Florida and Alabama a large number of persons had been vaccinated four months previously. Although complete data are not available for statistical analysis at the time this report is being written, the preliminary survey indicates that the incidence of influenza on the whole was somewhat lower among the vaccinated persons than among the unvaccinated.

The results which are available to date suggest that, although this vaccine is by no means perfect, it may have some practical value as a prophylactic measure against one type of influenza.

Yellow fever.—The year 1940 was marked by a sharp outbreak of yellow fever in the Nubian Mountains of the Anglo-Egyptian Sudan, involving thousands of cases and many deaths. The infected area had been shown to be endemic in a survey made by the Rockefeller Foundation in 1933 and 1934. This new epidemic was probably transmitted by the *Aedes aegypti* mosquito, although there is a bare possibility that other vectors were involved. Information recently received shows that the outbreak has largely been confined to the native population and apparently it has in no way been related to the movement of troops.

At the request of the British Government The Rockefeller Foundation has sent to the Sudan 250,000 doses of the yellow fever vaccine developed in the laboratories of its International Health Division and is preparing to send an equal amount in the near future. In this connection it should be reported that the Foundation is supplying yellow fever vaccine to the United States Army for the vaccination of military personnel, as well as to the United States Public

Health Service. The amounts involved may run to over a million doses.

As a result of the several avenues of investigation followed in Columbia, the tentative generalizations appear to be jungle yellow fever.

1. Yellow fever is primarily a disease of jungle animals. The classical form involving transmission from man to man by the *Aedes aegypti* mosquito is more of a secondary cycle depending largely upon conditions of population concentration and mosquito breeding created by man himself.

2. Transmission of jungle yellow fever appears to be by jungle mosquitoes from animal to animal.

3. There is no animal reservoir of virus in the usual sense. Virus continues to circulate in the blood of susceptible animals for three or four days only, and does not subsequently reappear. Mosquitoes, however, once infected tend to harbour the virus for the remainder of their lives, which may be several months under favourable conditions.

The most important control procedure with respect to jungle yellow fever is the vaccination of that part of the population which comes into contact with the infected forest area. It now appears that protection test studies in wild animals can be of great value in determining the risk to human beings entering a region. Previously, it was necessary to wait until human deaths occurred before considering the region as one of yellow fever interest. To-day the findings among the animals may be used to orient the vaccination campaign in order to give maximum protection.

The discovery that yellow fever can be transmitted in the jungle by carriers other than the *Aedes aegypti* mosquito does not minimize the significant part which the *aegypti* mosquito plays in the distribution of the disease among human beings. It is not too much to assert that if in urban areas this insect were brought under control as it has been in Brazil, the world could avoid the threat which in these days of fast transit might so easily develop into a cataclysm in East Africa, in India and even in the Orient, to say nothing of parts of the Americas, should the virus of yellow fever break through the barriers of quarantine, vaccination and medical vigilance.

REPORT OF THE SUDAN MEDICAL SERVICE FOR THE YEAR 1939

Kala-azar.—Three hundred and eighty-seven cases were reported with 104 deaths.

The distribution of the disease in the Sudan remains the same and the long endemic area along the whole length of the Italian East African frontier provides nearly all the cases.

Investigations are being carried out regarding the aetiology of this disease. No appreciable difference in incidence is recognizable from year to year and it appears to remain mildly endemic under normal public health conditions. The disease is of public health importance owing to the possibility that any lowering of the general standard of resistance by malarial or food scarcity might result in its becoming epidemic and invading the Gezira and other important thickly populated areas to the north. Much work is being carried out in Singa testing various new drugs in an attempt to discover more satisfactory methods of treatment than are available at present.

Sanitary control of aircraft.—Inspection and disinsection of aircraft has been centralized on Khartoum except where aircraft make a night stop at an airport near the frontier. On the west to east air route from West Africa these measures are carried out at Geneina and again at Khartoum. All passengers entering the Sudan from the west must be in possession of a certificate stating that they have not been exposed to the risk of infection with yellow fever during the previous six days. At Khartoum no mosquitoes of any kind were found on aircraft during the year. During 1939, 433 telegrams were despatched by the public health authorities of Khartoum to Egypt, India,

and other parts of Africa in connection with the control of yellow fever. At Geneina one infection of anopholes was found on an eastward bound machine.

REPORT ON THE STACK MEDICAL RESEARCH LABORATORIES

Research.—Apart from the continued malarial survey in the Gezira, the principal subject of research has been kala-azar. This has been carried on uninterrupted throughout the year.

Routine and educational activities.—The total 24,540 represents an increase of approximately 2,000 specimens over the 1938 figure, and the increase has been chiefly accounted for by a larger number of Kahn tests and Widal reactions.

Following the policy of decentralization commenced at Port Sudan, several other hospital laboratories have been equipped, during 1939, with the necessary apparatus and reagents for the Kahn test and selected Sudanese laboratory assistants were given special training in the performance of this test. The standard of accuracy obtained under expert supervision has been high but whether it will remain so when they are left on their own responsibility remains to be seen.

The positive isolations for bacillary dysentery and typhoid fever were much fewer than 1938, probably owing to the very light rains in Khartoum during the summer.

Owing to the outbreak of war a great deal of extra work in blood typing of volunteers, and preparation of blood transfusion apparatus has been thrown on the laboratory staff, but as such work can hardly be considered either routine or research, the figures are not included in this report.

There has been no increase in the number of hospital laboratories as with one or two exceptions all hospitals are now furnished with laboratory facilities. The total cadre of Sudanese laboratory assistants is 32 and their training and refresher courses remain unchanged.

Jaundice of obscure aetiology.—Livers from five cases were received during the year three of which were viscerotome specimens. In two cases it was possible to make a fuller examination, the results of which are summarized.

The first case, from Juba, showed an extensive acute necrosis with scattered fatty degeneration of the liver cells and an almost complete loss of structure of the lobule. Small foci of lymphocytes were sparsely scattered throughout the liver, but otherwise signs of acute inflammation were absent. The kidneys generally showed cloudy swelling but in some places there was an acute necrosis of the convoluted tubules, their lumina being filled with debris. The spleen showed no changes of note. The second case came from Omdurman Hospital and it has been possible to get clinical details. The patient—a Sudanese aged 22—was admitted with history of about three days' fever and died of sudden collapse four days later. Jaundice increased progressively and was deep at the time of death. The temperature ranged between 104°F. at night accompanied by rigors, and 99°F. in the mornings. Blood count showed leucopenia—the leucocyte count being 4,000—but no other abnormal changes. Examination for parasites negative. The spleen and liver were tender and enlarged (about 3 fingers). At post mortem the spleen and liver were large and soft; the other organs appeared normal.

Owing to the mistake of a native driver the organs were received 24 hours later and as the weather was hot they had undergone considerable putrefactive changes but it was possible to obtain sections of the liver. These showed a curious patchy necrosis ranging from some areas of a roughly mid-zone distribution to others in which destruction of the polygonal cells was complete. Fatty degeneration was scattered throughout but was not of marked degree. There was sparse infiltration of plasma cells and lymphocytes but no other signs of inflammation. Two other livers (viscerotome) showed such complete necrosis that it was difficult to identify the organ. In neither was

there any inflammatory reaction apart from scattered lymphocytes.

It is curious that in spite of intense jaundice none of these livers shows evidence of bile stasis.

The clinical course of these fatal cases of jaundice appears to be short and, although estimates before admission to hospital must be accepted with caution, in most cases the illness appears to last between five and eight days. There is some evidence to suggest, that if not fatal within this period, the chances of recovery are good.

Practically nothing is known about the regenerative changes in patients who recover but one specimen examined this year may throw some light on the matter; unfortunately no clinical details were supplied in this case.

The liver showed the usual areas of acute necrosis but in other areas there was evidence of a marked and rapid regeneration of the polygonal cells. There was a marked infiltration of lymphocytes and large mononuclears in Glisson's capsule and the appearance was that of an early multilobular cirrhosis. This condition is not uncommon in the Sudan and although some of the cases may be of bilharzial origin, in others there is no such history and it is possible that they represent later stages of this obscure jaundice syndrome.

Kala-azar.—The preliminary sandfly survey has been completed. The distribution of thirteen species or varieties has been recorded and it has been shown that at least six of these can bite man. It is interesting to note, that four of these six belong to the sub-genus *Prophlebotomus* Parrot, members of which were believed until recently to bite only cold-blooded animals. Infection of the skin has now been demonstrated in quite a high proportion of cases of kala-azar, suggesting that it is probably from this tissue that the vectors may take up the parasites, rather than from the blood.

The frequent occurrence of parasites in the skin, but not in the blood, suggests that the lymphatics may play an important part in the spread of infection through the body. It has been found that diagnosis can be confirmed in a high proportion of cases by finding parasites in the 'juice' obtained by gland puncture.

The glands to be punctured are the lower group of the superficial inguinal lymph glands, which are disposed vertically along the terminal part of the long saphenous vein. They can usually be readily palpated if a deep grip is taken with the thumb and forefinger. The skin having been sterilized, the glands are identified, pulled up from the underlying tissues and steadied above the thumb and forefinger of the operator's left hand. A dry, sterile hypodermic needle (no. 16 is a convenient size) is pushed through the skin and into the gland by the right hand of the operator. No syringe is attached to the needle, as once the gland has been penetrated the juice runs up into the needle of its own accord. It is usually easy to feel when the needle has entered the gland. Once the needle has entered the gland, it is held there for a second or two, then quickly withdrawn and attached to a small syringe, by means of which the 'juice' in the needle can be blown out on to a slide and a smear made and stained in the usual way for examination. With practice, the operation can be carried out very rapidly, and the amount of danger or discomfort to which the patient is subject, is negligible.

It has been recognized that a more effective specific is urgently needed in the Sudan, where the results of treatment of kala-azar with antimony preparations compare unfavourably with those reported from other countries. In collaboration with Professor Warrington Yorke, work has been undertaken during the latter part of 1939 to test the effectiveness of a series of very actively trypanocidal substances which have been produced by the Liverpool School of Tropical Medicine. The preliminary results with one of these (at present designated M. & B. 744) are encouraging, but it is too early yet to assess its final effectiveness.

JULY, 1941]

ABSTRACTS FROM REPORTS

KING EDWARD VII MEMORIAL PASTEUR
INSTITUTE AND MEDICAL RESEARCH INSTITU-
TUTE, SHILLONG. THE TWENTY-THIRD
ANNUAL REPORT FOR THE YEAR ENDING
31ST DECEMBER, 1939

THE treatment was carried out at Shillong and its authorized treatment centres which now number 24 public centres and 44 private centres. Two new private centres were authorized during the year.

Two thousand three hundred and thirteen persons applied for treatment at Shillong and its centres, the majority at the centres. Of these persons 1,986 or 111 more than in 1938 completed treatment and among these there were 8 deaths from hydrophobia. In addition 2 persons applied for treatment when they were in the late incubation stages of hydrophobia and did not complete treatment because the disease supervened during the course of treatment. Both died. Thus among persons applying for treatment there were 10 deaths from hydrophobia during the year.

There were 182 'advice cases' who did not receive treatment or whose treatment was discontinued because they were considered to be at no risk. One hundred and fifty-two of these advice cases were among persons attending the Institute at Shillong. Of the individuals placed under treatment and presumably at risk, 142 absconded before completing the course and there is no record of their eventual fate. In all these cases repeated efforts were made to induce these persons to complete their treatment, but without success.

There was one paralytic accident during the year, unfortunately of the fatal ascending myelitis type. This case occurred at one of the private centres. The patient was a woman 54 years of age bitten on the leg by a dog suspected to be rabid. The dog was killed and no examination of the brain was done. The patient reported for treatment on the third day after being bitten and developed symptoms of myelitis with pain in the lumbar region and paralysis of the lower part of the body including the sphincters, on the 13th day of treatment. The paralysis was progressive and she died with increasing difficulty in breathing two days later. At no time during the illness did the patient exhibit hydrophobia or convulsions.

With this case, the number of 'paralytic accidents' occurring as a result of antirabic treatment over the past five years has been 1 in 4,520 persons treated. The cause of these 'accidents' is quite unknown and there is unfortunately no known way of forestalling them.

Assam Medical Research Society

Dr. Rice, the Research Officer, retired from the service of the Society from 6th March, 1939, and Dr. D. K. Viswanathan, the present Research Officer, took charge on the 13th October, 1939. During the interim period the duties of the Research Officer were carried out by the Society's Malariaologist.

Malaria surveys.—Based upon the findings in the bhill survey referred to in last year's report a comprehensive report was submitted to the tea estates in Doom Dooma district stressing the need for joint effort with the co-operation of the Government for controlling Government-owned land. A full year's survey was carried out in Gillapukri Tea Estate and a report submitted.

Experimental control projects.—These were continued in 4 urban and 2 rural areas, and the results reported during the last year were not only maintained but even bettered in all but one urban and one rural area. In Gauhati Town the spleen rate was 7.2 per cent as against 5.4 per cent in the previous year and the parasite rate was 6.8 per cent as against 2.6 per cent in the year before. The Gauhati civil hospital figures show a considerable increase in the number of malaria cases treated in 1939, but as it caters both for urban and the surrounding rural areas it is apparent from the spleen rate furnished above that increased malarial prevalence in the neighbourhood affected Gauhati but slightly. The rural centre in Dishpur offered special difficulties for antilarval work on account of the obstructive attitude of the villagers in putting up hunds and removing oil booms. Besides the extent of breeding

grounds was very large and the cost of treating them disproportionately large for the small size of the population. Hence during the current year spraying houses with Pyrocide 20 has been instituted.

Treatment schemes.—This was continued with good results in Doom Dooma. The spleen rate in December 1939 was only 12.4 as against 56.5 per cent seven years previously when work was first started. The treatment scheme is however reinforced with antilarval work.

Technical guidance in routine control projects.—The Society continued to offer its technical guidance for all routine malaria control projects under the Public Health Department, and in tea gardens where the initial recommendations were made by the Society.

The report of the activities of the Society described from year to year clearly demonstrates that the purpose for which the Society was instituted is well served and all interests in the province are benefited by its activities. This province enjoys the unique distinction of having a separate research organization for the control of malaria and other communicable diseases. By reason of its being the greatest menace to the public health of Assam malaria doubtless engages the primary attention of the Society. Its constitution makes it possible to secure the co-operation of all interests in the province and pool their resources while the Government continue to obtain all the technical assistance from the Society. A time has now arrived for the Government of Assam to profit by the endeavours of the Society in the past and to undertake the control of malaria in an organized manner over the whole of the province in its twin aspects of extensive relief to the malarial sick by a wide distribution of the cinchona alkaloids and intensive control in selected areas both rural and urban. In carrying out such a policy the Society may be expected to play a useful and important rôle.

Cholera enquiry under the Indian Research Fund Association

During the first quarter of the year under review, the enquiry started in the previous year under Dr. S. R. Pandit was brought to an end and the investigations were transferred to Bengal.

Experiments carried out by Captain A. C. Vardon, I.M.D., and described in previous reports, had suggested a relationship between variants of the cholera vibrio, and produced in the laboratory by the action of bacteriophage, and certain water vibrios whose biochemical and serological reactions indicated an affinity to the true vibrio of cholera.

Certain vibrios isolated from natural water supplies and belonging to Heiberg's fermentation groups I, II and V, were found to be lysed by certain types of choleraeophage and to exhibit agglutination with 'O' sera prepared from some of the artificially prepared cholera vibrio variants, though not agglutinated by Inaba or Ogawa 'O' sera. These reactions closely paralleled the reactions of certain of the bacteriophage-produced variants of *V. cholerae*. It was therefore thought that these water vibrios might also be variants of the true cholera vibrio produced in nature by the action of bacteriophage and that removal from them of their bacteriophage resistance might cause them to revert to the true cholera vibrio.

How to bring about this reversion was the problem Captain Vardon set out to investigate. In this preliminary work an attempt was made to remove the bacteriophage resistance from the water vibrio bodies by growing the strain in the presence of appropriate anti-phage sera. It may be said that under the conditions of the experiment no diminution in phage-resistance was obtained by this method and the reactions of the vibrios remained practically unchanged after repeated passage in the presence of anti-phage sera.

REPORT OF THE BOTANICAL SURVEY OF INDIA FOR 1939-40

Cinchona and quinine.—At the beginning of the year the Government of India ceased to have responsibility

for the distribution of quinine to the provinces and states and sales remained restricted to the centrally administered areas of Ajmer-Merwara and Baluchistan. Coorg, however, got a free supply of 200 lb. and Bihar had 1,500 lb. at replacement cost as a special case from the stocks at Mungpoo.

The recommendations of the Wilson Report have yet to be implemented in full. The Imperial Council of Agricultural Research has, however, been evolving a scheme of research on cinchona. Enquiries from provinces and states indicate some interest in its cultivation.

Mungpoo factory.—There was no extraction of bark during the year. Conversion of quinine for the Government of India was also very small. The Government of India stocks at the factory at the end of the year were 84,850 lb. quinine, 7,102 lb. cinchona febrifuge, a small quantity of tablets and 256,106 lb. of unextracted bark.

Indian Museum.—Owing to the restriction of sale distribution from the Indian Museum was small. Sales of quinine to Ajmere and Baluchistan made a total of only 310 lb. The stocks in the Indian Museum at the end of the year were 7,694 lb. quinine, 1,110 lb. cinchona febrifuge and 44 lb. cinchona tablets.

Financial.—Out of the total grant of Rs. 16,600 for the cinchona portion of the budget of the Botanical Survey of India an expenditure of Rs. 5,292 was incurred. The bulk of the grant for extraction of quinine from bark and conversion of quinine into tablets was surrendered to Government.

ANNUAL REPORT ON THE CIVIL HOSPITALS AND DISPENSARIES IN THE CENTRAL PROVINCES AND BERAR FOR THE CALENDAR YEAR 1939

The salient features of the year were—(1) the steps taken by Government in extending medical relief in rural areas by (a) the establishment of *ayurvedic* and *unani* dispensaries, (b) increasing the number of allopathic dispensaries and (c) subsidizing allopathic, *ayurvedic* and *unani* medical practitioners and (2) the appointment of a committee for improvement of all the bigger hospitals and the medical school in the province.

Hospitals and dispensaries.—At the close of the year 1938 there were 362 hospitals and dispensaries in the province; 21 new dispensaries were opened and one private-aided dispensary was made a cheap-plan dispensary during the year under review. On the 31st December, 1939, therefore, there were 383 dispensaries, 204 in the rural areas and 179 in the urban areas.

Medical relief in rural areas is still inadequate and attempts are being made to expand it. Government made a provision in the budget for the year 1939-40 for the establishment of 83 *ayurvedic* and *unani* dispensaries in the rural areas and for 83 *vaidas* and *hakims* to settle in rural areas on subsidized system one in each *tahsil*. Allopathic dispensaries are also being increased, and arrangements are being made for 22 private medical practitioners to settle down, one in each district council rural area.

So far, subsidized medical practitioners have been appointed in the areas of the district councils, Nimar, Narsinghpur, Yeotmal and Damoh. Places for subsidized practitioners have also been selected in other district council areas but candidates passed from the Robertson Medical School, Nagpur, were not available for appointment. It is now intended to invite applications from candidates passed from medical schools outside the province but who are residents of this province. No appointments of subsidized *vaidas* and *hakims* have so far been made as action in the matter was held over for some time in view of the need for economy due to financial stringency. Action in the matter is being expedited and it is hoped that these *vaidas* and *hakims* will be appointed during the year 1940.

Establishment of *ayurvedic* dispensaries, one in each *tahsil*, has been sanctioned under the district councils, and it is hoped that *vaidas* at the dispensaries will soon

be appointed and that the dispensaries will function soon. Four *ayurvedic* dispensaries were opened.

A Provincial Hospitals' Enquiry Committee has been appointed by Government to suggest ways and means for the improvement of the provincialized hospitals at Nagpur, Jubbulpore, Raipur and Amraoti, the Main Hospital, Akola, and the Robertson Medical School, Nagpur.

Nurses.—The nursing staff in the Central Provinces and Berar hospitals is not up to the strength required. The four training centres for probationer nurses—the Mayo Hospital, Nagpur, the Victoria Hospital, Jubbulpore, the Silver Jubilee Hospital, Raipur, and the Irwin Hospital, Amraoti, continued during the year. A scheme for the training of male nurses in the province is still under consideration. Staff nurses were employed at the main hospitals, Saugor, Wardha, Akola and Bilaspur, and the appointments of such nurses at the main hospitals, Yeotmal, Hoshangabad and Bhandara, have been sanctioned during the year. The question of revising the scale of pay of the nursing staff employed in the provincialized hospitals in the province is under reconsideration.

Honorary physicians and surgeons.—Honorary medical officers are being employed in large numbers at the provincialized and other main hospitals as surgeons, physicians, dentists, radiologists and specialists in eye, ear, nose and throat diseases. They proved of great assistance to the staff and performed their duties with great zest.

Thus the total number of patients treated, both in-and out-door, stands at 4,323,056 (4,006,612) showing an increase of 316,444 over the past year. The increase is noticed in all the districts excepting Akola and Buldana. Of the total number treated 4,212,117 (3,899,814) were treated in the general hospitals and dispensaries and 110,939 (106,798) in the women's hospitals. The above statistics of attendance and work done in the medical institutions referred to give further indication of the growing appreciation by the public of their activities.

Malaria as usual remained the chief prevailing disease during the year. The number of cases treated for malaria during the year was 889,265 showing an increase of 183,884 over the figures of the past year (705,381). The increase is noticeable in all districts except Nimar 31,635 (32,194).

Four tuberculosis clinics in the province, one at each divisional headquarters and the Union Mission Tuberculosis Sanatorium at Pendra Road where the Government maintains 40 beds at its own expense did excellent work during the year. Dr. C. Frimodt-Möller, Medical Commissioner to the Tuberculosis Association of India, visited the tuberculosis clinics at Nagpur, Jubbulpore and Amraoti, and the tuberculosis sanatorium at Pendra Road, in November 1939. The suggestions regarding improvements to the clinics are being examined along with the whole question of dealing with the problem of tuberculosis in the province and a report will be submitted to Government in due course.

Treatment of venereal diseases and yaws.—Well-equipped centres have been organized at various district headquarters for the treatment of venereal diseases and the Government has sanctioned a special annual grant of Rs. 8,000 for treatment of these diseases on modern lines. The disease yaws is prevalent amongst aborigines of Sironcha and Garchiroli tracts in the Chanda district. The treatment for this disease was started from the year 1936. The assistant medical officers in charge of Ahiri, Bhamragarh, Allapalli and Sironcha dispensaries were supplied with medicines by the Director of Public Health, Central Provinces and Berar, and treated 1,741 cases.

As in the past the deputy commissioners and commissioners comment on the progressive reduction and impunctual payment of contributions to hospitals and dispensaries by local bodies. Local bodies are inclined to take their responsibility in regard to provision of medical relief lightly. The Deputy Commissioners, Akola, Yeotmal, Buldana and the Commissioner of the division have remarked that the financial condition of the main hospitals is extremely bad owing to reduction

or non-payment of grants by the local bodies and to the stoppage of payment of deposits by co-operative banks in which funds are locked up. The Commissioner, Berar, is of opinion that the only alternative that he sees to closing the hospitals is that Government should prescribe a minimum percentage of income which every local body must devote to medical relief. Deputy commissioners suggest that the amounts payable to hospitals should be deducted by the Government from the grants given to local bodies for general purposes and paid to hospital funds direct.

Correspondence

IDEAL MARRIAGE

SIR.—As a medical man interested in spreading sound knowledge of sex hygiene, I wish to protest against the irresponsible nature of the review of *Ideal Marriage* by Th. Van de Velde, printed on page 376 of your current number.

I read the review hoping for some information about the book and its contents. I found practically no such information. Instead I found a piece of writing of the type which I feel does harm to the cause it pretends to serve.

There are many points in the review on which I might comment. I will mention a few.

Why compare the degree to which this book and the *Bible* are or may be read? Is the implication that this is a new and better *Bible*? The suggestion that a study of this book might be made compulsory in all colleges in the world, would indicate that this implication is intended. Although not a professing Christian, I would oppose both the implication and the suggestion. The two books are in different realms. And why compulsory study? Surely most college students will have already studied this or some similar book. The market is flooded with them.

And surely it is nonsense to say that 'the credit for establishing man's claim' to the title *Homo sapiens* 'will belong to this wise cultured Dutch doctor'. Does the reviewer really think that a knowledge of sexual matters is all that is needed to make man wise? What an extraordinarily superficial view of man, history and wisdom!

And surely other writers deserve some credit. Does Van de Velde's book contain anything wonderful that is not contained in other books of a similar nature? If so the reviewer has neglected his duty in not indicating what this is.

The remarks about 'awareness of sex and all that it connotes' not being reached 'until we are among quite primitive peoples' and about knowledge of sex being 'in inverse ratio to what is ordinarily called civilization' are open to criticism. A good deal depends on what we mean by 'awareness' and knowledge.

The wisest sentence in the review is that which points out that only a fraction of the lack of awareness and knowledge can be attributed to oriental asceticism and early Christian writers, but this is immediately followed by a feeble joke in very questionable taste about the lack of definite instruction concerning coitus in the writings of Mahammed.

The whole review creates the impression that in the reviewer's opinion, sexual intercourse is the main if not the only important thing in life.

The review appears to me and to others to be unbalanced and irresponsible, not the work of a 'wise and cultured doctor'. It tells us practically nothing about the book under review.

I appeal to you to give us more balanced and more informative reviews of books on such subjects.

JOHN LOWE.

LEPROSY RESEARCH DEPARTMENT,
SCHOOL OF TROPICAL MEDICINE,
CALCUTTA.

[Note.—The writer of this review is one of our most competent and experienced reviewers. His initials were omitted inadvertently, but in the circumstances we do not propose to disclose them.

We are, naturally, not in entire agreement with our correspondent, but, as he has expressed a point of view that may be shared by others, we welcome his letter. It is unlikely, however, that we shall publish any further letters on this subject.—EDITOR, I. M. G.]

Service Notes

APPOINTMENTS AND TRANSFERS

COLONEL E. S. PHIPSON, C.I.E., D.S.O., I.M.S. (Retired), is appointed, with effect from the 7th April, 1941, to officiate as Health Officer, Simla, vice Major F. M. Khan recalled to temporary military duty.

The Governor is pleased to appoint Colonel W. C. Paton, M.C., Inspector-General of Civil Hospitals and Prisons, North-West Frontier Province, to act as Surgeon-General with the Government of Bengal, with effect from the 16th May, 1941, vice Major-General P. S. Mills, K.H.R., C.I.E.

Lieutenant-Colonel W. Ross Stewart, C.I.E., to be A.D. M. S. of a Division. Dated 1st February, 1941.

Lieutenant-Colonel E. C. A. Smith, Superintendent, Central Mental Hospital, Yeravda, has reverted to military duty. He was relieved of his civil duties on the forenoon of 20th May, 1941.

Lieutenant-Colonel W. C. Spackman transferred as Inspector-General of Civil Hospitals, Bihar.

Lieutenant-Colonel H. E. Murray, officiating Professor of Midwifery, Medical College, Calcutta, is appointed to act as Superintendent of the Medical College Hospitals, Calcutta, in addition to his own duties, vice Lieutenant-Colonel J. C. De, granted leave.

Lieutenant-Colonel F. J. Anderson, C.I.E., Professor of Surgery, Medical College, Calcutta, is appointed to act as Principal of the Institution, in addition to his own duties, vice Lieutenant-Colonel J. C. De, granted leave.

Lieutenant-Colonel F. J. Anderson, C.I.E., I.M.S. (Retired), Professor of Surgery, Medical College, Calcutta, and Lieutenant-Colonel A. Denham-White, I.M.S. (Retired), to be Honorary Surgeon and Honorary Physician respectively to His Excellency in Calcutta. Dated 15th May, 1941.

Major K. S. Fitch, Civil Surgeon of Darjeeling, to be Honorary Surgeon to His Excellency at Darjeeling. Dated 15th May, 1941.

Major H. S. Waters transferred as Professor of Midwifery and Gynaecology, Grant Medical College, and Specialist in Obstetrics with Gynaecology, Bai Motlibai and Sir D. M. Petit Hospitals, Bombay, vice Lieutenant-Colonel W. C. Spackman.

On relief of his duties as Civil Surgeon, Belgaum, Major H. S. Smithwick is posted as Civil Surgeon, Poona, vice Major H. S. Waters.

Major W. Scott, Civil Surgeon, Amraoti, who was granted leave for 1 month from 31st March, 1941, was posted to Hoshangabad with headquarters at Pachmarhi from 3rd May, 1941.

Major G. B. W. Fisher, 1st Resident Medical Officer, Presidency General Hospital, Calcutta, is appointed to act as Surgeon Superintendent of the same institution, vice Major J. C. Drummond, granted leave.

Captain J. Lightbody to be Staff Captain (Medical), Medical Directorate, Army Headquarters, to fill a new temporary appointment. Dated 13th March, 1941.

Captain W. M. Niblock, 2nd Resident Medical Officer, Presidency General Hospital, Calcutta, is appointed to act as 1st Resident Medical Officer of the same institution, vice Major G. B. W. Fisher.

Captain John Brebner made over charge of the Chittagong Jail to Dr. Subodh Chandra Gupta on the forenoon of the 1st May, 1941.

LEAVE

Major-General (local Lieutenant-General) W. H. Hamilton, C.B., C.I.E., C.B.E., D.S.O., K.H.P., Director of Medical Services in India, is granted privilege leave for 3 months, with effect from the 12th April, 1941.

(This General Officer will vacate his appointment on the expiry of the leave granted.)

Lieutenant-Colonel J. C. De, Principal, Medical College and Superintendent, Medical College Hospitals, Calcutta, is allowed leave for 2 months, with effect from the 10th May, 1941.

Major G. Kelly, Professor of Clinical Medicine, Medical College, Calcutta, is allowed leave for 6 months *ex-India*, with effect from the 29th March, 1941.

PROMOTION

Lieutenant-Colonel to be Colonel

R. L. Vance. Dated 27th March, 1941, with seniority from 15th February, 1937.

Captains (Acting Majors) to be Temporary Majors

W. Mackie. Dated 20th July, 1940.

G. S. N. Hughes. Dated 1st March, 1941.

RETIREMENT

Lieutenant-Colonel J. M. R. Hennessy. Dated 7th May, 1941.

Notes

'TABLOID' PHENOBARBITONE AND BROMIDE

THE simultaneous administration of potassium bromide and phenobarbitone is a valuable therapeutic measure in the treatment of nervous diarrhoea and other types of gastro-intestinal dysfunction in which sedative and antispasmodic medication is indicated. These medicaments are effectively and conveniently combined in 'Tabloid' phenobarbitone and bromide, a recent addition to the range of products issued by Burroughs Wellcome and Co., Snow Hill Buildings, London, E.C.1. Other conditions in which it may be prescribed include epilepsy and allied disorders involving hyperexcitability of the motor cortex, delirium tremens, nervous insomnia and thyrotoxicosis. The product presents soluble phenobarbitone gr. 1/3, with potassium bromide, gr. 7, and is issued in bottles of 25 and 100.

HEXESTROL

RECENT work on synthetic oestrogenic compounds has established the clinical value of hexestrol (4:4'-di-hydroxy- γ : δ -diphenyl-n-hexane), a substance closely related to diethylstilboestrol both in constitution and physiological action, but somewhat less toxic than the latter and consequently less liable to produce undesirable side-effects.

The compound is now issued by Burroughs Wellcome and Co., Snow Hill Buildings, London, E.C.1, as Tabloid hexestrol, a sterile solution in oil for intramuscular injection. It may be used in all conditions in which oestrogen therapy is indicated, and is particularly valuable in the symptomatic treatment of the menopausal syndrome and in atrophic conditions of the vagina.

DEXTROSOL AND ENERGY

PLAYING East Freemantle in the final of the West Australian National Football League's competition, under Australian rules recently, Claremont made an astonishing recovery in the second half, and finished the game with a 23 points lead after being 38 points in arrears at half-time.

The secret of their amazing rally when all seemed lost was that at half-time each member of the team was given 'Dextrosol', which, in the words of a spectator, 're-energized them to such an extent as to make them almost a new team'!

Interviewed after the game, the Claremont chairman frankly admitted that the success of his team was largely due to 'Dextrosol'.

One week later, again pinning their faith to 'Dextrosol' as a re-energizer, Claremont lifted another trophy in the final of yet another cup competition.

HORLICKS SPONSORS FREE THEATRE IN LONDON FOR DEFENCE FORCES

HORLICKS LIMITED of England has instituted a daily three-hour entertainment in a London theatre where all 1,200 seats are free and are set aside for the exclusive use of the civil, navy, army, and R. A. F. defence workers, and the women's branches of the various services.

The entertainment consists of films, a well-known orchestra, four or five vaudeville 'turns' and community singing. On Sundays, one-half hour of the programme features the country's leading theatrical talent with such outstanding stars as Vivien Leigh, Lawrence Olivier, John Gielgud and others.

This half hour has become such a feature that, under the title of 'Colonel Horlick's Matinee for the Forces and Civil Defence Services', it is broadcast by the B. B. C.

The project has been a success from the first, according to the London Office of J. Walter Thompson Company which produces the show. The theatre has been packed every day.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints gratis; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more, after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributors should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

REPORT ON THE EPIDEMIC OF ORIENTAL SORE IN DELHI

By M. H. SHAH, M.R.C.P. (Lond.), D.P.M. (Eng.)
MAJOR, I.M.S.
Civil Surgeon, Delhi

Introductory note

ORIENTAL sore is a specific infective granuloma of the skin which breaks down to form large chronic indolent ulcers lasting for several months. Sores may be single or multiple, and being usually present on the exposed parts of the body often cause severe disfigurement. They result from infection by *Leishmania tropica* which is generally believed to be transmitted through the bites of infected sand-flies. Although a large number of remedies have been suggested as 'specifics', only a few of them can be recommended with any degree of confidence, patients having a common tendency to drift to the *jarahs* who are reputed to have more effective cures for the sores.

The disease is widely distributed throughout the world. It is endemic in several parts of Asia, Africa and cases have been reported from different parts of Southern Europe and Australia. Nearer home the whole of the western and drier portions of the Indo-Gangetic plain from N. W. F. P. and Baluchistan on the west to Delhi on the east is a big endemic centre; the sores in this area being known by the names Quetta sores, Lahore sores, Delhi sores, etc.

Incidence of the disease in Delhi

The sore appears to have been present in Delhi at least since the time of Aurangzeb, for the Emperor himself has been recorded by the historians to have been suffering from a sore of a similar description. It is presumably on account of this that the oriental sore is popularly known in Delhi as the *Aurangzebi phora*. It is interesting that the very first observations on the parasite of this disease were made by Cunningham in Calcutta in 1885, from the examination of a patient from Delhi. Odd cases of the disease are seen almost every year, but in 1939-40 Delhi saw the outbreak of an epidemic which appears to have involved, on a modest estimate, 15,000 to 20,000 individuals in Karol Bagh alone.

The first information about the outbreak was received in June 1939 when Dr. H. C. Gupta, medical officer, Ramjas High School No. 2, reported the occurrence of multiple sores amongst the boys at the Ramjas School. As the sores were proving refractory to ordinary methods of treatment, he asked for help and advice regarding their management.

On visiting the school I learnt from the headmaster, that except for a suspicious ulcer which

he once observed in 1938 on the nose of a boy, Sham Saran, he had never seen such sores until the beginning of that year. He also mentioned that some of the dogs in that area were found to have a large number of sores during the previous winter and that he believed quite a number of these dogs eventually died of the disease. A general inspection of the boys showed that a large number were suffering from lesions characteristic of the oriental sore. As the line of treatment to be adopted was rather vague, it was decided to run parallel treatments and incidentally investigate, as far as possible, the origin of the epidemic. Observations were made as follows :—

Features of the place.—The school as well as the adjoining college are residential institutions, each with 300 to 350 boys on their rolls. Just beneath the school there is a colony of about 200 persons mainly consisting of the staff and their families.

Both the institutions are well-ventilated double-storied *pucca* buildings, and, except for a small section of the platform in front of the hostel, there was little evidence of any loose earth or masonry. The general sanitation of the place was, however, extremely unsatisfactory. Although latrines had been provided they were seldom used, the boys being in the habit of defaecating in the open.

Both the school and the college are built on top of the 'Kala Pahar', an irregular rocky ridge near Sarai Rohilla. The country on the south-western side of this ridge is, for miles around, dry, barren and rocky. Between the ridge and Karol Bagh is a large tract of land which until 1938-39 was a big dumping place for the refuse of the adjoining localities and a great cesspool for the promiscuous drainage of Raigerpura and other neighbouring localities. It was, however, levelled up by the Improvement Trust in 1938 and since then, though still far from being sanitary, it has at least begun to look respectable.

Survey of the population

Originally attention was only confined to boys, but in December 1939 a survey of the entire population of the ridge was carried out. The various particulars about the sores in school boys were recorded on 'spot' diagrams while those of the colony were entered in a register. It was found that the college had 55, the school 123, and the colony, excluding 14 boys who were attending the school, 109 affected with the disease. The distribution of cases in the colony according to their age and sex is given in table I.

Laboratory examination.—A large number of sores were examined by Dr. H. R. Bhambi, in charge, Irwin Hospital Laboratory. On account of the absence of a suitable incubator the cultural examinations did not prove very successful. The majority of the smears were

however readily found positive for leishmania bodies.

TABLE I

TOTAL POPULATION		AFFECTED			UNAFFECTED		
Age groups	Number	Male	Female	Total	Male	Female	Total
5	29	10	9	19	5	5	10

60	8	2	2	4	3	1	4
70	2	2	2
90	1	i	..	i
TOTAL	233	83	40	123	68	42	110

Leishmin test.—One c.c.m. of leishmin diluted 1 in 10 with distilled water was given intradermally to each boy in the school. Results were read after 48 hours; it was found that 75 out of 76 boys affected with the disease and 140 out of 206 of the unaffected gave positive results. A control examination of the boys in the Reformatory School situated at a considerable distance from the affected area showed that 12 out of the 40 boys there were also positive.

Inspection of the dogs.—All the dogs (17 or 18) in the locality were examined. Two of these were found to have sores. One of these dogs becoming annoyed with the daily attempts to catch him left the locality, but the other which was caught was found to have five sores distributed as follows:—Two below the lower lip, one by the side of the nostril, one beside the outer canthus of eye, and one over the ear. Examination of these sores revealed the presence of leishmania bodies.

Sand-flies.—With the help of an assistant lent by the Imperial Entomologist, Delhi, attempts were made to catch sand-flies. These efforts did not prove successful until Dr. R. O. A. Smith, who came to Delhi in connection with the Research Workers' Conference, was requested to visit the school. Although it was mid-winter he easily caught a number of excellent specimens. These were subsequently reported by him as *P. sergenti*, heavily infected with the flagellate forms of *Leishmania tropica*.

Treatment.—Boys in the school were divided in batches and parallel treatment with the following were given:—

- (1) Antimony tartrate ointment, 2 to 4 per cent.
- (2) Prontosil rubrum ointment, 5 per cent.
- (3) Sulphonamide 'P' ointment, 5 per cent.
- (4) Barber's ointment.
- (5) Wheat-germ oil.
- (6) Herb satyanasi.
- (7) CO₂ snow.

- (8) Injections of sodium antimony tartrate.
- (9) Injections of leishmin.
- (10) Injections of berberine sulphate and orisol.
- (11) Injections of neostibosan.
- (12) Scraping.

On account of distance, the limited time available for the purpose, the interruptions of the autumn and Christmas vacation and the lack of a steady supply of drugs and dressings the experiment got rather confused, and it was not until 4th January that the question was taken up systematically. The treatment this time was given with strict regularity and the progress of each case was recorded in a register. Results noted on 29th January, 1940, are given in table II.

From table II it will be observed that by the end of January the majority of the sores were either partially or completely healed and those which did not show signs of improvement, began to do so after changing over to new lines of treatment. Seeing the encouraging results obtained in the school, other affected individuals in the same locality as well as those living in various parts of Karol Bagh began to clamour for a similar treatment. By this time it had become fairly obvious that a big epidemic was raging, not only over the ridge but in the whole of Karol Bagh including the neighbouring quarries at Jhandewala, where hundreds of labourers were suffering from the disease. Indeed, cases began to appear in Sadar Bazar, Sabzimandi, Pahar Gunj and the Imperial Agricultural Research Institute, and it looked as if the epidemic was going to involve the whole of Delhi and New Delhi areas. A report was accordingly made to the chief medical officer, Lieut.-Colonel R. E. D. MacGregor, with the recommendation that a special dispensary should be provided in the centre of Karol Bagh. As a result of his interest and encouragement, two private practitioners, three Government sub-assistant surgeons and a number of compounders from the various dispensaries volunteered for the work. The equipment having been brought from the Irwin Hospital, in a few days time a fully-fledged dispensary, the oriental sore dispensary, Karol Bagh, began to function from 5th February, 1940. The chief health officer, Lieut.-Colonel W. H. Crichton, took up the work of publicity and by distributing leaflets not only brought the dispensary to the public notice but also gave information about the various preventive measures against the disease. The dispensary, which was then working only for 2 hours in the afternoon, soon began to overflow, and before the end of March the daily attendance rose to 450. With the treatment not always being an injection but an ointment like that of the barber's, to not one or two sores but to dozens, all to be cleaned, dressed and bandaged, the controlling of such a large number of patients created a big problem. It was at this time that the present chief medical officer, Lieut.-Colonel M. M. Cruickshank, arrived and quickly sizing

* Healed under the same treatment.

† Healed subsequently under other treatments.

‡ Scraped on 22nd January, 1940.

up the needs of the situation secured a whole-time and a more permanent staff for the dispensary.

With the extension of the epidemic areas even beyond Karol Bagh, it became obvious that further centres of treatment were needed. For this purpose the sub-assistant surgeons from the Willingdon Hospital, the Pusa Institute dispensary, and the Jama Masjid dispensary were given training at Karol Bagh and subsequently asked to start centres of treatment in their own localities. During 1940, about 1,150 cases at the Willingdon Hospital, 650 at the Jama Masjid dispensary and 150 cases at the Imperial Agricultural Research Institute were dealt with by these doctors. The Lady Hardinge and Tibbia College independently treated a large number of cases amongst their own out-patients, and the National Council of Women improvised arrangements on the spot for the treatment of women labourers in the quarries at Jhandewala. In addition a considerable number of the afflicted went to private practitioners and local *jarrahs* for their treatment. Although the main force of the epidemic appears to have subsided, a small number of fresh cases are still being seen.

The dispensary which has since been taken over by the Delhi Municipal Committee continues to function even now with an average of 80 cases attending daily. During the first four months of the rush, the dispensary was regularly visited by me every day, but from June 1940 the work has been practically carried out by Dr. S. K. Kohli and by Dr. A. P. Mitra, an honorary medical officer. From the start until the end of 1940, 4,215 cases, as detailed below, have been treated at the dispensary :—

	New cases	Old cases	Total
February	.. 1,147	3,608	4,755
March	.. 839	7,640	8,479
April	.. 507	5,113	5,620
May	.. 360	3,671	4,031
June	.. 169	2,769	2,938
July	.. 264	3,131	3,395
August	.. 265	3,489	3,754

October	.. 162	2,998	3,160
November	.. 140	2,765	2,905
December	.. 158	3,163	3,321
 TOTAL	.. 4,215	41,648	45,863

In view of the experience gained during the management of such a big epidemic observations on the following may be worth recording :—

1. *The origin of the epidemic.*—Because of the long incubation period of the disease extending in some cases to over 9 months or more, the various factors contributing towards the outbreak could not very well be investigated with

any degree of confidence. Efforts made in this direction, however, showed that

(i) Sand-flies collected from Ramjas College in the middle of December 1939 were identified by Dr. R. O. A. Smith as *P. sergenti* and were found infected with flagellate forms of leishmania. This apparently confirms the suggestion of Shortt, Sinton and Swaminath (1935) about this species, *P. sergenti*, being the vector in India.

(ii) Infected dogs were found in the school. The outbreak of the disease in the dogs which preceded the epidemic amongst the boys would however appear to show that the dogs may be the possible reservoirs of the infection, as suggested by Sinton and Shortt (1934). Excepting for the subsequent finding of infected dogs, the observation by the headmaster regarding the occurrence of the disease amongst dogs in its fatal form unfortunately missed scientific confirmation.

(iii) The two years preceding the epidemic were dry and deficient in rainfall. A similar observation was made in Quetta where there was practically no rain in the year before the epidemic.

(iv) The Quetta outbreak followed the earthquake of 1935. That the Delhi epidemic followed the large scale disturbance of the land by the Improvement Trust in 1938 would appear to be more than a chance occurrence. The relation of this disturbance to the origin of the epidemic is, however, not clear. The ready explanation in terms of the suitability of ground for the breeding of sand-flies would not be reasonable when nobody could say that sand-flies, which have always been quite common in Delhi, showed a particular increase in any of the years preceding the epidemic.

If excessive breeding of sand-flies had been responsible the more extensive levelling up of the ground in the Bela around Daryaganj, Kotla Ferozeshah, and Hardinge Avenue, going on at about the same time would have led to a similar outbreak of the disease in these localities as well. It may be noted that the Bela with its sandy soil and a greater degree of moisture is apparently more suited for the breeding of sand-flies than the altogether dry and rocky area of Karol Bagh.

The epidemic was found to be more intense particularly in Jhandewala and in the southern bastees of Raghpura and Beadonpura. It spread to the adjoining localities of Sabzimandi, Sadar Bazar and Paharganj, but, although the neighbouring New Delhi was practically unaffected, the Imperial Agricultural Institute situated at about 2½ miles from Karol Bagh was rather heavily involved.

If the spread had been due to the simple question of sand-flies with the prevalent winds in Delhi being westerly and north-westerly the epidemic would have spread more extensively to

Sabzimandi on the north, rather than to the Imperial Agricultural Institute situated on the south-west. From May until the end of September easterly and southerly winds prevail but New Delhi lying in the direction of these winds was, however, left unscathed. A similar irregularity of spread in relation to the vicinity of the ruins was mentioned by Dr. R. O. A. Smith in his report on the Quetta outbreak. On account of the irregularity and because of there being no particular increase in the number of sand-flies, he attributed the origin of the Quetta epidemic to the over crowding which followed the earthquake. As no over crowding can be said to have occurred in Karol Bagh I am forced to the conclusion that any hypothesis based on the sand-fly theory would be inadequate in explaining its origin, at least in this area.

The transmission of the disease through the bites of sand-flies has been postulated on exceedingly plausible evidence, and one as a clinician naturally hesitates to say anything against the conclusions arrived at by various eminent epidemiologists. But in view of the repeated failure of different workers in transmitting the disease through the bites of the infected sand-flies the matter cannot be accepted as entirely closed. The following remarks are therefore put forward tentatively :—

(a) The distribution of the sores in the majority of cases was observed to be, as is usually the case, on the exposed parts of the body. A small number of cases were however seen with sores on parts which are generally kept covered and thus protected against the bites of sand-flies. Although the possibility of exposure in these cases could not be excluded, the finding of sores over the nipple of a female patient, over the genitals of a boy and on the umbilicus of an infant indicated some mode of infection other than the bites of some insect vector.

(b) It is common knowledge that mosquitoes rarely bite over the lips and the nose. Oriental sores were frequently seen to occur over these parts and often enough as solitary sores which could not have resulted from any auto-inoculation. One would have thought that the movement of the in- and out-going air we breathe would be strong enough to prevent the sand-flies comfortably sitting and biting over these parts, which are even respected by sturdier and bigger insects like mosquitoes.

(c) The dogs observed by me at the Ramjas School showed sores only on the face. From the previously recorded observations on the dogs it would also appear that the face is the usual site of the disease in these animals. Although sores have been seen on the legs in a few cases the body has never been reported as being ever affected by the disease.

It is strange that the insect vector should spare the canine body which is equally exposed to its bites.

(d) As the inhabitants of Karol Bagh chiefly belong to the lower middle and poor classes, the bulk of cases were naturally supplied by them. It however did seem to appear that the poorer people and the labourers were comparatively more commonly affected by the disease than the better class people living in the same area.

If the infection takes place through the bites of the sand-flies, why do the exposed parts receive particular attention in the case of labourers ?

From this brief discussion it will be seen that many points regarding the epidemiology of the disease still remain obscure. The theory of transmission by the sand-fly does not appear to cover all the observed facts. Hence the possibility of other modes of transmission should not be ignored.

Being one mainly interested in the clinical aspects of the problem I am fully aware of my limitations. But I cannot help suggesting that the question requires approach from a wider standpoint than that of the sand-fly. In the allied infection of kala-azar, the possibility of its spread through the faeces has been seriously considered. Both to kala-azar and oriental sore man and dog are equally susceptible and the close association that exists between the two presents many possibilities for the transference of infection. I am not aware of any study demonstrating the presence of *L. tropica* in the faeces of human beings or dogs. The strictly local nature of the manifestation of this disease perhaps militates against the generalized prevalence of the infection in the body and the consequent possibility of the organism being excreted in the faeces. Nevertheless, it may be useful to investigate whether the organism is present in the faeces of dogs and men suffering from oriental sore. If so, a study of the viability of the organism in nature and of the possibility of its inoculation into minute abrasions in the skin through infected dust may prove useful.

It will be remembered that the disease is particularly prevalent in the dry areas of the Middle East, Southern Russia and North-western India, a wide stretch of territory where low rainfall and high temperature tend to create a high concentration of dust in the atmosphere. If infected dust, the irritation it causes, and the consequent scratching of the affected part by the individual do play a part in the spread of oriental sore, then the possibility of the occurrence of the sore in the usually unexposed parts of the body becomes clear, as also the frequency of the disease amongst the labourers, and the limitations of the affection in dogs to the face.

It is recognized that not even the shadow of any proof has been advanced for this theory and that, in consequence, it will hardly receive any serious consideration. But if some research worker, who has the requisite facilities for such a study, is perhaps tempted to undertake a

re-examination of the whole problem of transmission my purpose will have been amply served*.

Intensity of the epidemic.—Karol Bagh is inhabited chiefly by the lower middle and poor class people. In this area there was hardly a family which did not reveal at least two or three cases of the disease. It has a population of about 50,000 people. Taking into consideration the large number of individuals infected in the adjoining localities, it will not be too much to say that more than 20,000 individuals suffered from the disease during 1939-40.

With regard to the severity of the disease it has not been possible to give comparative figures, but it was evident that cases with all degrees of severity were present. A labourer in the quarries at Jhandewala was recently found by Dr. Mitra and myself with not only 239 active sores on his body, but also with innumerable scars of the lesions which had healed.

Clinical features.—During the epidemic it was observed that the pattern of sores was so varied that the classification proposed by Varma (1927) into types I to IV as papule, scab, ulcer, septic sore did not satisfactorily convey the true impression about the variety of the sores. Varma's classification being more descriptive of the evolutionary state of the sores,

*[Note.—Major Shah's article on oriental sore is in our opinion the most valuable contribution, on all aspects of the subject, that has been made for some time. However, we feel that we must comment on his discussion on the transmission problem.

We admit that the proof of the sand-fly transmission is not 'cast iron', but the evidence is so strong that a much better case against it, than that put forward by Major Shah, will be necessary before any extensive *de novo* re-examination could be recommended.

(a) He admits that the vast majority of the bites were on the exposed parts of the body. A few exceptions are not of importance, and certainly not the ones he quotes; the opportunities at night for a sand-fly to bite the umbilicus of an infant and the genitals of a boy, not to mention the nipples of a female, are considerable, and the last-named might easily have been infected from a suckling infant.

(b) and (c) We do not agree that mosquitoes and sand-flies seldom bite the nose or lips of man, and, as far as dogs are concerned, we believe it is the site of choice; the skin is much thinner and very vascular here, and there is little or no hair. This is in fact a strong point in favour of the sand-fly transmission.

(d) The points here seem to us self contradictory, or perhaps we have failed to grasp them.

Major Shah's hypothesis, that the leishmania may be excreted in the stools of man and/or dogs and transmitted in dry dust, takes one right back to the earliest days of the kala-azar investigations. There is little evidence that *Leishmania tropica* infection ever becomes generalized, in man at least, and none that it infects the intestinal mucosa, as it may in kala-azar. No resistant form of leishmania has been established and from a protozoological point of view the probabilities of the existence of such a form that would resist considerable drying seem remote.

However Major Shah gives his hypothesis for what it is worth and makes no claims.

An important observation in connection with the sand-fly hypothesis, which we feel should have been accorded separate publication, is reported here, namely, Dr. R. O. A. Smith's findings of leishmania-infected sand-flies in nature. The author gives full credit to Dr. Smith (L. E. N., Editor, *I. M. G.*).

rather than of their particular variety, the following classification was adopted at the dispensary:—

- A. General types:—
 - 1. Papules:
 - (a) Small.
 - (b) Fleshy.
 - (c) Exudative.
 - 2. Scabs:
 - (a) Dry.
 - (b) Septic.
 - (c) Exudative.
 - 3. Ulcers:
 - (a) Clean.
 - (b) Septic.
 - (c) Exudative.
- B. Special types:—
 - 4. Eczematous:
 - (a) Primary.
 - (b) Secondary.
 - 5. Lupoid.
 - 6. Fungating.
- C. Complication:—
 - 1. Lymphatic spread.
 - 2. Phlebitis.
 - 3. Generalized dissemination.

Of these types nearly all have previously been recognized, but the exudative forms do not appear to have been described. Unlike the other varieties they show a good deal of reactionary redness and swelling, which led to their being originally described by me as allergic. The erythematous and oedematous character of the sores does not appear to be due to secondary infection, at least to any extent, as this feature is present even in sores whose surface is unbroken, and those which are ulcerated lack the usual type of discharge present in the septic sores. Exudatives occur more commonly amongst the children and adults of a phlegmatic disposition. They are most difficult to manage and under local treatment have a great tendency to a lymphatic spread. This is especially apt to occur when irritating ointments are used in the treatment of this type.

Generalized dissemination as a complication has been illustrated. Quite a few cases of this type have been seen. The lesions are papular and reminiscent of a chronic urticarial state, but there is seldom any itching. As *Leishmania tropica* has not been observed in the smears of the few cases examined, one cannot really say if they are directly due to the infection by *Leishmania tropica*.

Diagnosis.—Clinically the general appearance of the sores, in the majority of cases, was quite characteristic of the disease. There were, however, various types of lupus cases which occasionally presented some degree of difficulty, but the oriental sore invariably showed the characteristic scaling on its surface.

Cultural examination did not prove a ready help until the proper incubator was received and Dr. Bhambi began to work with the original N.N.N. medium rather than its modifications which were being previously tried. Smears were often found to be quite dependable. On account of the varying shapes and sizes of the

parasites and the consequent difficulty in the recognition of the macro- and micro-nuclei, discrete bodies, particularly when lying free, are often difficult to make out from the particles of stain and the blood platelets. Even on a single examination of the smear, however, it was generally possible to find endothelial cells riddled with the organisms. Positive results in almost 7 out of 10 cases were often obtained. A similar proportion of positive findings was also reported by the provincial laboratory.

A high percentage of positive reactors was found amongst the affected boys of the Ramjas but the subsequent finding of 32 per cent of positive reactors, even amongst the boys of the Reformatory School, showed that the intradermal test with leishmin is, if of any, only of a negative value.

Treatment

Although records of all cases treated at the dispensary have been kept in the form of treatment cards, the big rush of patients, frequent changes in the medicines, the irregular attendance have all combined to cripple their statistical value.

After excluding the 1,883 defaulters who failed to attend beyond a week the 2,332 cases which continued to attend the dispensary various treatments were given as follows :—

1. Local applications	1,382
2. Scraping	285
3. Injections of berberine sulphate and orisol ..	155
4. Injections of antimony compounds ..	453
5. Injections of leishmin	43
6. Local injections of sulphonamide	15

The treatment was carried out according to the following scheme :—

A. Papule :—

- (1) Small—berberine sulphate followed, if necessary by the application of tartar-emetic (TE) ointment.
- (2) Fleshy—TE ointment after an initial scratching of the surface. Applications continued daily till necrosed.
- (3) Exudative—injections of antimony compounds.

B. Scabs :—

- (1) Dry—scraped.
- (2) Septic—TE ointment till necrosis.
- (3) Exudative—antimony injection.

C. Ulcer :—

- (1) Clean—4 or 5 applications of TE ointment.
- (2) Septic—ditto.
- (3) Exudative—antimony injections.

D. Fungating :—Scrape.

E. Lupoid :—Antimony injections.

F. Eczematous :—Ditto.

G. Lymphatic :—Ditto.

Injections of antimony tartrate were generally preferred in cases with a larger number of sores and with sores on the face, particularly if of the exudative, eczematous, lupoid and lymphatic types. Scraping was generally avoided in the exudative type of sores and in sores on the face, but was done in all those with a dry and fungating type of sore, provided the patient was agreeable to this form of treatment.

Tartar-emetic ointment was employed in cases which were not considered suitable for either scraping or the injections of antimony compounds. Papules were often submitted to the berberine sulphate injections.

Details of treatment :—

1. Local applications :—

1. Tartar-emetic ointment, 4 per cent.
2. Sulphonamide 'P' ointment, 5 per cent.
3. Callot's fluid.
4. Boric ointment.
5. Zinc ointment.
6. Silver nitrate.
7. Carbolic acid.
8. Nitric acid.
9. Barber's ointment.
10. Magnesium sulphate paste.

Most of the cases in this group were treated either from the first, or subsequent to the failure of other applications, with tartar-emetic ointment. Barber's ointment was employed only sparingly as it generally gave severe reactions. Of the other applications sulphonamides gave a hopeful impression, but it was soon found that the beneficial effect was only in some of the dry and septic sores.

I. Tartar-emetic ointment (4 per cent antimony tartrate in vaseline)

As a result of the initial experience gained at the Ramjas School, the strength was deliberately increased to 4 per cent as the conventional 2 per cent had been found to be too slow and uncertain in its action. The strong ointment often causes a marked local reaction but the resulting inflammation is seldom severe. Ointment was generally applied daily until the sores became thoroughly necrosed. This was usually evident from the appearance of a line of demarcation between the necrosed tissues and the surrounding healthy skin. When this became obvious, hot poultices were applied until the inflammation subsided, when applications of magnesium sulphate paste or boric ointment only were made. As the ointment was apt to make the surrounding skin sodden and ulcerated at several points, it was successfully protected by a thick covering of the zinc ointment.

(a) *Barber's ointment*.—The formula as revealed by Jarrah Abdur Rashid was as follows :—

Arsenic	1 ounce
Catechu	4 drachms
Hard paraffin	1 ounce
Butter	4 ounces

Application was made daily on a piece of lint. At the end of 4 to 5 days hot poultices were applied until a clean granulating surface was obtained, when daily dressings with some simple ointment, such as zinc or boric, were applied.

II. Injections of antimony compounds

The majority of the cases in this group were treated with intravenous injections of sodium antimony tartrate.

A solution of the sodium antimony tartrate was made up daily in the strength of 1 grain

to 2 c.cm. of distilled water. After an initial injection of 1 c.cm. subsequent doses of 2 c.cm. were given twice weekly to all adults, until the sores dried up completely or a total dosage of 18 grains had been given. Cure was generally observed before the maximum dose was reached. During the course of injections local dressings were avoided unless a particular sore was found to be septic, when it was dressed with glycerine magnesium sulphate paste. In all other cases it was recommended that the sores be kept clean with oil or left alone.

Side effects.—These were rarely serious, but now and again patients who failed to show quick improvement demanded a change to other treatment.

These effects were:

1. Local inflammation at the site of injection from leakages.
2. Coughing and vomiting.
3. Febrile reactions.
4. Fleeting joint pains.
5. Sudamina-like rash over the body.

Children were generally treated with intramuscular injections of anthiomoline, a May and Baker product which gave equally good results, and indeed, on account of the freedom from bouts of coughing, vomiting and febrile reactions after this drug, it was often advised to well-to-do adults, who could afford to buy it.

III. Scraping

Volkman's spoon was freely used, usually without any anaesthesia. The base as well as the edges of the sore were thoroughly scraped until the fibrous layer was reached.

Generally, only 3 to 4 sores were treated at each sitting. The resulting wounds were cleaned with ether and dressed with plenty of tannic acid powder. Usually on the fourth day after the scraping, dressings were removed, if possible, with liquid paraffin. The use of paraffin permitted the scab formed by the tannic acid to remain intact and thus obviated the need for subsequent dressing, the sore generally healing by itself under this scab. In the majority of cases aseptic necrosis of the scraped area however led to a good deal of discharge which necessitated cleaning the surface, and in these cases daily dressings with magnesium sulphate paste were applied to the ulcer until it healed. Lately, occlusive dressings with coal tar have been employed with still better results.

IV. Injections with berberine sulphate

Orisol, an M. and B. product, or alternatively with 2 per cent solution of acid berberine sulphate were used for local infiltration. Two to three injections were made to each sore using a maximum of 4 to 5 c.cm. for the full treatment of the sores at any one sitting. This process was repeated once weekly. If the response was lacking after 2 to 3 injections, the treatment was discontinued, as it was found that cases which failed to improve after this number seldom healed under prolonged treatment.

Results

As a result of the preliminary trials with the various medicines, it was found that the secret of successful treatment lay in the recognition of the particular type of sores and the choice of corresponding medicines for their management. A number of drugs like sulphonamide gave high hopes, but after more extensive trials it was found that they were really quite inadequate. The sores which yielded to such medicines were generally either the dry type which readily heal up under the mildest help or the septic sores in which the specific infection appeared to have been largely overcome by the secondary invaders. In such sores it appeared to be more a matter of keeping them clean and giving a chance of proper healing.

The general efficacy of the local applications has been considered to be finally dependent upon their ability to induce local necrosis, thus leading to the destruction of infection by physical means rather than by specific action of the medicines.

Of the local treatments, it was found that scraping was the best measure against the sores, provided they were not of the exudative type or extensive patches of the lupoid and exanthematous types. Under this treatment the sores generally healed up within two to three weeks, and, excepting for a few cases which had probably been ineffectively scraped, never showed any relapses.

Of the local applications, barber's ointment and 4 per cent tartar-emetic ointment were the only preparations which appeared to be reliable. Barber's ointment was, however, found to give more severe reactions and consequently its use had to be limited to only a few cases.

Four per cent tartar-emetic ointment gave fairly good results. An average case required 8 to 10 applications, when healing followed in 4 to 6 weeks under zinc or boric ointment. A few cases apparently became resistant, and required scrubbing of the surface, in order to achieve a quicker effect.

Berberine sulphate infiltrations were generally unreliable. In a few cases the papules dried up after 2 to 3 injections or formed into ulcers which subsequently healed under the application of simple ointments, but in the majority of cases, they did not appear to have any favourable influence over the sores.

Applications of carbolic and nitric acids were found to be too superficial in their action, as the papules to which they were applied often reappeared after the healing of their cauterized surface.

Injections of the antimony compounds appeared to act in a specific manner, as the lesions healed by progressively getting drier, until they disappeared leaving a smooth pigmented surface behind. Their use however was resented by those who had only a few sores and was also considered to be too severe a line of treatment, where only a few simple papules or

ordinary scabs and ulcers were involved. Further it was found that a few cases without showing much of a response began to show signs of intolerance and even after very great persuasion failed to continue the injections of these compounds.

The vast majority of the patients who persisted with the course generally healed in 6 to 8 weeks.

Summary

1. An epidemic involving nearly 20,000 individuals in Delhi has been described.
2. A few observations have been made regarding the mode of transmission.
3. A description of the exudative types of oriental sore has been given.
4. A new classification for the various types of sores has been proposed.
5. Scraping has been found to be the treatment of choice provided the sores are of a suitable type.
6. The curative action of the tartar-emetic ointment has been considered to be due to its necrogenic properties rather than the results of any specific effect. The strength of the ointment has been recommended to be increased to 4 per cent for achieving quicker and more certain results.
7. Injection therapy with the trivalent and pentavalent antimony compounds has been found to be the only possible 'specific' for the disease.

Acknowledgments

I am obliged to Dr. H. C. Gupta, medical officer, Ramjas High School, and Mr. R. S. Gupta, the headmaster, for supplying the necessary information about the epidemic and for generally assisting me at the school.

My thanks are due to Dr. Bhambi, medical officer, in charge Irwin Hospital laboratory, for doing the bulk of the laboratory investigations and for assisting me in the surgery and treatment of cases at the Ramjas School, and to Dr. R. O. A. Smith for reporting on the sandflies and for giving me some excellent suggestions.

I am indebted to a large number of other doctors who came forward to help; of these particular mention must be made of Dr. S. K. Kohli who after working honorarily for several months subsequently agreed to give his whole-time services to the dispensary on a nominal remuneration and to Dr. A. P. Mitra who ever since the inception of the dispensary has continued to give two hours of his valuable time every afternoon. I am also obliged to Dr. J. C. Ray of the Biological Laboratories, Calcutta, for the generous supply of leishmin and to Abdur Rashid Jarrah who generously supplied me with the formula of his ointment.

I am grateful to Lieut.-Colonel Crichton, the chief health officer, for placing the services of

SULPHONAMIDE, SULPHATES AND ORDINARY DIET

A CLINICAL INVESTIGATION INTO THE EFFECTS OF THEIR SIMULTANEOUS ADMINISTRATION

By W. McN. NIBLOCK, M.A., M.B., B.CHR., F.R.C.S. (Eng.) CAPTAIN, I.M.S.

Second Resident Medical Officer, Presidency General Hospital, Calcutta

IN 1936 the publication of the work of Colebrook and Kenny and others on the action of prontosil caused the English-speaking medical world to adopt the new chemotherapy with enthusiasm. That this enthusiasm was sometimes untempered by caution can be judged by the large number of reports published in 1937 describing toxic complications following the use of sulphonamide*.

Among these complications sulphæmoglobinæmia figured prominently though not the most frequently; that it is still most readily brought to mind may be due to two factors. The first is the mistaken idea (which dies hard) that cyanosis indicates sulphæmoglobinæmia, and the second is that the restrictions that have been

*The term sulphonamide is used generically for purposes of simplification in this article.

(Continued from previous column)

Dr. Pershad, his anti-malaria officer, at my disposal for assistance during the rush of the earlier months.

I need hardly add that but for the personal interest and encouragement from my successive chiefs, Lieut.-Colonel R. F. D. MacGregor and Lieut.-Colonel M. M. Cruickshank, such results as have been achieved would not have been possible.

recommended regarding diet and drugs exert a popular appeal to doctors, nurses and even patients. Nor is this surprising, as the majority of writers on the subject of sulphonamide seldom fail to mention that patients must not be given sulphur-containing compounds, especially the saline purgatives, and eggs and onions must be excluded from the diet. One writer has even gone the length of issuing a warning against the use of hypodermic injections of the sulphates of atropine and morphia while sulphonamide is being exhibited.

Lately, however, a few dissentient voices have been heard deplored the prohibition of such valuable remedies as the sulphates and such an important dietetic article as eggs. Smith (1940) gave thirty cases pentothal sodium (which contains 12 per cent sulphur) although they were receiving sulphapyridine at the same time, and noted no untoward results. One case actually received no less than 3 grains of sulphur in this way while receiving intravenous sulphapyridine. He also states that he gives saline purgatives to cerebral cases receiving sulphonamides whenever indicated and has seen no complications.

Tisdall (1940) has published the sulphur content of various foods, which may be tabulated as follows :—

TABLE I
Sulphur content of foods (after Tisdall)

Foodstuff	Sulphur content in parts per million
Boiled onions	23
Cauliflower	29
Boiled Brussels sprouts	77
White flour	108
Wholemeal flour	123
Eggs	170
Cheddar cheese	230

While admitting that eggs do contain a fairly high proportion of sulphur, Tisdall argues that the amount of sulphur ingested in 24 hours by an invalid through eggs and through bread would not be materially different.

On the other hand, Campbell and Morgan (1939) were able to produce sulphæmoglobinæmia experimentally by giving 3 grammes of sulphonamide and 4 grammes of confection of sulphur to individuals for two days. Sulphur in uncombined form was therefore not used in the series to be described.

Plan of investigation

The object of this investigation was to observe the effect, if any, of combining the administration of sulphonamide with therapeutic doses of sulphates and standard hospital diets.

One hundred cases were taken without selection, and, apart from about fifteen cases which had to be discarded for reasons not relevant to the investigation, they were consecutive. Sixty-one cases were young adult males because of the type of hospital accommodation available.

Every opportunity, however small, was taken to administer drugs containing sulphates, but excessive dosage was avoided.

Method of administration

(a) *Sulphonamide*.—Thirty-two cases received an initial dose of 2 grammes of 'M. & B. 693' by mouth followed by a further 2 grammes after 4 hours. Thereafter 1 gramme was given 4 hourly night and day until 16 to 20 grammes had been given. Forty-seven cases received 1 gramme of various sulphonamide preparations, either orally or by injection, three times a day until between 9 and 24 grammes had been given. Children received doses proportionate to their age.

(b) *Sulphates*.—These were given in the following forms, and many cases received more than one form :—

	Dose.
Saturated solution of sodium and magnesium sulphate ..	$\frac{1}{2}$ to 1 oz.
Mistura alba* ..	$\frac{1}{2}$ to 2 oz.
Mistura ferri aperiens*	$\frac{1}{2}$ to 1 oz.
Mistura quininæ sulphata ..	$\frac{1}{2}$ to 1 oz.
Pulv. ipecac. co.	10 gr.
Atropine sulphate (injection)	100 to $\frac{1}{2}$ gr.
Morphine sulphate (")	$\frac{1}{6}$ to $\frac{1}{4}$ gr.
Hyoscine co.* (") containing atropine sulphate ..	$\frac{1}{80}$ gr.

* For formulae see Presidency General Hospital Pharmacopœia, the Extra Pharmacopœia Vol. I, Thompson's Compendium, etc.

(c) *Diet*.—The majority of cases were at first given a 'milk diet', which includes 2 eggs daily (the eggs average $\frac{1}{2}$ oz. each). They then progressed to higher diets containing 2 eggs on alternate days. Onions are a favourite ingredient and flavouring medium in these diets.

Results

No case of sulphæmoglobinæmia was observed. Cyanosis was observed in two cases of pneumonia, and in one of acute pleurisy. The cyanosis was unaffected by the administration both of methylene blue as recommended by Wendel (1939) and of glucose intravenously as recommended by Brooks (1940). No abnormal spectroscopic bands were observed in the blood. It was therefore concluded that neither methæmoglobinæmia nor sulphæmoglobinæmia were present in these cases.

Case 1.—G. M., male, aged 67 years. Past history of treatment in hospital for heart failure. Admitted on 17th January, 1941, with bilateral bronchopneumonia of 48 hours' duration. Slight cyanosis present on admission. Treatment included M. & B. 693 2 grammes and then 1 gramme four-hourly. Dover's powder 10 grains on 17th and mistura alba 1 oz. on morning of 18th. Marked cyanosis noted on morning of 19th. M. & B. 693 discontinued. Died on 21st January of cardiac failure.

Case 2.—E. F., male, aged 19 years. Admitted on 9th December, 1940, with history of fever, pain in the chest and rusty expectoration for three days.

TABLE II
Analysis of cases, showing types of sulphates given.

Type of cases	SULPHATES GIVEN DURING SULPHONAMIDE THERAPY							Totals
	S. S. Sod. et Mag. Sulph.			Mist. Alba		Mist. Quin.	Mist. Ferri aperiens	
	$\frac{1}{2}$ oz. 4-hourly	$\frac{1}{2}$ oz. daily	Less than $\frac{1}{2}$ oz. daily	1 oz. daily	Less daily	1 oz. t.d.s.	1 oz. t.d.s.	
Septic surgical conditions	10	7	8	4	..	3	32
Infected operation wounds	4	4
Sepsis associated with filariasis	1	2	6	2	11
Ear, nose and throat conditions	8	8	3	19
Gonorrhœa	2	7	1	10
Malaria	6
Respiratory diseases	3	..	3	7	6	..	13
Sepsis coincident with other medical conditions.	i	2	..	2	5
	1	28	24	21	15	6	5	100

Examination revealed right lobar pneumonia. Treatment included M. & B. 693 2 : 2 : 1 : 1 grammes four-hourly, and then $\frac{1}{2}$ gramme, t.d.s., until 13th December. Mistura alba 1 oz. every morning. On 15th December he developed a fresh patch in the left upper lobe and M. & B. 693 $\frac{1}{2}$ gramme, t.d.s., and mistura alba 1 oz. every morning were again given.

Cyanosis was observed on 16th December, and M. & B. 693 was discontinued. The cyanosis persisted for five days. Recovery. Discharged on 18th January, 1941.

Case 3.—J. F., male, aged 36 years. Admitted on 21st March, 1941, complaining of fever and pain in the chest for eight hours. Examination revealed acute fibrinous pleurisy on the left side, but an effusion rapidly formed later. Treatment included M. & B. 693 2 : 2 : 1 : 1 : 1, etc., grammes four-hourly until 20 grammes had been given. Saturated solution of sodium and magnesium sulphate $\frac{1}{2}$ oz. every morning while receiving M. & B. 693. Mild cyanosis appeared after the fourth day, taking about ten days to subside. Recovery. Discharged on 14th April, 1941.

Six cases were given quinine sulphate by mouth simultaneously with sulphonamide. They all suffered from vomiting and their speed of recovery was noticeably slower than the expected speed. With the exception of these cases, the administration of sulphates simultaneously with sulphonamide had no adverse effect upon progress or speed of recovery, and no toxic phenomena (other than the cyanosis already recorded) were observed.

Conclusions

(1) Experience with 100 cases leads to the conclusion that patients receiving sulphonamide need not be subjected to special dietary restrictions.

(2) They may also be given sulphates in therapeutic doses provided proper care is exercised.

(3) If cyanosis occurs, sulphonamide should be discontinued until its cause has been determined.

(4) As there are alternatives to oral administration of quinine sulphate, this drug should not be used at the same time as sulphonamide.

Permission to publish this series of cases is kindly given by Major J. C. Drummond, I.M.S., Surgeon Superintendent, Presidency General Hospital, Calcutta.

TOXAEMIA OF PREGNANCY*

By SUBODH MITRA, M.B. (Cal.), M.D. (Berlin), F.R.C.S. (Edin.), F.R.C.O.G.
Associate Professor of Obstetric and Gynaecology,
Carmichael Medical College, Calcutta

TOXAEMIA of pregnancy is such a vast and important subject that it would be impossible for anybody to do justice to it in a short period like this. I shall therefore confine myself, as far as possible, strictly to the clinical aspects. The importance of the subject is shown by the two figures (1 and 2), one English figures and the other Calcutta figures; both of them show practically identical percentages of maternal mortality from toxæmia of pregnancy, which stands second in order of importance in both countries. No attempt on our part, either in the form of a laboratory study, clinical investigation or a statistical analysis, would be

* Paper read under the joint auspices of the Bengal Obstetric and Gynaecological Society and Calcutta Medical Club, March 1941.

too much for the toxæmia of pregnancy considering the grave prognosis and the enormous mortality.

Toxæmia of pregnancy comprises a group of abnormal conditions of pregnancy. Unfortunately no toxin has as yet been isolated from

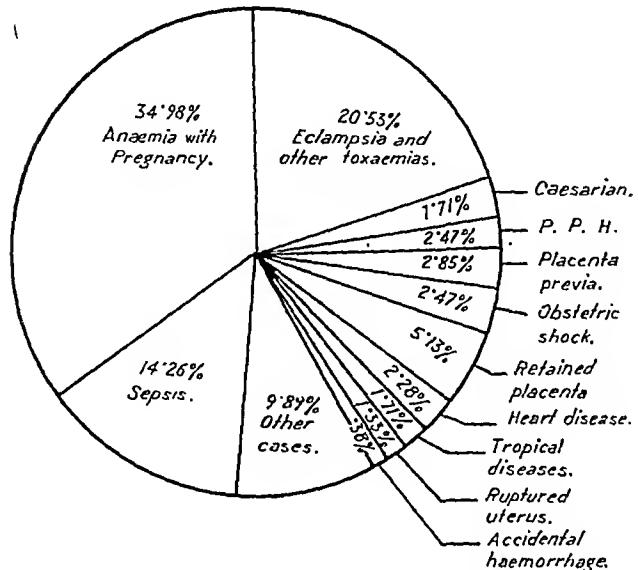

Fig. 1.—Incidence of mortality in different obstetric conditions (Chittaranjan Seva Sadan).

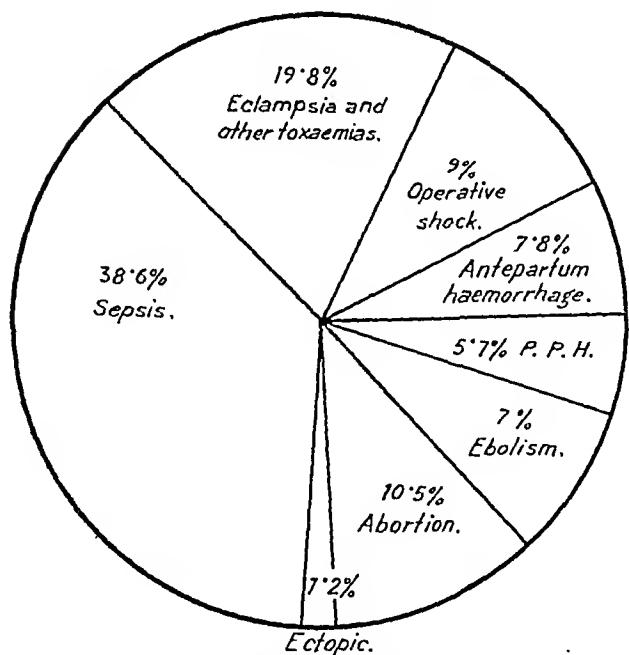

Fig. 2.—Incidence of mortality in different obstetric conditions (from 'Interim Report of the Departmental Committee, Maternal Mortality and Morbidity', 1930).

any of these groups and the modern conception is not exactly so much in favour of the toxæmic theory. Whether it is toxæmic or allergic or due to endocrine imbalance, the fact remains that these complex conditions take a heavy toll of our women in the prime of life and make many more disabled and invalid.

Although toxæmia of pregnancy has been differently classified by different investigators, the following classification appears to me a practical one:—

In early pregnancy (1) hyperemesis gravidarum;

In late pregnancy (2) essential hypertension in pregnancy, (3) nephritic toxæmia, (4) pre-eclamptic toxæmia, (5) eclampsia, and (6) acute yellow atrophy of the liver.

The term 'nephrosis' according to Stander (1929) serves no useful purpose in classifying toxæmia of pregnancy. By it is understood a mild degenerative tubular process with œdema but without hypertension. According to Stander, it serves only to cloak our ignorance and obscure still further our knowledge. In short, 'low reserve kidney', 'kidney of pregnancy', 'recurrent pregnancy toxæmia', 'albuminuria of pregnancy', 'occult nephritis', and some form of 'nephrosis' can be put under pre-eclamptic toxæmia. Concealed accidental haemorrhage has not been classified separately as it has been considered to be one of the manifestations of pre-eclamptic toxæmia.

Hyperemesis gravidarum

Perhaps all patients with vomiting of pregnancy are neurotic to start with. Many investigators go so far as to assert that the only relation which hyperemesis has to toxæmia is the fact that both occur in pregnant women. The changes in the blood and urine chemistry, the histopathological changes in the liver and the ketosis are not peculiar to hyperemesis but are the inevitable result of vomiting, dehydration and starvation. The high ammonia coefficient of the urine which was at one time thought to be a grave toxic manifestation has ultimately been found to be the effect of starvation; so also the central degeneration of the liver cells, which was considered a characteristic landmark of toxæmia in hyperemesis gravidarum, is found to be the result of vomiting and starvation.

It is less important to decide whether it is neurosis or toxicosis as the root cause, than to find a proper remedy of this disease. The death rate in some places is about 6.8 per cent of the whole maternal death-rate of the hospital*.

The management of a case of hyperemesis gravidarum should from the beginning be *energetic*, *systematic*, and *adequate*. I qualify the treatment with these trio with a definite purpose. Whether one believes or not in the theory of 'anxiety-neurosis', it has been definitely shown by Munro Kerr and others that the *energetic* isolation of the patient to some institutions with complete physical and mental rest reduces the death-rate to a negligible factor, provided of course she is transferred before sickness becomes intractable. The *systematic* treatment consists in the maintenance of water balance and of

* Glasgow Royal Maternity Hospital (1926-30) (McIlroy, 1936).

carbohydrate metabolism. Lastly, I put great stress on the adequate treatment, because on most occasions the patient suffers from dehydration and starvation. Unless a sufficient amount of saline and glucose is given to replace the fluid loss and to supply sufficient calories for the maintenance of basal metabolic functions, the treatment will be an utter failure. Thus, to give a practical shape to the line of treatment it should be arranged as follows :—

(1) Immediately a case is diagnosed as one of hyperemesis gravidarum—the patient should be sent to a hospital or a nursing-home or completely isolated in a quiet room of the house, where there should be no admission for sympathetic friends and relatives. The nurse in attendance must be strict, quiet and not without courtesy.

(2) No solid food to be given by mouth for the first 24 to 48 hours. She may have occasional sips of water, fruit juice, and lemonade.

(3) A saline enema is to be given to wash out the lower bowel.

(4) Normal saline with 10 per cent glucose to be administered per rectum by drip method.

(5) About 50 c.cm. of 25 per cent glucose solution is given twice daily intravenously. In more severe cases the quantity may be increased to 100 c.cm. each time. In such circumstances, the intravenous glucose is best given by a continuous method by inserting the cannula into the saphenous vein over the ankle-joint and letting in 10 per cent glucose in normal saline by the drip method to the extent of about 10 pints in 48 hours and not exceeding 30 drops per minute. This appears to be the ideal method as it can be administered without producing any waterlogging of the tissues and one knows exactly the amount of the fluid given—a thing which cannot be ascertained if given per rectum on account of the irritability of the rectum and consequent rejection. For the first 2 or 3 days chances of water intoxication are remote as the tissues are both hungry and thirsty. Ten pints of 10 per cent glucose solution in 48 hours will yield about 1,800 calories and should be considered the minimal requirement. It is expected that from the third day there will be remarkable improvement, vomiting will stop, and the continuous intravenous saline may be replaced by fluid given by mouth. Five units of insulin may be given to prevent the loss of the sugar in the urine from the second day.

(6) Sedatives may be given in the form of bromides or barbiturates, about 40 to 60 grs. of bromides can be added to the night enema. Occasionally morphine gr. $\frac{1}{4}$ can also be given.

(7) Intravenous administration of calcium is recommended by some (5 to 10 c.cm. of 10 per cent solution) every other day to protect the liver against necrotic changes.

(8) Endocrines, e.g., proluatan, lutocyclin, corpus luteum, and extract of adrenal cortex are being used nowadays rather liberally.

The question of termination of pregnancy will only arise when the patient's condition goes down hill in spite of this energetic, systematic and adequate treatment. If properly treated, very few cases would require evacuation but the medical treatment should not be carried on too long. A case should be considered *severe* when, in spite of treatment, the vomiting persists, the patient's condition steadily goes down hill, she loses weight, the pulse rate increases, fever sets in, jaundice appears, vomiting becomes coffee-ground, bile appears in the urine, blood pressure drops, and psychosis develops. Of the various methods used, I would prefer slow dilatation by laminaria tents if the duration of pregnancy is less than 3 months, and vaginal hysterotomy if the duration is 3 months or over.

Essential hypertension in pregnancy, nephritic toxæmia and pre-eclamptic toxæmia.—My reason for taking these together is obvious; it is wellnigh impossible to make a sharp line of demarcation between these groups during pregnancy.

Pre-eclamptic toxæmia is characterized by high blood pressure, oedema, and albuminuria with subsequent development of oliguria, headache, giddiness and dimness of vision. *Abnormal increase in weight* is an early sign of pre-eclamptic toxæmia. No definite oedema is noticeable at the beginning except that the skin feels unusually firm. A few weeks later an increase in blood pressure is discovered, and later on, albuminuria and oedema may appear, the oedema usually preceding the albuminuria.

Hypertension is decidedly the most predominant feature, not only in pre-eclamptic toxæmia but also in nephritic toxæmia and essential hypertension in pregnancy, with this difference, that in the last two conditions it appears much earlier, whereas in the former it usually occurs later. The blood pressure is often much higher in essential hypertension than in either pre-eclamptic toxæmia or nephritic toxæmia, and remains high in spite of rest. There is a previous history of hypertension before conception in essential hypertension, and albuminuria is often absent throughout pregnancy. In nephritic toxæmia, a previous history of nephritis is also present, as well as cardiovascular changes which are absent in pre-eclamptic toxæmia. In nephritic toxæmia there is retention of urea-nitrogen in blood; the urea concentration may be below 2 per cent and urea clearance 50 or under.

Thus, the differentiation between nephritic toxæmia and pre-eclamptic toxæmia can to a certain extent be made by prolonged observation and investigation, by charting systolic and diastolic pressure regularly, by systematic urine examination, and by charting out kidney-function tests, namely, the urea-concentration test and the urea-clearance test. Even after doing all these, one still remains in doubt until after delivery, when the persistence of high blood pressure and albuminuria will give substantial

help in differentiating nephritic toxæmia from pre-eclamptic toxæmia, though it must not be forgotten that there still remains a mild form of chronic nephritis, I mean, occult nephritis, which is manifested neither by hypertension, nor by albuminuria, nor by any other delicate kidney-function tests, but by the acid test of pregnancy itself. This is why I took these groups together.

The management will be mostly medical: sufficient rest, low diet, consisting mainly of carbohydrates, vegetables, fruits and milk; saline purgatives and sedatives. If œdema is marked, restrict fluid and give salt-free diet; venesection may be needed, if the blood pressure remains persistently more than 180 mm. Hg. In more urgent cases, termination of pregnancy is advocated by induction of premature labour.

Eclampsia

Eclampsia forms the most important group in the chapter on toxæmia of pregnancy on account of its increased frequency and enormous mortality. In spite of every possible sincere attempt, the maternal mortality rate remains practically the same.

The following tables and graphs will give a perspective view of the clinical aspect of eclampsia with reference to its incidence, prognosis and mortality.

Table I shows frequency of eclampsia as reported from different parts of the world. Curiously enough it is found to be commonest in India.

TABLE I

Frequency of eclampsia as reported from different parts of the world

Guy's Hospital Charity	1 in 842
New York City	1 in 700
Galabini	1 in 500
Vienna (General Hospital)	1 in 318
Eden Hospital, Calcutta (from 1848 to 1894).		1 in 106
Chittaranjan Seva Sadan, Calcutta (from 1927 to 1937).		1 in 33
Madras (Mudaliar)	1 in 58
Bombay (Telang)	1 in 131

Some time ago I made a study of the incidence of eclampsia in relation to different meteorological factors, *viz.*, maximum and minimum temperature, rainfall and humidity. The only relevant factor found was that when the mean monthly temperature increases by 10°F., the incidence of eclampsia diminishes by 1 per cent.

TABLE II

Distribution of primiparæ and multiparæ with mortality rate

Parity	Number of cases	Number of deaths	Percentage of deaths
Primiparæ ..	179	28	16
Multiparæ ..	53	9	17

TABLE III

Incidence of mortality according to œdema

No definite cause found	8	

Regarding the management of eclampsia, I believe that the radical surgical method has now been abandoned entirely, in favour of the conservative. Accouchement foreé has become a thing of the past and Cæsarean section is very exceptionally resorted to. The main principles of the conservative line of treatment are those indicated by Stroganoff's dictum which is : ' avoidance of all irritation to prevent the occurrence of fits'. Each successive fit will further damage the brain-cells and so they should be stopped at any cost, to prevent irreparable injury to the vital cells of the body. A practical outline of treatment would be as follows :—

Immediately on arrival (either of the patient at the hospital or of the physician to the patient) the patient should be put into a quiet, warm and well-ventilated room.

Excepting one or two strong-minded responsible persons, all relatives and visitors should be firmly requested to vacate the room. If possible, the patient is to be kept under the vigilant care of two obstetrically experienced nurses.

The patient will have a few whiffs of chloroform, the room is darkened and external noises excluded. The underlying principle

being to avoid all irritation, the patient should be kept away from all sorts of stimuli that might reach her either through ears, eyes and bodily movement. That is why chloroform is to be occasionally given whenever manipulations, external or internal, are done.

Immediately the patient has dozed off from the effects of chloroform, a quarter of a grain of morphine and $\frac{1}{20}$ grain of atropine are injected subcutaneously.

Now the clothes are loosened and a catheter specimen of urine is taken, and a mixture containing 30 grains of chloral hydrate, 2 drachms of infusion of digitalis and 4 ounces of normal saline in each dose is ordered.

After exactly one hour, one dose of the above mixture is given per rectum slowly, and if the patient is restless, under chloroform. This is repeated at the 7th hour after the onset of treatment. By the time the patient is fairly under the narcotic, a careful vaginal examination is done and membranes ruptured, even if the os is not open. Only under exceptional circumstances, that is, when the patient is not at term and labour not likely to start, are membranes not ruptured. The idea of rupturing the membranes is to reduce the quantity of liquor amnii and thus to lower both intra-uterine and intra-abdominal pressure. This also hastens labour.

At the 3rd hour from the onset of the treatment, another injection of morphine is given, either gr. $\frac{1}{4}$ or gr. $\frac{1}{8}$, depending on the irritability of the patient.

The patient is kept on her side as much as practicable and changed to the other side every 2 hours.

The physician in charge sits by the side of the patient all the time noting if any prodromal symptoms are appearing, as evidenced by restlessness, twitching of the muscles of the face and extremities, tossing of the head, fixation of eyes, and a fixed deviation of the head to one side. He should immediately start administering chloroform which is continued until the patient passes into the tetanic stage; it is then withheld. It will be a veritable danger to push on chloroform at the tetanic stage, because, soon after, the patient takes one long gasp in the next stage and concentrated chloroform will be inhaled by her. Oxygen inhalation is to be given liberally after each fit.

Generally, eclamptic fits occur one after another, and, if the fits are not controlled, the question of venesection should be seriously considered. According to Stroganoff (1930), if there are more than 3 fits after the treatment is instituted, venesection should be done immediately. About 7 to 10 ounces of blood are to be let out. Venesection has been found indeed life-saving on many occasions. Besides the question of fits, which stop in most cases almost immediately, even when the patient is found in a deep comatose condition with laboured stertorous breathing, venesection brings about

a complete change of picture. The patient becomes quieter, breathes easily and the rhonchi in the lungs which are the indication of approaching oedema decrease or even disappear. After venesection, blood pressure falls and angiospasm lessens; it facilitates the activity of the heart, lessens the oedematous condition; it lowers the concentration of toxins in the blood being a contributory factor towards diluting the blood; it lessens the chances of a haemorrhage in the brain and contributes to a more intensive absorption of the narcotics by the intestines' (Stroganoff, 1930). If fits continue, venesection is to be repeated and there are cases where I have done it thrice with satisfactory results. Two points in this connection are worth while noting, i.e., eclampsia with low blood pressure and anaemia. Venesection is no contraindication in these conditions if there are other indications present. It is advisable to inject glucose solution if there is low blood pressure, and to draw less blood in anaemia.

The patient should be kept covered with light warm clothing, and, to stimulate kidney function, warmth by way of poultices may be applied over the kidney region.

Obstetric interference in an eclampsia case should be practically *nil*, except rupturing the membranes artificially and hastening the second stage of labour by low forceps when the head is low down in the pelvis.

This practically completes the picture of treatment, except continuing the sedative mixture to the 22nd hour. But this time the dose of chloral hydrate can be reduced to 20 grains, provided there is a long interval between subsequent fits. This is the basal structure of the treatment but the individualization should never be overlooked.

There are certain modifications of treatment which require brief elucidation and criticism. Of late chloral hydrate has to a certain extent been replaced by paraldehyde. Chloral hydrate is a very effective medicine, but is supposed to be a cardiac depressant, although according to Stroganoff (1930) one can push it up to even 4 drachms in 24 hours. My experience with paraldehyde is not very encouraging. The patient becomes very restless and on some occasions she is quietened after a rectal wash.

Magnesium sulphate treatment is given more frequently nowadays than before. It apparently increases diuresis, diminishes oedema, lowers blood pressure and controls fits. It is administered either subcutaneously or intramuscularly. Not more than 24 grammes should be given in 24 hours. In certain cases the injections cause serious toxic effects and prove fatal. Acute cyanosis, feeble pulse and laboured breathing may develop for which the best antidote is calcium given intravenously.

Certain complications are worth while noting. Hyperpyrexia in eclampsia is dreaded by every obstetrician. Table V has shown how the death-

(Continued at foot of next column)

SHOULD ANTI-TYPHOID INOCULATION BE PRACTISED IN A HOUSEHOLD EXPOSED TO TYPHOID INFECTION?

By A. J. H. DEMONTE, D.P.BACT., I.M.D.

and

S. K. GUPTA, M.B., D.T.M.

(From the Calcutta School of Tropical Medicine)

ANTI-TYPHOID (T A B) inoculation has proved to be a valuable prophylactic agent, if employed when the immediate chances of contracting typhoid fever are minimal, but the opinion has been expressed from time to time that preventive inoculation undertaken during the course of a typhoid epidemic is dangerous. Many

(Continued from previous column)

rate increases with each degree of temperature. Out of 227 cases of eclampsia reviewed, 6 cases had temperature of 107°F. and one 108°F. All patients died except one. It is not humanly possible to do anything in these cases.

In some cases after the fits stop the patient may pass into a peculiar asthenic stage. These cases require vigorous cardiac stimulants and I know of cases where strychnine had to be given to get over this asthenic condition. I use cardiac stimulants in some form or other in all my eclampsia cases, because one does not infrequently notice that some patients while progressing well suddenly die of heart-failure with a negligible amount of strain.

Maniacal symptoms occurred in 7 cases (i.e., about 3 per cent), of which one patient was too violent to be kept at rest and died after a fall from bed. Cases with psychical disturbances should be placed under post-natal care. Post-natal care of the eclampsia cases forms a very interesting study and remarkable revelations have been made by Young and others.

Eclampsia cases have strikingly low resistance to infection. About 10 per cent of our cases had morbidity after confinement.

I will conclude by striking a note of warning that, frankly speaking, we have not made great progress in curing really bad eclampsia cases. The only secret of success lies in introducing thorough ante-natal care which can certainly prevent the bulk of eclampsia cases and render it less dangerous when eclampsia does supervene.

This has been done with striking success in other countries, for example, DeLee had no eclampsia in a service of nearly 3,000 obstetric cases in 1936.

practitioners are undecided as to the best specific prophylactic procedure to be adopted in a household when one of its inmates is being treated in the house for typhoid fever. The difficulty that confronts them is, should the other members of the household be inoculated with T A B vaccine or not? The negative phase, it is suggested, may cause some individuals to acquire the disease who would otherwise have escaped, and yet others to develop the disease in a virulent form instead of suffering a milder attack.

A recent incident.—A colleague recently sought our help in this matter. He informed us that typhoid fever was introduced into a household of 25 members (including servants); one of the inmates fell ill with typhoid fever six days after his return from a long visit to his aunt who had typhoid fever at the time of the visit. All the members of the household were inoculated with T A B vaccine one month after the first outbreak and during the illness of the primary case. Two doses were administered, 0.5 and 1 c.cm. each, with 7 days' interval between. About eight weeks after the second T A B inoculation, one of the inmates fell ill with typhoid fever (diagnosed bacteriologically). It was a mild attack and the temperature reached normal on the 15th day. There was no relapse. A second case occurred 11 days after the first post-vaccinal case. This was a very severe infection; toxic symptoms were prevalent from the outset, fever continued for more than 7 weeks and the case was complicated with intestinal haemorrhage. *Bacterium typhosum* was isolated by blood culture on the 10th and 17th day of illness, but the Widal reaction, carried out concurrently, showed no H or O agglutinins for any of the enteric group of organisms.

A third case occurred 2 $\frac{1}{4}$ months after the T A B inoculation and about three weeks after the second post-vaccinal case. It was a moderately severe infection; blood examination was not allowed but a stool from this patient was secured for us on the 21st day of illness and *Bact. typhosus* was isolated. A fourth post-vaccinal case occurred on the day following the onset of the preceding case. It was a mild infection and no bacteriological or serological examination was done. There had been, therefore, four (three bacteriologically confirmed) cases of typhoid fever that occurred from 2 to 2 $\frac{1}{4}$ months after T A B vaccination. The practitioner who administered the vaccine maintained that the domestic and personal hygiene of the household in question was such that it was not surprising that the vaccine was not able to ensure a 100-per cent protective value. The

head of the household maintained that either the vaccine used was not T A B vaccine, or, alternatively, if it was, then the inoculation had rendered the household susceptible and not resistant to typhoid fever.

Recent work on this subject.—Ramsey (1935) reported that of 2,886 contacts who did not receive prophylactic vaccine 7.03 per cent developed typhoid fever, whereas of 2,402 contacts, who were given three doses of vaccine subsequent to the primary case, only 0.3 per cent contracted the disease. Although Ramsey and others point out that there were many other factors besides preventive vaccination that may have influenced the above results, nevertheless there is no convincing evidence that typhoid vaccination has rendered contacts susceptible to infection.

Topley (1938) appears to be of the opinion that the argument in favour of inoculation of those who are in close contact with a case is greater than of those who are at risk as members of a population during a typhoid epidemic, because the risk to infection is greater, but that the danger of inducing provocative typhoid should always be considered.

Schütze (1939) found no increased susceptibility in mice experimentally infected with *Salmonella typhi murium* and inoculated with *typhimurium* vaccine during the incubation stage. He expressed the opinion that anti-typhoid vaccination of a community was, by analogy, to be recommended.

The present investigation.—The opportunity was seized to study the problem in the light of present-day knowledge afforded by the work of Felix and others on the Vi antigen of *Bact. typhosum*.

The material available was (a) T A B vaccine obtained from the same batch as that used for the inoculation of the typhoid-stricken household; (b) the typhoid strain (labelled by us 'typhoid corp') from which the vaccine had been prepared; and (c) *Bact. typhosum* isolated by us on the 21st day of the disease from the stool of the third case that contracted typhoid fever subsequent to T A B inoculation (labelled H/180).

The T A B vaccine was soon established as containing typhoid antigen by inoculation into rabbits and demonstrating the presence of typhoid H and O agglutinins in the serum raised.

Next, various tests were put up to detect any differences between the vaccine strain 'typhoid corp' and the case strain H/180. *Antigenic difference* was searched for by doing agglutination tests employing different typhoid sera. The results were:—

			Typhoid serum O 901	Typhoid serum H 901	Typhoid Vi serum
Vaccine strain ('typhoid corp')	+ (1/10,000)	+	
Case strain (H/180)	- (- 1/400, + 1/200)	+	- (1/20)
Vi strain Ty. 2	- (- 1/400, + 1/200)	+	+ (1/400)
Vi strain Bhatnagar	- (- 1/400, + 1/200)	+	+ (1/300)
					+ (1/200)

The type of the clumps formed during agglutination was very different in the two strains under examination. The vaccine-strain clumps were large and flocculent, whereas the case-strain clumps were small and closely resembled those of 'Ty. 2' and 'Bhatnagar'.

Differences observed by bacteriophage action.—Pasricha and others (1937) showed that typhoid phage type I had a range of activity limited to strains known to contain Vi antigen and no activity for strains like O 901 and H 901, known to be devoid of Vi antigen. Craigie and Brandon (1936) showed that the sensitivity of Vi strains and V phage action are intimately related to Vi agglutinogen and that the W forms of typhosum which do not possess this antigen are not susceptible to the action of V phage.

The V phage of Craigie and Brandon and the type I typhoid phage of Pasricha are said to be identical and subsequent investigation has confirmed this. This test was therefore employed to determine if there was this difference in the two strains under investigation. The following is the result of the test :—

for verifying if this was true for the two strains under investigation. Sixty mice between 18 and 20 grammes weight were divided into three equal groups of approximately the same weight. One group was inoculated subcutaneously with two doses of a vaccine prepared from the vaccine strain 'typhoid corp' and a second group was injected similarly with a vaccine prepared from the case strain H/180. The doses injected were 4 millions and 20 millions for the first and second dose, respectively, and there was an interval of three days between the two doses. The vaccines were prepared from 24-hour-old agar cultures, were suspended in normal saline, then heated at 55°C. for 20 minutes, standardized and finally carbolized to contain 0.5 per cent phenol. They were taken into use one month after preparation. The third group of 20 mice was given the same amount of 0.5 per cent of carbol-saline subcutaneously as the two vaccine-injected groups, and served as controls. On the seventh day after the second injection, each group was further divided into two; the mice in one half of each group were infected

" " IV ..	+	+	+	+	+	+

+ = phage action; — = no phage action.

Virulence test.—Two groups of ten mice each, of approximately the same weight, were inoculated each with one of the two strains under examination after preliminary trials had indicated the approximate lethal doses. 7,000 million organisms per animal of the strain H/180 killed all the 10 mice within 10 days, whereas 15,000 million organisms of the vaccine strain 'typhoid corp' were necessary to give similar results.

The tests clearly show the difference between the case strain and that employed for the preparation of the vaccine that had been given to the family with such, apparently, disastrous results. The indications are that the vaccine strain 'typhoid corp' is devoid of Vi agglutinogen and the case strain H/180 is a Vi strain.

The distinct differences noted in the two strains raised the question as to whether a vaccine prepared with the one was capable of inducing protection against infection by the other. Schütze (1936) showed by animal experiments the importance of employing a full Vi strain in the preparation of antityphoid vaccine. Mice protected with a Vi strain had immunity 100 per cent greater than when an intermediate Vi strain was used. We took this opportunity

by injecting subcutaneously 15,000 million organisms of vaccine strain 'typhoid corp' and those in the other half of the three groups were given similarly 7,000 million organisms of the case strain H/180. The mice were observed for one month following the administration of the infecting dose. The results obtained are as follows.

It will be observed that the protection obtained by the inoculation of the vaccine strain ('typhoid corp') is of a low order (25 per cent saved) in both the groups and that resulting from the use of the case strain H/180 is sufficient to save 80 per cent of the 20 animals from death. The vaccine prepared from the case strain H/180 is able to protect 90 per cent of the mice when infected with the strain 'typhoid corp' and 70 per cent of those infected with the case strain. In both the groups of protected mice the numbers dying from infection with the case strain H/180 were slightly greater than those from infection with the vaccine strain 'typhoid corp'. This is probably due to the greater virulence of H/180 and in spite of the effort made to ensure that the lethal effect of the resulting doses of both the strains were approximately the same.

It may be inferred from this test that the vaccine strain 'typhoid corp' is not a suitable strain for immunizing purposes; that Vi typhoid strains are capable of raising resistance against infections by Vi and W typhoid strains and that Vi strain H/180 gave about three times greater protection than the W strain 'typhoid corp'.

From this experiment it is evident that vaccination of mice during the incubation stage does not render them less resistant to infection. The number of mice dying in the group inoculated with the vaccine prepared from the strain 'typhoid corp' is almost the same as those in the control group and the average length of life in all three groups is also very similar in all the

	INFECTED WITH 15,000 MILLION ORGANISMS OF STRAIN 'TYPHOID CORP'			INFECTED WITH 7,000 MILLION ORGANISMS OF STRAIN H/180		
	Alive	Dead	A. L. L. (days)	Alive	Dead	A. L. L. (days)
Group 1 Mice injected with vaccine prepared from strain 'typhoid corp' (20).	3	7	11.66	2	8	10
Group 2 Mice injected with vaccine prepared from strain H/180 (20).	9	1	13	7	3	12
Group 3 Control mice (20)	0	10	7.1	0	10	7.25

A. L. L. = Average length of life of those dying during the period of observation.

N.B. = *Bact. typhosum* was isolated from all the mice that died.

A further experiment with mice was conducted on the lines adopted by Schütze (1939) to demonstrate, if possible, whether there is any increased susceptibility to infections in mice infected with a Vi strain (H/180) and inoculated during the incubation stage with a vaccine prepared from a typhoid strain in which the Vi antigen was minimal (like in 'typhoid corp').

Three groups of forty mice each of approximately the same weight were inoculated subcutaneously between the shoulders; each mouse received 6,000 million organisms of the case strain (H/180) that had been seeded on agar, incubated at 37°C. for 18 hours and suspended in distilled water. The volume injected was 0.5 c.cm. per mouse. The same two vaccines prepared previously, but taken into use three months after preparation, were administered 24 and 72 hours after infection. One group was given 4 million organisms at the first dose and 40 millions at the second, of the vaccine prepared with the strain 'typhoid corp'. The second group received similarly two doses of the vaccine prepared with the strain H/180.

The third group received 0.5 c.cm. carbolized saline and served as controls.

The following are the results obtained:—

three groups. A point worthy of notice is that vaccination with H/180, 24 and 72 hours after infection, not only does not render the mice less resistant but that it appears to increase their resistance.

Discussion.—Four cases developed typhoid fever subsequent to preventive inoculation, none of which could reasonably be considered as infections in which clinical symptoms had been precipitated by preventive inoculation. Provo-
cative typhoid is usually a severe infection occurring soon after the inoculation, whereas here the first case developed clinical typhoid eight weeks after T A B inoculation and the disease was an usually mild infection considering that the primary case and the other two post-vaccinal cases were severe infections. The other possibility is that the post-vaccinal cases were the result of lowered resistance consequent to preventive inoculation. The investigation carried out shows that the typhoid strain employed for the preparation of the vaccine injected into the inmates of the typhoid-stricken household was a W strain and unsuitable for immunizing purposes. The first animal test conclusively shows that in mice the strain 'typhoid corp' induces a low grade of protection

	GROUP 1		GROUP 2		GROUP 3

in marked contrast to that produced by the case strain H/180. Animal experiments conducted to ascertain if lowered resistance can be induced in mice by inoculating a vaccine prepared with the strain 'typhoid corp' shortly after infection with H/180 showed no definite lowered resistance.

The opinion that anti-typhoid preventive inoculation is dangerous during epidemic times is based mainly on coincidence. No investigation to our knowledge has been conducted to determine the precise conditions under which preventive inoculation induces a refractory state. This particular household (where 4 post-vaccinal cases occurred among 25 close contacts) might have served as an additional example of the danger of T A B inoculation and the existence of a negative phase, if our investigation had not indicated otherwise. It is useless to speculate as to how many of the individuals who developed typhoid after anti-typhoid inoculation had received a vaccine prepared from unsuitable strains.

It is suggested that, where possible, instances in which T A B inoculation appears to have rendered individuals susceptible should be carefully investigated before the presence of 'negative phase' is accepted as an explanation.

Our animal experiments were designed to reproduce in mice the two main conditions, namely, inoculation of a vaccine prepared from the same strain as that used for the preparation of the vaccine administered to the household and the injection of the same infecting typhoid strain. The vaccine was administered before infection and subsequent to infection, and in neither instances was any evidence of lowered resistance to the progress of infection detected.

Although drawing analogies from animal experiments is not always safe, the more so as they were not entirely parallel, in that the end point in these experiments was death, whereas development of the disease, irrespective of whether death or recovery ensued, should have been the criterion, nevertheless it may be recommended that preventive T A B inoculation may be practised in a household of close contacts. Some physicians recommend Besredka's bili-vaccine, others typhoidphage. We have no experience of these two agents as preventives in typhoid fever and until evidence that they are effective preventive agents is obtainable, or until it is definitely shown that preventive T A B inoculation does induce a 'negative phase' preventive anti-typhoid inoculation in addition to general hygienic measures should be adopted, provided that the vaccine used had been prepared from a fully Vi typhoid strain.

Summary

- Three cases of post-vaccinal typhoid fever occurred in a household of 25 members all of whom had been inoculated with T A B vaccine from $1\frac{1}{2}$ to $2\frac{3}{4}$ months previously.

KERATODERMIA BLENNORRHAGICA

A BRIEF REVIEW AND REPORT OF A CASE

By R. V. RAJAM, M.B., M.S. (Mad.), M.R.C.P. (Edin.)
Venereal Specialist, General Hospital, Madras
and

P. N. RANGIAH, M.B., B.S.
Honorary Assistant Medical Officer, Venereal Department, General Hospital, Madras

KERATODERMIA blennorrhagica is a comparatively rare but characteristic cutaneous condition usually associated with gonorrhoea and polyarthritis. Vidal in 1893 was the first to observe and describe this syndrome in a patient suffering from gonococcal polyarthritis. Since then cases have been published both in Europe and in America. In 1924 Keim described the histogenesis of the cutaneous lesion from a case under his observation and distinguished it from pustular psoriasis. Lees and Percival (1931), in a brilliant contribution and report of eight cases, discussed in detail the histology and clinical characteristics which confirmed Keim's observations.

(Continued from previous column)

2. The vaccine used was proved to contain typhoid antigen.

3. The strain used for the preparation of the vaccine was a W strain, whereas the infecting organisms in at least one case was a Vi typhoid strain.

4. Animal experiments showed that the vaccine strain induced only a low grade of immunity, in marked contrast to that produced by the case strain.

5. Preventive inoculation of the vaccine strain 'typhoid corp' to mice, 24 and 72 hours after infection with the case strain H/180 does not render the animals less resistant to the progress of the infection; and preventive inoculation of the case strain H/180 similarly infected with the case strain H/180, not only does not lower resistance but actually increases their resistance, so that a larger percentage of mice survive.

6. In the absence of more definite evidence that T A B inoculation is dangerous and of any alternative specific prophylactic measure, T A B inoculation may be recommended for close contacts of typhoid fever.

Aetiology

Though the association of keratodermia, urethral gonorrhœa and polyarthritides was a constant feature in most of the observed cases, indicating a condition of gonocoœal septicæmia, the culture of the blood and scrapings from the lesions have invariably yielded negative results. The consensus of opinion now points definitely to the cutaneous eruption being an allergic expression of a sensitized skin, the sensitization taking place either directly or indirectly through the nervous system (Lees and Percival, 1931). The observation of Scholtz (1927) of the sudden appearance of fresh crops of cutaneous lesions, after the administration of a gonocoœal vaccine—a sort of Herxheimer reaction—suggests the gonotoxic nature of the lesions. The occurrence of an endogenous conjunctivitis, a polyarthritides and a temperature of a septic type certainly points to a profound systemic toxic-allergic disturbance.

Attempts to reproduce the lesion by auto-inoculation have given conflicting results. According to Haase (1916) any abrasion of the skin during the height of eruption is liable to result in the formation of a keratoma. Strandberg, Hedencus, Adamson and Bogrow, however, throw doubt on the gonocoœcal nature of the cutaneous eruption. They contend that the clinical and histopathological features of the fully-developed keratodermia blennorrhagica and of arthropathic psoriasis are so nearly identical that it is unnecessary to bring in the elusive gonococcus as the aetiological offender in these cases and that the former are only examples of the latter. But Keim (1924) and later Lees and Percival (1931) have proved that the initial lesion in keratodermia blennorrhagica is a vesicle which becomes a pustule and rapidly undergoes desiccation. Plasma cells, which are a prominent feature in keratodermia blennorrhagica, are totally absent in arthropathic psoriasis; and endogenous conjunctivitis never occurs in the latter.

Clinical characteristics

The disease is rare. The incidence of this condition varies from 1 in 5,000 (Harrison) to 1 in 7,500 (Brown and Hargreaves) of gonorrhœal urethritis. Up to 1940, only 93 cases have been reported in the literature. The cutaneous eruption occurs almost exclusively in men though a few cases of the condition in women, and one in a girl of four years, have been reported by Isaac, Lees, Robert, Finlay and others.

From the recorded description of the clinical manifestations of this disease, the syndrome of keratodermia blennorrhagica may be said to comprise (1) urethritis of gonorrhœal origin, (2) polyarthritides, (3) inflammatory eroded horny lesions of the skin, which may be generalized but are usually symmetrical, (4) a swinging temperature, (5) a profound cachexia and anaemia, and (6) other associated lesions which

are not constant. (1) and (2) almost always precede the appearance of the cutaneous eruption.

The urethral infection is usually subacute or chronic with involvement of the prostate and seminal vesicles; and is followed by a severe type of polyarthritides.

Several joints, either symmetrically or asymmetrically, are simultaneously affected. The knee, the ankle or the wrist joints are most commonly involved. The swelling and redness of the joints are minimal; the pains are excreting and the tenderness and limitation of movement very disabling. In severe and neglected cases there is atrophy of the muscles above and below the joints.

The cutaneous lesions are usually, if not invariably, preceded by chills and a temperature of a swinging hectic type. The eruptions may be generalized but have a predilection for the soles, palms and genitals. The distribution is symmetrical. Less frequently they may also occur on the trunk, scalp, legs, forearms and mucous membrane of the mouth.

The eruption starts as a number of vesicles which enlarge and undergo pustulation, desiccation and crust formation. The fully-developed lesion presents the appearance of a conical, dirty, dark brown, horny mass with a slightly truncated and umbilicated top. Contiguous masses may coalesce, forming large geographical areas, and giving the appearance of mountains on a relief map. The greater part of the sole may be entirely covered by one of these heaped-up caked conical horny masses. Slight pressure on the lesion with the tip of the finger gives a sensation resembling that caused by pressure on an empty vesicle or bulla. It takes, on an average, about two weeks for the development of the mature lesion. Removal of the crust leaves a superficial, slightly moist, eroded surface which quickly assumes a blotchy pigmented appearance. There is no bleeding, scar or induration left after the masses fall off.

Keratoses of the nails of the toes is not uncommon and is particularly distressing to the patient. The lesion appears underneath the nail plate which is lifted from the bed, becomes dry, brittle and opaque with the free border broken and serrated. A subungual keratoma is often associated with contiguous lesions on the integument surrounding the nail.

Lesions of the mouth and genitalia are sometimes observed. They are different in appearance from the cutaneous lesions and the evolution is more rapid. Umbilicated papules with greyish borders appear on the mucous membrane of the palate, cheek, tongue, prepuce and glans penis. They disappear in a few days leaving raw eroded areas.

During the course of the disease other clinical lesions have been observed and recorded by various investigators. Of these, recurrent endogenous conjunctivitis, usually bilateral, is a not infrequent occurrence. Iritis, corneal

ulceration, retinitis and anterior synechia have also been reported. A rare condition is an associated endocarditis or myocarditis.

Diagnosis

The triad—urethritis of Neisserian origin, metastatic polyarthritis of the same aetiology and the presence of the characteristic cutaneous eruptions—should render the diagnosis a comparatively easy matter.

Keratoderma blennorrhagica is distinguished from arthropathic psoriasis with which it has a superficial clinical resemblance, by the distinct histological architecture of the keratoma lesion, so ably described by Keim and others. Cachexia and endogenous conjunctivitis are usually absent in the latter. Crusted syphilitic lesions should offer no difficulty to the experienced clinician as the clean-cut ulcer of a rupioid or ecthymatous syphilitic is revealed on detaching the superimposed crust; other evidence of syphilis will be present.

Treatment

The treatment of this condition consists essentially in the attack on the primary focus of the infection in the urethra, prostate and seminal vesicles. Both the arthritis and cutaneous manifestations will subside with the eradication of the primary infection.

The most effective therapeutic procedure comprises (i) oral administration of one of the sulphanilamide compounds, (ii) induction of artificial fever by one of the many methods, (iii) in chronic cases, promotion of drainage from obscure foci in the urethra, prostate and seminal vesicles, and (iv) general measures such as rest in bed, careful nursing, nourishing food, and tonics during convalescence. As these patients are highly allergic and cachectic, specific vaccine therapy is not advocated by the majority of clinicians. The cutaneous lesions do not require any special treatment. With measures (i) and (ii) the joint condition shows rapid amelioration; pains subside and mobility is restored. The urethritis responds well to chemotherapy but any residual focus of infection in the adnexal structures may require treatment by massage, instillations, dilatations, etc. Even in an adequately and thoroughly treated case, it is a matter of three to four months before the patient regains completely normal health.

If, according to European and American clinicians, keratoderma blennorrhagica is a rare condition in their countries, it seems to be rarer still in this country. A review of the statistics of the Venereal Department of the Government General Hospital, Madras, shows that there have been approximately 20,000 cases of gonorrhoea treated during the past decade. Yet the following case is the first and only authentic report of keratoderma blennorrhagica for Madras, if not for the whole of India, because we are not aware of any report of a case of keratoderma blennorrhagica from this part of the world within the past ten years.

Case report

A Hindu male, aged 25 years, was admitted to the Venereal Department of the Government General Hospital, Madras, on 20th December, 1940. He gave a definite history of gonorrhoeal urethritis with a terminal haematuria about six months ago. On the advice of a medical practitioner he took about 25 tablets of one of the sulphanilamide compounds orally. Two months before he sought admission to the hospital, pain and swelling developed in a number of joints and simultaneously there appeared crusted cutaneous lesions on the soles, legs, knees, etc.

Physical examination.—The patient was brought on a stretcher. He looked very ill, emaciated and cachectic. The temperature was 100.8°F. and the pulse rate was 120 per minute. He had multiple arthritis involving the knees, ankles and the metacarpo-phalangeal joints of the right thumb. The periarticular swelling of the joints was minimal but there was excruciating pain on palpation or on slight movement of the joints; so much so that he was miserably helpless in even trying to turn in bed. There was marked atrophy of the muscles above and below the affected joints.

The outstanding feature was the cutaneous eruptions which were almost generalized though most marked in the lower extremities. The distribution was as follows:—

- (a) discrete scattered lesions on the back (plate XXV, fig. 1), anterior abdominal wall, both inguinal regions,
- (b) closely-set lesions on the dorsal aspect of left elbow, volar aspect of left forearm, round about both knees and legs (plate XXV, fig. 2).
- (c) confluent lesions on the soles of the feet, particularly on the instep and balls of the toes, and
- (d) subungual keratomas involving almost all the nails of the feet (plate XXV, figs. 3 and 4).

The eruptions were a dirty dark brown, cone-shaped, or umbilicated at the top with peripheral crust. Some of the younger lesions were dark yellow and waxy looking. Removal of a fully-matured crust revealed a shiny moist surface without ulceration or bleeding.

The nail of the great toe on the right foot was loose in its bed due to the pressure of a subungual keratoma.

There was marked congestion and redness of the conjunctiva without any chemosis. The lips were dry, fissured and scaling. The tongue was brown and coated.

Investigations.—A urethral smear and centrifuged deposit of urine showed only pus cells and no gonococci on repeated examination. Prostate and vesicles nil abnormal. A dark-ground examination of the lesion was negative to *Treponema pallidum*. A stained smear of scraping from the base of the lesion was negative to gonococci. The serological reaction of the blood was reported as positive to syphilis though no history or clinical evidence of syphilis was available. The routine cytological examination of the blood showed a mild anaemia with a moderate leucocytosis. The blood pressure was 110/80.

Treatment and progress of the case.—The patient was kept in bed and absolute rest enforced. Sulphanilamide tablets were administered orally at the rate of 4.5 grammes daily for three days and stopped on account of intolerance. Artificial pyrexia was induced by the intravenous administration of T. A. B. vaccine. A course of six injections in increasing doses of 25, 50, 100, 200, 400 and 800 millions was given on alternate days. The arthritic condition rapidly improved and the patient was able to move his limbs without pain at the end of the pyrexial therapy. The endogenous conjunctivitis subsided and the crusted lesions on the body dropped off or were easily removed. By the end of the third week of therapy the skin lesions disappeared leaving slightly blotched pigmented areas. The subungual keratomas were removed with some of the loose nails. The patient was able to move about freely by the end of a month after therapy; and now three months after cessation of treatment the patient has put on weight and remains well, with no

DOES A LUNG CAVITY EVER HEAL SPONTANEOUSLY?: G. C. CHATTERJEE

MEDIASTINAL HERNIA

By R. VISWANATHAN, B.A., M.D., M.R.C.P. (Lond.),
T.N.N. (Walcs)

Lecturer in Tuberculosis, King George Hospital,
Vizagapatam

MEDIASTINAL hernia is the protrusion of a portion of the contents of one hemi-thorax with the mediastinal pleura, through the mediastinal space into the contralateral hemi-thorax.

(Continued from previous page)

recrudescence of either the arthritic or the cutaneous manifestations.

Comment

Though the patient gave a definite history of gonorrhœal urethritis when he came under our observation, repeated examination of the smear, urine and prostatic secretion failed to show any Gram-negative diplococci but only pus cells and banal organisms. According to Epstein (1939) the absence of gonococci does not hamper the diagnosis of keratodermia blennorrhagica as gonococci were demonstrated in only 74 per cent of 23 cases investigated by him.

Downing (1934) pointed out that Vidal considered keratodermia blennorrhagica to be a syphilitic manifestation. Even to-day this theory appears to find favour with MacKenna (1937) who writes in his book on skin diseases that some of the cases reported have been syphilitic in origin. Though the case under report had a positive serology there was no history or clinical evidence of syphilis and the lesions themselves did not bear any resemblance to cutaneous syphilitic eruptions.

Summary

A review of keratodermia blennorrhagica is presented.

A case of keratodermia blennorrhagica, the only one of its kind observed in the Venereal Department of the Government General Hospital, Madras, is described and its rarity stressed.

We thank the superintendent of the Government General Hospital for permission to utilize the records of the department and to the staff of the Barnard Institute of Radiology for the photographs.

Herniation of the mediastinum should not be confused with the deviation of the mediastinum, common in thoracic disease. Some mediastinal displacement is usually associated with herniation, but in mediastinal hernia a portion of the pleura itself penetrates the mediastinum to the opposite side.

Etiology and pathogenesis.—Even though there is almost complete and effective separation between the two pleural sacs, there are three 'weak places' where the two pleuræ are separated from each other only by loose connective tissue. The first area lies subjacent to the sternum in the anterior mediastinum where the medial reflections of the pleura are normally very close together. The second spot is in the lower posterior mediastinum between the aorta posteriorly and oesophagus anteriorly, from the 5th to the 11th thoracic vertebra. The third weak spot is in the posterior portion of the mediastinum lying between the vertebræ posteriorly and the oesophagus anteriorly, from the third to the fifth thoracic vertebra. This upper posterior weak space is separated from the lower by the vena azygos. Through any of these weak spots, more commonly through the first two areas, can herniation occur.

It is not uncommon to get mediastinal herniation during the administration of therapeutic pneumothorax. Packard (1927), Doub and Jones (1937), and the writer (1939) have reported the incidence of this complication during artificial pneumothorax therapy. Maier (1938), on the other hand, has noted the occurrence of mediastinal hernia in the absence of pneumothorax, and has emphasized the clinical importance of recognizing this condition, particularly when surgical procedures are adopted for intra-thoracic diseases.

Any condition that produces a marked difference in the intrapleural pressure on either side might result in a mediastinal hernia. This is more likely to occur in the absence of thickening and fibrosis of the mediastinal pleura.

The pleural protrusion might occur towards the normal side as in cases of massive effusion or pneumothorax which produces increase of intra-hemi-thoracic pressure of sufficient degree to produce bulging of the mediastinal pleura into the opposite side. In other cases there is an invagination of the diseased side by compensatorily enlarged contralateral lung. This occurs in those cases of pulmonary tuberculosis where there is a considerable amount of contraction fibrosis of one lung. It also might occur in conditions producing massive collapse of one lung, as in tumours of or foreign body in the bronchus. Other conditions in which herniations might occur are unilateral bronchiectasis with marked fibrosis and cystic disease of one lung.

Symptoms and diagnosis.—A diagnosis can be made if the possibility of hernial protrusion is borne in mind associated with any chronic thoracic disease which is likely to cause a

IN view of the very extensive surgical procedures that are being adopted in the treatment

* Abridged by the Editor.

(Continued from previous page)

shifting of the mediastinum. No doubt during the course of artificial pneumothorax therapy the possible occurrence of mediastinal hernia should be borne in mind. In the writer's series very few cases suffered from any symptoms pertaining to this complication. Only one complained of dyspnoea. A few complained of substernal tightness sometimes amounting to actual pain.

In cases of pulmonary tuberculosis with atelectasis of a large portion of one lung existing for a long time or with marked shrinking of the lung due to fibrosis, mediastinal hernia is liable to occur. The physical signs due to this complication are very few. If it is through the anterior mediastinum there might be resonance present over the sternum and near the sternum on the opposite side.

The diagnosis of the condition mainly rests on radiographic examination. The radiological appearance of the hernia occurring during artificial pneumothorax therapy is that of a well defined curvilinear shadow on the opposite side of the mediastinum. In other conditions, particularly in tuberculous fibrosis, it may be difficult to diagnose hernia owing to the increased density of the shadow due to the pathological condition of the lung itself. Tomography is useful for diagnosis of the mediastinal herniation. In its absence stereoscopic röntgenograms with the Potter-Bucky diaphragm are a great aid. Lipiodol bronchography of the diseased lung will help in the diagnosis of anterior mediastinal hernia, as it will show the downward and backward displacement of the bronchial tree of the upper lobe of the affected lung associated with the large amount of the herniated lung in which no lipiodol will be seen.

Hernia of the mediastinum can be distinguished from displacement by the fact that in the former condition the lung is found protruding beyond the trachea into the opposite side.

Treatment.—Reduction of pressure in cases of pneumothorax is enough to reduce the mediastinal hernia. In those cases where the hernia is due to contracture of one lung, treatment of the diseased side, preferably by thoracoplasty, will give relief to the symptoms if there have been any.

of tuberculosis, it behoves one to consider whether a cavity ever heals spontaneously, and, if it does, under what conditions and how, so that, guided by this knowledge, the physician may avoid, in such cases, surgical interference, with its attendant risks. It is also necessary to enquire whether surgical interference here has the same curative value, as the removal of the septic joint or limb, or an appendix which removes for all time the causative element from the system altogether, or whether it is done to help in the fight against the germ of tuberculosis which was begun long before the operation and will be continued for even longer after the operation.

A quotation from one of the most outspoken writings of an advocate of one type of surgical interference (operators are not unanimous in selection of their procedures, one set condemning the other's procedure), namely partial thoracoplasty, or apycolysis, as it is termed, will give us an insight into their line of thought. Coryllos (1935) the advocate of this method says, in justification of applying his method in curing cavities, the following:—

'Instead of being a passive observer of letting nature act and hoping for the best, he (the surgeon) is becoming an active, daring, open-minded and scientific crusader, his immediate objective is the definite, early and economic cure of tuberculosis patients. His further aim is the eradication of the disease by early suppression of tubercle bacillus carrier. The objective of the method devised for the purpose is not only the cure of the disease, but also the preservation of the anatomical and physiological integrity of the healthy part of the lung. These procedures represent the modern ideas, actual trend and tendency in the treatment of pulmonary phthisis.'

Though the natural interpretation of the above lines taken from its context would suggest that this operative procedure is the only method advocated by the above writer, for all cavities and with it tuberculosis of the system, yet, to do justice to the writer, I must say that he admits in the same paper the occurrence of spontaneous cure of a certain type of cavity, which should not therefore be operated upon* and also that there is difficulty in recognizing a cavity by x-ray, for example in annular absorption of an exudative lesion which very often simulates a cavity. Lastly, in general criticism of the above assertion without going into details, it is necessary to state also that the operative procedures are changing from year to year, newer methods are continually being advocated by fresh workers. For example, apycolysis advocated by the above writer has a reputation of not more than five years and, even within this limited period in some of his cases which were operated upon by this method with expectation

* 'The acute benign exudative productive form of pulmonary tuberculosis of Ornstein, Ulmar and Dittler, heals as a rule spontaneously by bed rest alone and requires no surgical interference, so also the chronic productive form of Ornstein and Ulmar. The question of cavities is complicated by the existence of so-called annular shadows.'—Coryllos (1935).

of complete cure, the tubercle bacilli did not disappear and others have flared up ending in death. So the above sweeping assertion that these operative procedures will cure cavities, and with them tuberculosis, is not supported by facts. Moreover, the finding of a large number of cases with cavities, who have not been operated upon at all remaining healthy for years (for 20 years or more) with subsequent disappearance of cavities, as proved by x-ray, will make one wonder whether the optimism to rely on sanatorium treatment only has not a better basis in fact and whether the conservative treatment should be set aside lightly in favour of the above procedure.

So, without discussing further the merits and demerits of operative procedure, I will describe one case among several others with which I have had to deal where this spontaneous healing took place.

Summary of one case

Case note.—The patient, aged 35, who was employed in a business firm in Calcutta, stated that his weight before his complaint started was 112 lb. He suffered at first from pleurisy in the right side, for which he underwent some form of treatment but there was no fever nor did it incapacitate him for his work; he only lost weight. He suddenly one day started after an attack of influenza bringing out a huge quantity of blood and being unrelieved by ordinary treatment, artificial pneumothorax (A-P) was performed, and as this apparently stopped the haemorrhage, he was persuaded, for complete cure of his disease, to take further A-P (as will appear later, air could not be introduced on account of adhesions, so this was more or less a show). During this period, covering two years, two x-ray films were taken; one showed infiltration and the second a cavity in the right apex. Finding that he was not getting cured, the patient went to a sanatorium situated in a hill station where the doctor in charge, taking another film, agreed in the opinion of the previous doctor that there was a huge cavity, but as there were adhesions he said A-P was not possible.

Phrenic nerve avulsion was advised but not done; then he started giving him calcium and gold. As haemoptysis and fever followed this line of treatment, the patient came out of the hospital, as a hopeless case of tuberculosis and, his funds being exhausted, came back to his home to die. He lay in bed for two years, when I saw him for the first time in March 1940; he was apparently in enjoyment of good health, but had a markedly crepitant patch in the right supra-clavicular region, accompanied with cavernous breathing. As I found no justification for making him lie down, for he had no fever, I encouraged him to come to my clinic, which he did three months after I saw him. At that time, I found his weight 144 lb., no crepitant patch could be found in the apex, but, in its place, blowing breathing; no cough and no fever. Weight increased by weekly tuberculin treatment from 144 to 151 lb. He was able to walk a good distance without getting any fever and there were no physical signs. An x-ray taken at this period showed the fibrosed remnant of the old cavity with the heart drawn to the left side (plate XXVI).

Discussion.—It is well known that whenever the tubercle bacillus enters the system, the latter responds by producing what is termed allergic response by which the invading germ is prevented from making any further inroads. As a result the disease either becomes localized or the germ is destroyed altogether. The reverse can

take place—the activity of the invading germ may break down the resistance and may destroy the organism. The former condition is under consideration here, where, as a result of localization of the disease, the system became immune, completely or partially, to the further invasion of the germ. When this immunity was in process of taking place, the physiological condition of the patient improved, and he started picking up in health. The lesion became fibrosed giving here a concrete illustration of how immunity is produced, the surgeons fixing their attention entirely on the x-ray findings and ignoring the fact that the cavity was getting fibrosed. It could not be made out by x-ray alone that he was healing by himself, in spite of the surgical interference, which was unnecessary; they did not in fact succeed in what they aimed at, namely, immobilization of the lung by putting air into the pleural cavity.

The next question to be decided is whether all cavities left after quiescence of the disease become obliterated by fibrosis as happened in this case, or remain as open spaces, with the sword of Damocles hanging over the patient's head, as at any time the unsupported arteries around the cavity may burst and lead to instantaneous death, or whether secondary metastasis will take place from caseous unhealed portions in the walls of cavities. Though these dangers are not absolutely groundless (I have seen one case dying in this way), yet the fact remains that in many patients with whom the writer has had to deal the cavities have not collapsed. This fact has been found out only by x-ray taken more out of curiosity a long time after the active symptoms have passed away, the patients being at that time in enjoyment of perfect health and without physical signs.

So the conclusion to which we come is that healing by fibrosis of the cavity takes place, with the healing of the tuberculosis of the system, in many cases and is a part of ordinary healing process. Whether it does so in all cases, it is not possible to say.

Note.—As Dr. Chatterjee has been one of the leading spirits in the anti-tuberculosis movement in Bengal and has had considerable experience, we feel that we must allow this expression of opinion on the surgical treatment of tuberculosis, though many, amongst whom we include ourselves, will not agree with him on this subject.

The case he quotes is a good example of how a cavity may heal up without treatment. It is also a sad story that—on the face of it for the evidence rests mainly on the statements of the patient—suggests malpraxis on the part of one doctor, culpable condonation on the part of another (see appendix), and extreme gullibility on the part of the patient. It however provides no criticism of the honest surgical treatment of tuberculosis in appropriate cases.

The report conveys the salutary warning that one should not attribute success to any particular treatment, just because a patient happens to get better after he has received this treatment. Nature may be following its natural healing course despite treatment.—EDITOR,
I. M. G.]

APPENDIX.

FULL REPORT OF THE CASE, WITH DESCRIPTION OF SKIAGRAM AND ITS INTERPRETATION

A summary of the record of the case, as made out from the written statement by the patient.

1928.—Dry pleurisy in right side. Weight 112 lb. Working.

1928-30.—Slight pain in the right side. Weight 108 lb. Working.

1931-33.—No complaint. Weight 104 lb. Working.

1934.—Influenza, followed by severe haemorrhage. Artificial pneumothorax (A-P) done to stop haemorrhage and then after its stoppage continued almost every other day as treatment of tuberculosis, though it was pointed out by the physician in charge that no air was getting in, due probably to adhesions; 40 'A-P's' done. X-ray film showed at that time infiltration in the right apex; no fever all the time; weight 148 lb. Then he started getting fever. X-ray taken in September showed a big cavity.

A-P was resumed, followed by fever and bleeding. Then this line of treatment was discontinued. This time a drop of arnica stopped the bleeding.

1936.—Fever, bed-ridden. Weight 149 lb.

1937.—Went to a sanatorium in the hills. It was snowing at the time. Temperature stopped within three weeks of his going there. X-ray taken there showed even then a big cavity. Weight 161 lb. Phrenic nerve avulsion was suggested, but not done on account of the patient's unwillingness. Then calcium and gold treatment was adopted—followed by fever and bleeding. Left sanatorium. Weight 148 lb.

1938.—After coming home, fever stopped for a while, but haemoptysis occurred with occasional slight fever, making him bed-ridden. Weight 140 lb.

1939-40.—No treatment, bed-ridden.

1940-41.—The writer saw him for the first time in March 1940 apparently as a hopeless case of phthisis. He found a crepitating patch and blowing breathing over the right apex. The patient was advised to move about, which he did, and to take a course of tuberculin treatment at the writer's clinic, as an ambulant case. Weight has gone up from 144 to 151 lb. Now has no fever, nor bleeding, and no physical signs can be elicited. X-ray taken on 6th February, 1941, showed a marked fibrosed patch replacing what was a cavity.

Copy of report of radiologist of x-ray film of case taken on 3rd February, 1941

Diaphragm excursion.—Restricted movement right side.

Heart.—Cardiac retraction. Skiagram—heart pulled to the right side—smaller.

Hila.—Right—obliterated, due to cardiac retraction and peritracheal thickening. Left—few fibro-calcific nodes and congested vessels.

Lungs.—Right: Apex—homogeneous dense shadow involving the upper lobe with marked cardiac and tracheal retraction, probably indicating chronic diffuse interstitial fibrosis of the lung. Base: Slight pleural thickening and adhesion of the lung.

Left: Apex—accentuated broncho-vascular trunks and evidence of cluster of coarse nodular infiltration in the periphery (1st, 2nd and 3rd) intercostal space. Base: Costo-phrenic angle free.

Conclusions.—Fibrosis—right upper lobe and left coarse nodular infiltration—periphery.

A NOTE ON COMPLEMENT-FIXATION TEST IN LEPROSY AND KALA-AZAR WITH WITEBSKY, KLINGENSTEIN AND KUHN (W. K. K.) ANTIGEN

By S. D. S. GREVAL

LIEUTENANT-COLONEL, I.M.S.

Imperial Serologist

S. N. CHANDRA

CAPTAIN (late I.M.S.)

First Assistant

and

B. C. DAS, B.Sc.

Chemist

(*Imperial Serologist's Laboratory, School of Tropical Medicine, Calcutta*)

THE intention is to draw clinicians' attention to a newly described serological technique for the laboratory diagnosis of leprosy and kala-azar, and make observations on the possible use of the test in studying aetiology and epidemiology of the diseases.

A newly developed technique

The antigen.—This preparation is essentially a solution in benzol of the alcohol-insoluble, pyridin-soluble and acetone-insoluble fraction of human tubercle bacillus (Witebsky, Klingenstein and Kuhn, 1931). A residue is obtained after evaporating benzol and suspended in normal saline. The suspension is standardized and used in a constant dose in the reaction. Different lots of the antigen are compared by their reaction with known dilutions of pooled positive sera. Details of preparation and comparison have been recently published elsewhere (Greval, Das and Sen Gupta, 1941).

The original antigen, used in the work on leprosy and kala-azar commenced two years ago, was obtained from a European source. The question arose almost immediately whether a satisfactory antigen could be prepared locally. This was necessary before suggestions for the application of the test could be presented to the medical profession. A satisfactory antigen has now been prepared.

The essential features of the technique.—The technique has been described in detail elsewhere for leprosy (Greval, Lowe and Bose, 1939) and for kala-azar (Greval, Sen Gupta and Napier, 1939; Greval, Das and Sen Gupta, loc. cit.). The essential features are two. (i) The dose of the antigen is linked to the haemolytic system: it is not anti-complementary when used with 1 M.H.D. of complement and is not haemolytic even when multiplied by three. (ii) The reaction is linked to the Wassermann reaction and is put up only when a complement of optimal reaction and titre for the latter reaction is available (Greval, Chandra and Das, 1940). A Wassermann reaction is done on the

serum at the same time. The quantitative relationship between the serum dilution, the antigen and the haemolytic system is the same as in the Wassermann reaction.

The serum is tested in a dilution of 1 in 25 routinely and in other dilutions afterwards, if so indicated and desired. The complement is used in a constant dose of 2 M.H.D. Only one tube is required as a rule: the usual Wassermann control of the 1-in-5 serum dilution if negative or even doubtful, as it generally is, controls this tube also.

Originally the serum was tested for leprosy in a 1-in-5 dilution. Now a 1-in-25 dilution is used for both leprosy and kala-azar.

The sensitiveness.—The sensitiveness of the reaction is of a very high order. Like the strongly positive Wassermann reaction of secondary syphilis the reaction cannot be missed or masked by any error or irregularity which is likely to creep into a serological procedure. Because of this high degree of sensitiveness only a complete inhibition of lysis (without a trace of haemolysis after the tube has stood in the cold overnight) is read as positive.

The specificity.—While there is ample excuse for using the term specificity in connection with the reaction of the sera of lepers with the antigen, because of the group relationship between the *M. tuberculosis* and *M. lepræ*, the use of the term in connection with the reaction of the sera of kala-azar patients is not justified. In the latter disease the reaction is undoubtedly non-specific like the Wassermann reaction in syphilis and has probably a similar immunological basis. The diagnostic significance of the reaction, however, is of a very high order.

The utility.—(i) In nodular leprosy (recently renamed lepromatous, apparently without regard to the fact that the adjective and the noun are derived from the same source) the diagnostic aid given by the reaction is very good. It has been said that cases of this type of leprosy do not require much aid in diagnosis beyond a microscopic examination of the lesion. The fact, however, remains that taking blood is a much easier procedure than removing bits of tissue for the microscope. Besides, a determination of the end point of the reaction is capable of measuring improvement, spontaneous or resulting from treatment. (ii) In neural leprosy the aid given is not of a high order. (iii) In kala-azar the aid given is even better than in nodular leprosy. Cases in early stages, not detected by formalin test, give strong reactions. Again, taking blood is a much easier process than puncturing internal organs and drilling into bones, and a determination of the end point of the reaction can give useful indication of cure or relapse.

A positive reaction indicates only four possibilities: (1) kala-azar, (2) other form of leishmaniasis, (3) leprosy, and (4) tuberculosis (presumably).

CAPILLARIA HEPATICA IN A WILD RAT IN CALCUTTA

By C. L. PASRICHA

MAJOR, I.M.S.

Professor of Bacteriology and Pathology

G. PANJA, M.B. (Cal.), D.B. (Lond.)

Assistant Professor of Bacteriology

and

N. V. BHADURI, M.Sc., M.B.

Assistant Research Worker, Department of
Helminthological Research

(From the Department of Bacteriology and Pathology,
School of Tropical Medicine, Calcutta)

DURING the course of a survey requiring post-mortem examination of a series of rats one rat (*Nesocia bengalensis*) was found in which there were a number of small whitish slightly-elevated irregular areas in the liver. A smear from the cut surface of one of these areas showed large masses of oval eggs with radially

(Continued at foot of next page)

(Continued from previous column)

Observations on the possible use of the test in studying aetiology and epidemiology of kala-azar and leprosy

In the nodular type of leprosy and in all cases of kala-azar the reaction of complement fixation is found to be fully developed and of a high order early in the disease. Is the reaction indicative of a stage in the immunological response of the subject when the hypersensitivity has developed into an allergic shock? Has this shock been conditioned by extrinsic factors? When does the reaction start? Will it be found at a low level in subjects who are responding immunologically but are not yet stricken, in areas where kala-azar is assuming an epidemic form or in experimental transmission of the disease? How many of them will not be stricken at all? Does the reaction of the known poorly reacting lepers, treated and untreated, rise when seasonal conditions favour leprosy? These are the questions suggested by the reaction. Their bearing on aetiology and epidemiology is obvious.

INTRADERMAL TEST AS AN INDEX OF VITAMIN-C NUTRITION OF THE BODY—OBSERVATIONS AT VIZAGAPATAM*

By D. V. S. REDDY

and

P. B. SASTRY

(From the Department of Physiology, Andhra Medical College, Vizagapatam)

An intradermal test for assessing the state of vitamin-C nutrition of the human body was first described by Rotter (1937), using the dye 2,6-dichlorophenol indophenol. Rotter stated that the decolorization time of the dye was a fair index of the vitamin-C status of the body. If the time was less than 5 minutes, the person was saturated; if the time ranged between 5 and 10 minutes, the person was said to be getting adequate amounts of vitamin C. If the time for decolorization was prolonged beyond 10 minutes, the individual was considered to be suffering from a deficiency of vitamin C. Portnoy and Wilkinson (1938) confirmed the results obtained by Rotter. They also stated that they found a good correlation between the level of blood ascorbic acid and the decolorization time of the intradermal test in 103 patients. Later, Wright and MacLenathen (1939) who also investigated dietary history and determined blood ascorbic acid levels, gave the contrary opinion that Rotter's test was not a reliable

guide for the vitamin-C status of the body. Meanwhile, Sujuki (1939) observed the decolorization time of Rotter's test to be inversely proportional to the ascorbic acid level of blood both in normal healthy human subjects and in pathological states. Beck and Krieger (1939) also considered the test as adequate for all practical purposes.

In India, Banerjee and Guha (1939) investigated how far the test could serve as a correct index of vitamin-C nutrition. In their experiments, the time of decolorization was longest in scorbutic guinea-pigs and was definitely diminished when ascorbic acid was added to the diet of the same animals and was prolonged again by withholding the supplement of ascorbic acid. In human subjects, they found that administration of massive doses of ascorbic acid resulted in reduction of the decolorization time. More recently, Banerjee and Guha (1940) reported again on experiments on guinea-pigs and human subjects, where an attempt was made to find out the minimum decolorization time. They first ascertained the time of decolorization in guinea-pigs and human beings on normal diets. Large doses of ascorbic acid were then administered for some days and the time of decolorization was observed, from day to day, during and after the administration of these massive doses. They noted that, both in guinea-pigs and human beings, the decolorization time became shorter with increasing ingestion of vitamin C and finally they recorded a minimum of 1 minute 20 to 30 seconds. These workers suggest that the minimum decolorization time may perhaps give a truer picture of the vitamin-C status of the body than the common urine (saturation) test.

A preliminary experiment

To acquire first-hand knowledge and experience of the value of the intradermal test and the duration of the decolorization time under certain known conditions we carried out the following tests and observations for a number of days on both of ourselves. At the outset we noted the urinary excretion of ascorbic acid using the simplified method of Harris (1940) and simultaneously noted the time of decolorization of the intradermal test. Then every day a test dose of ascorbic acid (at the rate of 70 mg. per stone weight of body) was administered. The ascorbic acid excreted by the individual in the specimen of urine (collected between the end of the fourth and the seventh hours after injection of the dose) was estimated daily. The intradermal test also was done daily during the same period. In one subject, on the second day of the test dose, 52.5 mg. of the ascorbic acid was excreted. This indicated body saturation according to Harris. A decolorization time which was 10 minutes before the test became shorter gradually. On the fifth day of the test dose, when ascorbic acid excreted in urine was 103 mg. the decolorization time of the intradermal test was 3 minutes 10 seconds. Later, a daily dose of 100 mg. of

(Continued from previous page)

striated shell and plugs at either pole bearing a general resemblance to the eggs of *Trichocephalus* except that these were uncoloured. A number of worms were dissected out of the liver tissue by gently teasing the nodules in saline. Unfortunately no complete specimen was secured but one almost whole specimen measuring up to 3 inches was straightened out. These worms had the morphology of *Capillaria hepatica* (Banerjee, 1894) Travassos, 1915. The eggs measured 0.056 mm. to 0.067 mm. \times 0.031 mm. to 0.034 mm.

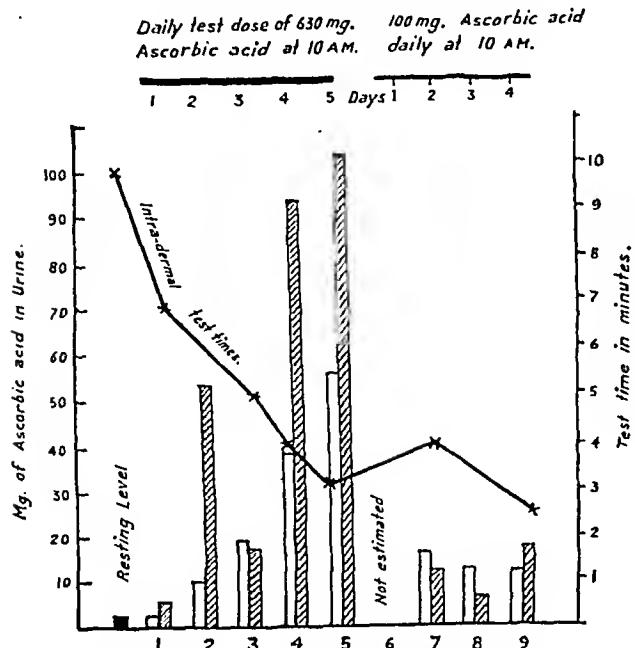

This parasite is usually found in rats and other rodents. It has also been found as a natural infection in cats, dogs and chimpanzees. According to Baylis (1931 and 1939) a single case of human infection has been recorded in India by Dive, Lafrenais and MacArthur in 1924.

ascorbic acid was continued for 4 days and on the ninth day of the test the decolorization time was found to be 2 minutes 30 seconds (fig. 1).

Text-figure 1

- 'Resting level':—Average excretion of ascorbic acid in milligrammes in the specimen of urine between 9 a.m. and 2 p.m., before the beginning of the test.
- Milligrammes of ascorbic acid in the urine excreted daily during the period of the test from 9 a.m. to 2 p.m.
- Milligrammes of ascorbic acid in the urine excreted daily during the period of the test from 2 p.m. to 5 p.m.

In the other subject also the decolorization time which was 6 minutes 40 seconds before the administration of the drug at the same rate of 70 mg. per stone weight was gradually reduced to 3 minutes 20 seconds on the seventh day of the test. These findings demonstrated that an increased and cumulative intake and utilization of the vitamin C reduces the decolorization time of the intradermal test. We are inclined to believe with Banerjee and Guha that the intradermal test is of value as an index of vitamin-C nutrition of the body. We too consider that the test needs to be standardized and improved.

The present investigation

As far as nutritional studies are concerned, Vizagapatam and its environs (situated midway between Madras and Calcutta) may be regarded as an unexplored area. To find out the time of decolorization of the intradermal test in healthy people of different ages, an investigation was started to collect data on the dietary habits of various sections of the population with special reference to vitamin C, doing at the same time the intradermal test on these persons. The test was carried out in two different samples of population : (1) healthy medical students in a fair state of nutrition, (2) elementary school children with no history of

recent illness and no definite evidence of malnutrition. We also attempted to collect similar data on men in the third and fourth decade of life employed in various capacities as clerks, attenders, etc., and on women from lower middle-class families. But as the number of these individuals is not sufficiently large, we hope to present these data at a later date.

Technique of the test

The technique adopted for the intradermal test is as follows :—

Twenty mg. of the dye (2 to 6 dichlorophenol indophenol) is added to about 30 c.cm. of hot double-distilled water. The solution is filtered and a sample of it is titrated against ascorbic acid solution of known strength, and the necessary dilution is made in order to obtain a proportion of 20 mg. of the dye in 49 c.cm. of the solution. The solution was taken in a sterilized coloured bottle and preserved in the ice chest. A small drop of the dye solution is injected intradermally so as to raise a weal (2 mm. in diameter) and the time taken for the blue colour to disappear completely is noted by means of a stop watch. An area on the volar aspect of the forearm free from hair and veins was selected for the test. During these investigations, whenever the weal was not satisfactory or whenever there was any slight doubt regarding the result, the individual was subjected to repeated intradermal tests, sometimes at intervals of days.

The data collected

The first series (medical students) were living on diets common among the middle-class society of these parts. Some were living in their own homes and taking vegetarian or non-vegetarian diet according to their family traditions. A fair number reside in the medical college hostel where the diet is well balanced, nutritious, and varied. The rest were getting their food from various local hotels. No detailed information was available regarding the types and amount of articles of food consumed from day to day as sources of vitamin C. Almost all were having in their diets some amounts of green vegetables, even the non-vegetarians being accustomed to a mixed diet. The only definite information that could be elicited and relied upon was the intake of citrus fruits. These data afforded a basis of classifying the students according to the amount and frequency of fruit intake into three groups :—

Group I consists of students who take fruits daily and others who take fruits at least on alternate days.

Group II includes students who take citrus fruits once or twice a week.

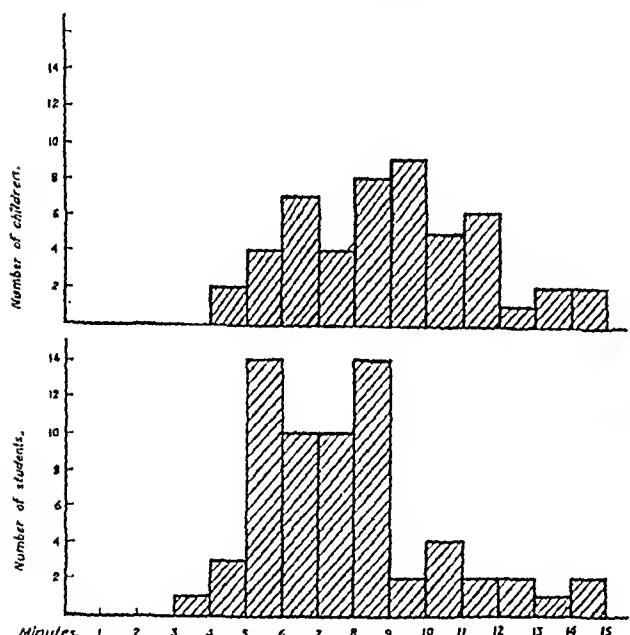

Group III shows students who either very rarely or never take citrus fruits.

The second series (school children) belong to two representative institutions : one providing instruction for the children of the middle-class society and the other for the children of the poorest class of society. For the performance of the test, we selected only children who had not suffered from any long or acute illness recently and who were also in a fair state of nutrition, as judged by our present physical and clinical standards. In these children, it was

difficult to get a reliable history of intake of fruits but their teachers gave us reliable information that certain pupils belonged to families who stocked and sold oranges and other fruits. These children also stated that they were eating oranges and other fruits regularly, while other children invariably replied in the negative to our queries.

Discussion of the results

The results of our tests on medical students are summarized in the tables. It will be seen that, according to the standards of Rotter, 83 per cent of all medical students can be said to be normal and that only 17 per cent are in a state of hypovitaminosis C. The largest number of students 48 out of 65 showed decolorization time ranging between 5 and 9 minutes as can be seen from graph 1. Our results therefore are in

Graph 1 showing the number of boys with different intradermal times, ranging from 3 to 15 minutes.

general agreement with those of Rotter. We have therefore taken the same range of decolor-

With regard to school children, the decolorization times range between 4 minutes 10 seconds and 14 minutes 30 seconds with an average of 8 minutes 50 seconds as compared with the average of 7 minutes 45 seconds for medical students. Applying Rotter's standards to these children, it will be noted that 70 per cent can be declared normal while 30 per cent have to be judged to be in a state of hypovitaminosis C. On further examining, the data at our disposal on the social and economic condition of the families from which these children come a significant difference is noted. In the school for middle-class society only 20 per cent of the children record decolorization time above 10 minutes whereas in the school for the poorest classes of society the figure rises to 37 per cent. In the middle-class children the decolorization time ranged between 4 minutes 10 seconds and 11 minutes 40 seconds with an average of 8 minutes 12 seconds while the children from the other school recorded decolorization time ranging between 4 minutes 40 seconds and 14 minutes 30 seconds with an average of 9 minutes 15 seconds. But even these figures do not really and correctly represent the position in the poorest classes. As many as 8 out of the 30 in the school for poor children came from families of fruit-sellers and were actually eating fruits regularly. If the decolorization time of these 22 children are considered separately they range between 6 minutes and 14 minutes 30 seconds with an average of 10 minutes 20 seconds. This is the longest time of all the averages for different groups. The percentage of hypovitaminosis C is as high as 50 per cent in this limited but representative sample of population from the poorest strata of society. It may be pointed out here that the percentage of hypovitaminosis among the medical students as well as the school children of middle-class society is almost the same, i.e., less than 20 per cent, while the percentage among the poorest classes is as high as 50 per cent.

There were no significant variations among different age groups or sexes in the elementary school children.

TABLE I

Age	Number of students	Range of decolorization time				Average time	Incidence of hypovitaminosis, per cent		
		mins.	secs.	mins.	secs.				
6-8	16	6	30	to	11	30	9	5	25
8-10	16	4	10	to	14	30	8	36	31
12-14	18	4	40	to	14		8	47..	33

ization time, 5 to 10 minutes, as enough indication of adequate intake and utilization of vitamin C by the individual.

Ten girls with ages ranging between 8 to 10 years showed decolorization time between 5 minutes 30 seconds and 14 minutes and 30

seconds, and an average time 9 minutes 48 seconds. The only interesting finding here is that nearly 50 per cent were in a state of hypovitaminosis. It must be added here, however, that all these girls belong to the poorest class of society. Girl students of the medical college recorded decolorization time between 3 minutes 45 seconds and 12 minutes 45 seconds with an average of 7 minutes 7 seconds. And only 13 per cent were in a state of hypovitaminosis. Though all of them came from middle-class families, they were no doubt the most favoured children in the family.

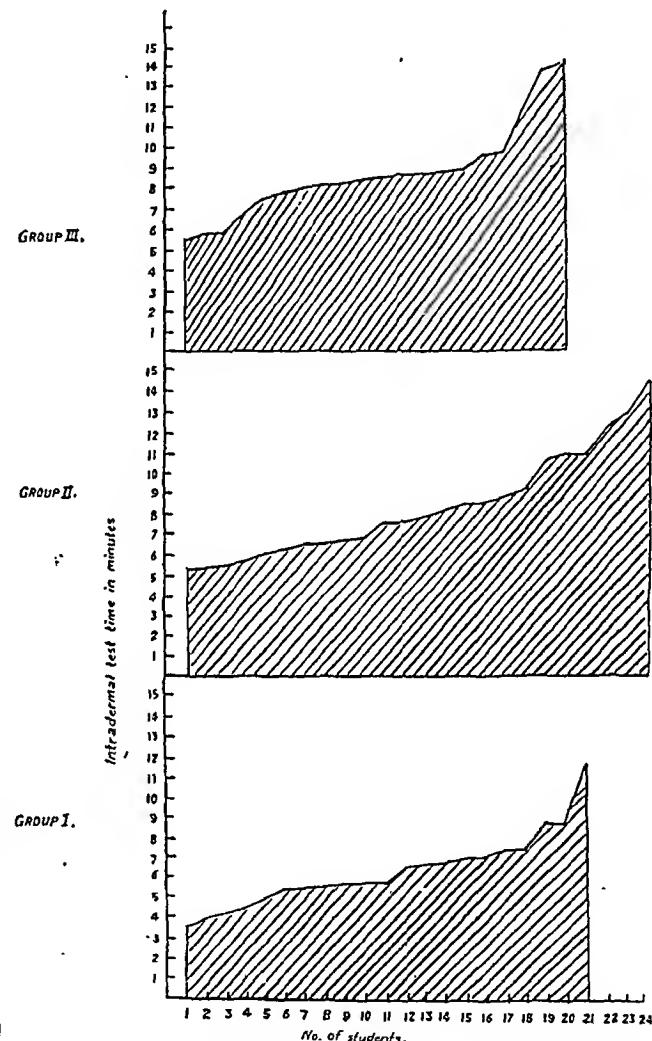

The amount of vitamin C ingested in the diet or as supplement is not always easy to determine by ordinary questioning regarding the kinds and quantities of foodstuffs supposed to be provided. Even a personal examination of quantities of foodstuffs actually served is not free from fallacies. The students do not eat all that is served, nor do they eat the same proportion of the article every day. As has been already stated, almost everybody says he takes greens and vegetables. But how much of it and how frequently is not definite. Hence we classified all the subjects examined into 3 groups, according to their consumption of citrus fruits. The effect of vitamin-C supplement in the form of fruits is obvious from a perusal of graph 2. The range of decolorization time among medical students taking fruits is between 3 minutes 45 seconds and 11 minutes 38 seconds, and the average 6 minutes 21 seconds. Among the school children also who take fruits regularly the decolorization time ranges between 4 minutes 40 seconds and 8 minutes 10 seconds, with an average of 6 minutes 16 seconds. In our whole series, we had 30 persons who were taking fruits regularly. In this group only one gave a decolorization time of more than 10 minutes, and in this case we have no means of verifying the statement about the consumption of fruits. In the course of our examination of medical students and elementary school children, we came across two interesting findings. The decolorization time in one medical student was 7 minutes 15 seconds on the first examination. He began to take Batavian oranges daily. After three weeks, his decolorization time fell to 3 minutes 30 seconds. The elementary school children coming from the families of fruit-sellers invariably recorded a shorter decolorization time than the rest.

Conclusions

1. The intradermal test is a simple but fairly reliable test of the vitamin-C status of the body. Its chief merit is that it can be used in public health work as well as in schools and hospitals where the elaborate methods of determining blood ascorbic acid level or of doing urinary saturation tests cannot be carried out easily and on a large scale.

2. Young adults and school children who are eating citrus fruits regularly or those who were

getting an all-round mixed diet recorded decolorization time generally within 10 minutes. Rotter stated that individuals showing a decolorization time of less than 10 minutes may be considered to be getting adequate amounts of vitamin C in their diet. The same standard, namely, 10 minutes, may be provisionally adopted to differentiate the subjects getting adequate doses of vitamin C from those who are in a state of sub-clinical hypovitaminosis.

Graph 2 showing the distribution of intradermal test times in students.

- Group (i). Students taking fruits at least on alternate days as a vitamin-C supplement to their diet.
- Group (ii). Students taking fruits at least once a week as a vitamin-C supplement to their diet.
- Group (iii). Students either taking fruits very rarely or not taking fruits at all.

3. The incidence of hypovitaminosis C in various groups of young adults and school children has been investigated using the intradermal test and Rotter's standards. Among middle-class students the incidence of hypovitaminosis C is less than among the children of the poorer classes.

4. As far as young adults and children are concerned age, sex, etc., do not seem to have

A Mirror of Hospital Practice

A CASE OF BACILLARY DYSENTERY SIMULATING ACUTE ABDOMINAL CATASTROPHY IN ITS EARLY STAGES

By R. J. SINHA

Chief Medical Officer, Bird and Company, Sijua

R. N. ROY, M.B.

Medical Officer, Mudidih Colliery
and

T. BHATTACHARJEA, M.B.

Pathologist, Bird and Company, Sijua

D. R., aged 30 years, Hindu male, was admitted into the Mudidih Colliery Hospital of Messrs. Bird and Company on the 22nd February, 1941, with the following complaints:—

- (1) Severe pain in the abdomen since last evening.
- (2) Vomiting of bilious material since last evening.
- (3) Retention of urine since last night.

On enquiry it was discovered that the patient had eaten the roasted skin of a goat two days before his admission into the hospital. He was feeling out of sorts on the day before admission and in the evening

severe gripping pain in his abdomen with bilious vomiting began. He had no stool and passed no flatus during the previous 24 hours. He has not passed urine since the night before.

Examination.—The patient was thinly built, anaemic and looked ill. Temperature—99°F. Tongue—coated and dry, eyes sunken with dark rings under them. Pulse rate—110 per minute.

The abdomen was soft, slightly distended and tender all over. Tenderness was especially marked in the hypogastric region. The bladder was full, the liver and the spleen were not palpable. Liver dullness was not obliterated. Rectal examination revealed no abnormality except general tenderness. Prostration was marked. Blood count showed leucocytosis with 86 per cent polymorphonuclear cells.

By way of treatment it was decided to (a) combat the toxæmia, (b) relieve the bladder and (c) stop irregular peristalsis and hence griping.

To relieve the toxæmia 50 c.c.m. of 25 per cent glucose solution was injected intravenously and saline given per rectum by the drip method.

To relieve his bladder he was catheterized and a small quantity of pus came out at the beginning, showing that the cause of retention was partly local.

To allay griping he was given tincture hyoscyamus one drachm with tincture belladonna 15 minimis in an ounce of water repeated every 6 hours, guided by the size of the pupil.

On the following day there was no improvement in the clinical picture, the temperature went up to 101°F. and it was decided that the patient should be given a high soap and water enema with asafoetida. The result of the enema was that some flatus together with faecal matter came out and the patient was slightly relieved. He was given 50 c.c.m. 25 per cent glucose solution intravenously, and the hyoscyamus mixture was continued.

Next morning, there was a well-marked mass in the left iliac region, and tenderness was marked in the right iliac fossa as well. It was thought to be impacted faecal matter and a high enema with soap and water preceded by olive oil and glycerine was given; the result was that a lot of faecal matter came out and the mass disappeared. The patient now began having frequent loose motions (20 to 25 a day) and the griping continued.

He was now given castor-oil emulsion thrice daily with the result that the frequent loose motions continued but the pain became much less in intensity.

On the 7th day of the disease the castor-oil emulsion was stopped, and the following day the patient started having the griping pain and loose motions with mucus and blood.

Microscope examination of the stool revealed pus cells in large number, large number of red cells lying discrete and macrophage cells.

No *Entamoeba histolytica* was found, but there were plenty of bacteria (it was the 8th day of the disease).

A diagnosis of bacillary dysentery was made and Shillong bacteriophage was administered, one ampoule every 4 hours.

The stools quickly improved, the pain became much less, the patient began to feel better and in 3 days' time he was passing almost normal stools once a day and eating his food.

He was kept on a saline mixture with belladonna thrice daily.

Discussion

The interesting features of this case are that it resembled a case of acute abdominal catastrophe at the onset and it was only after a time, when the obstruction of the gut was removed, that the actual condition was discovered.

The questions that might be raised are :—

(1) What was the obstruction to the large gut due to ? Was it (a) toxic paresis of the muscles of the large gut ? (b) obstruction by scybala ? or (c) any other type of obstruction that was removed by enema ?

(2) Was it a case of bacillary dysentery from the beginning ?

From the case notes it is obvious that the patient was markedly toxic, as shown by the rise of temperature, signs of dehydration and prostration. The leucocytosis combined with the clinical picture is in favour of some inflammatory condition within the abdomen. The absence of rigidity eliminates the possibility of such conditions, as appendicitis, cholecystitis, etc.

The scybala were neither hard nor large enough to account for the obstruction to the lumen of the gut.

The stool examination showed definite evidence of an acute inflammatory condition within the large gut and the microscopic picture was that of acute bacillary dysentery.

Combining all the above facts the diagnosis of bacillary dysentery seems to fit in best and it is corroborated by the condition disappearing with phage therapy.

Our explanation of the clinical manifestations of obstruction is as follows :—

The initial toxæmia due to infection by the organisms of bacillary dysentery caused a paresis of the large gut which resulted in inability to expel the faecal matter and flatus. The distension could not increase much because of early attempts to relieve the obstruction by compound enemata.

On the removal of the infected mass, containing a large amount of toxins of the organisms by enema and subsequently by castor-oil emulsion, the clinical picture improved and again became worse when the emulsion was omitted.

Bacteriophage cured the condition by eliminating the organisms and thus stopping the further formation of toxins.

Our thanks are due to Messrs. Bird and Company and the Chief Mining Engineer, Mr. Tarlton, for kindly granting us permission to report this case.

ECLAMPSIA TREATED WITH INTRAVENOUS INJECTION OF MAGNESIUM SULPHATE SOLUTION

By S. K. ROY, B.Sc., M.B.

Medical Officer, Irhpala Charitable Dispensary,
Midnapore

(1) Date of attendance—31st August, 1939. Patient—age about 15 years.

The patient was seen after she had 4 to 5 fits in the course of half an hour. She was at full term. Oedema present all over the body. Stroganoff's treatment was immediately started and 50 c.c.m. of 25 per cent glucose solution was also injected intravenously. The interval between fits was lengthened but they could not be stopped even after treating the patient for 13 hours, and the number of fits was 22 up till then. Then 15 c.c.m. of 10 per cent magnesium sulphate solution was injected intravenously and there was another fit after 5 hours, after which 10 c.c.m. more of the solution of magnesium sulphate was given intramuscularly. After this there were no more fits. A few minutes after the second injection there was spontaneous delivery of an asphyxiated child which was resuscitated in 15 minutes. The patient and child are living and healthy.

(2) Date of attendance—30th April, 1940. Patient—age about 17 years.

The patient was seen after she had had 10 to 12 fits in very quick succession. The patient had much oedema all over the body and was comatose even during the interval between the fits. Stroganoff's treatment was immediately instituted and even after 3 hours the fits were coming in as quick succession as before. Then 15 c.c.m. of 10 per cent magnesium sulphate solution was injected intravenously, there was a lengthening of interval between the fits but they did not stop. The delivery of the child was hastened by forceps but the patient died an hour later.

(3) Date of attendance—16th December, 1940. Patient—age about 17 years.

The patient was seen after she had 3 to 4 fits. She had no oedema anywhere. Stroganoff's treatment was started and 25 c.c.m. of 25 per cent glucose solution was injected intravenously. After 13 hours, though the interval between the fits was lengthened they could not be stopped. Another 25 c.c.m. of glucose solution was injected followed by 15 c.c.m. of 10 per cent magnesium sulphate solution intravenously. After this injection

there were no more fits and a dead child was born spontaneously 2 hours after the appearance of 'show'. The patient had restlessness for another 24 hours and 10 grains of chloral hydrate in 4 ounces of 2½ per cent glucose solution was given per rectum every 4 hours. The patient was cured and is alive and well.

(4) Date of attendance—7th March, 1941. Patient—age about 14 years.

Full term of pregnancy. Having pains for the last three days. No oedema anywhere. I saw the patient 3 hours after the appearance of the first fit, and in the course of these 3 hours there were altogether 6 fits. I gave 50 c.c.m. of 25 per cent glucose solution intravenously and then 15 c.c.m. of 10 per cent magnesium sulphate solution intravenously. Immediately after the last injection there was a fit. Six hours later there was a fit but the duration was very short. A few minutes after this fit there was spontaneous birth of a dead child. Four hours after the injection of magnesium sulphate solution 10 grains of chloral hydrate in 4 ounces of 2½ per cent glucose solution was administered per rectum every 4 hours. The patient recovered.

In the same period I had 3 other cases of eclampsia:—

(1) *Postpartum eclampsia*—in which case the fit stopped after the first injection of morphine and Stroganoff's treatment was carried out all through. The patient recovered.

(2) Eclampsia at the full term of pregnancy. The patient was extremely swollen with very scanty urine exactly like case 2 above. Morphia and chloral treatment was given but the fits could not be stopped in 6 hours. After that, delivery took place assisted by forceps but the patient died a quarter of an hour after delivery.

(3) Eclampsia at the full term of pregnancy. Patient's age was about 18 years. No oedema anywhere. Stroganoff's treatment was instituted and the fits were stopped in 8 hours. Delivery of a dead child took place 3 hours later, assisted by forceps.

All the cases treated were primigravidae.

Discussion.—The number of cases treated is too small to give a definite opinion regarding the value of treatment either by Stroganoff's method, by magnesium sulphate alone or by combined treatment.

It seems that suitably selected cases may better respond to magnesium sulphate treatment combined with intravenous glucose and venesection where the blood pressure is high, and chloral hydrate if there be irritability.

Patients treated by magnesium sulphate seem to be more generally delivered spontaneously than the cases treated by morphia and chloral, in many of which forceps are required.

EFFECT OF SULPHAPYRIDINE ON ROUNDWORMS IN A CHILD WITH PNEUMONIA

By H. L. HALA, L.C.P.S. (Bom.)

Mission Hospital, Ratlam, C. I.

A BOHRA child, aged two years, was brought to the out-patients' department, Mission Hospital, Ratlam, with cough and fever, duration six days. General examination showed marked anaemia and rickets changes. Both lungs were affected with bronchopneumonia, and the abdomen was distended.

Following treatment was given:—(i) Sulphapyridine, half tablet every four hours for two days and in reduced doses for successive five days, (ii) stimulant cough mixture every four hours, (iii) sugar solution by mouth frequently, (iv) mustard oil to the chest and back every four hours, and (v) glycerine enema with good result but without any effect on distension. Admission of the child into the hospital was also advised.

The following day the father came to me with a cigarette tin full of roundworms. The patient passed

148 roundworms on three successive days. After two days, as the temperature came to normal, sulphapyridine was reduced; gradually the condition improved. After two weeks the patient looked fairly well and the pot-belly disappeared; no antihelminthic was given. The stool was examined; it showed no ova of roundworms. The child is improving on anti-rachitic therapy and iron mixture.

I would suggest that some experimental work be done in this connection, as we have found in practice the treatment with santonin in some cases unsatisfactory.

In conclusion, my thanks are due to Dr. W. G. Anderson, physician-in-charge of Mission Hospital, Ratlam, for kindly allowing me to publish this note.

A CASE OF DISPUTED PARENTAGE

By G. P. CHARLEWOOD, M.B., Ch.B., M.R.C.O.G.
CAPTAIN, I.M.S.

Civil Surgeon, Coorg

The following case was unusual, in that the maternity, as well as the paternity of a child was under dispute. The case was heard in the Criminal Court in Mysore on 10th June, 1941.

Kengappa and his wife Chennamma claimed that their four-year-old son had been kidnapped a year previously by Syed Fakir and his wife Fathima Bee, who however stated that the boy was their own. They pointed to the fact that Fathima Bee was feeding the child on the breast.

Blood examinations of the 'A B O' variety were conducted on all four 'parents' and the child. It was found that the child and Fathima Bee were group A (or group 2, Moss). Her husband, Syed Fakir, and both Kengappa and Chennamma were all group O (4 Moss) showing that the child could not belong to Kengappa and Chennamma and that the charge of kidnapping was false.

The magistrate decided the case entirely on the results of the blood test. Indeed no other evidence of any value was forthcoming.

The case is interesting because the ordinary A B test is generally held to be hardly worth trying since it gives so few definite results (Lynch and Harley, 1938). Where, however, the maternity as well as the paternity is in dispute, as in the above case, the chances of a definite result from this test are obviously greatly increased.

There is approximately a 30-per-cent chance of proving non-paternity where the M N test is used in addition to the A B test (Lynch and Harley, loc. cit.). But where the maternity is also in doubt this figure would also be greatly increased.

CORRIGENDA

MULTIPLE PRIMARY EPIDERMOID CARCINOMA: DE AND TRIBEDI

In the above-mentioned paper which appeared in our July issue, on page 398, first column, the 31st line from the bottom which reads 'nature with marked differentiation (figures 4 and 5)' should read 'nature with marked dedifferentiation (figures 4 and 5)'. The same mistake also occurs in plate XX, figure 5, case 1, second line of letterpress which should read 'magnification to show the marked dedifferentiated condition'.

Indian Medical Gazette

AUGUST

THE PUBLIC HEALTH SECTION

In an editorial in our April number last year we attempted to trace, in the barest outline, the evolution of medical science from the time when primitive man depended entirely on instinct for both treatment and prevention, to the present day. During any 'civilized' period in the world's history, when sane men have been allowed to follow sane thoughts, the tendency has always been towards prevention; in the dark ages, when the individual ceased to look for anything good from his rulers and in return gave as little as he could and that grudgingly, it was a case of every man for himself; man sought medical relief from wherever he could get it, and prevention, except in so far as it could be practised by the individual for himself or his family, was forgotten. It was in this environment that our present 'system' of scientific medicine was born and the foundations of medical education laid, and whilst, in practice, medicine in all progressive countries of the world is steadily emerging from this stage, medical education is lagging behind.

The organization of preventive medicine is essentially a matter for the state. In this organization there are, broadly speaking, two schools of thought, the democratic and the totalitarian. In the latter, rules and regulations that are sound in principle but are often totally opposed to the inclinations and upbringing of the people on whom they are imposed are laid down, and on the face of it enforced; whereas, the democratic way is first to explain to the people the reasons for giving up certain practices or adopting others, and then, when if not a majority at least an appreciable and influential minority have grasped the importance of the matter, to introduce legislation with a considerable number of loop-holes, which, as the advantages of the legislation are gradually understood by the people, are closed one by one. We are not prepared to be dogmatic about which is the best method; on paper the totalitarian way is the most efficient, but its success will depend on the attitude of the people towards the state; if they worship it, as we are led to suppose that they do in the totalitarian states, then their system probably works best. In democratic countries, this system does not work and whenever it has been tried it has proved a failure.

In India we follow the democratic system and must therefore start by educating the people in the advantages of preventive methods, which can only be done by first educating the medical

profession, and this brings us up against a serious defect in our present system of medical education.

We wrote in our previous editorial that it would be more rational if the medical student were given a thorough training in the general principles of medicine and in the practice of preventive medicine before his qualifying examination; those who wished to specialize in clinical medicine could then take a post-graduate course in this subject. We repeat that this would be more rational than the reverse which is the present procedure, but we agree that it would not be practical under present-day conditions. A change, however, both in the curriculum and in the outlook of the teacher of medical subjects is urgently required; perhaps the latter change is the more important, and it is the one with which we ourselves are mainly concerned.

In the average textbook on medicine, only a few lines are devoted to the aetiology of the disease and the references to prevention are usually of the most perfunctory nature. It is little wonder that the student learns to concentrate on the patient himself and not to consider him also in his relationship to the community. The practitioner's first duty is to make a diagnosis, for this has an important bearing on both treatment and prevention but often a more vitally important one on the latter. His second thoughts should be for the community; whether the disease is likely to affect others and if so what can be done to reduce the chances of this happening? After this he can turn to the treatment of his patient. We fear that these second thoughts are often omitted, or, if they arise, amount to little more than wondering if there are any irksome regulations which have to be complied with.

The reason for this attitude of the average practitioner towards prevention is primarily that he has not been taught to think otherwise, but it is also fostered by the present artificial division of the medical services into the curative and preventive sides; when there are others paid to prevent disease, there are many practitioners who honestly believe that their duties end when they have prescribed for their patient.

This journal has always included preventive medicine within its scope, and few numbers have been published that do not contain at least one original article directly or indirectly concerned with prevention of some special disease or of disease generally. In other sections of the journal also, we have given space to subjects mainly concerned with prevention; for example, by arrangement with the Tuberculosis Association of India, we have published nearly every month for some time a short item under the heading 'Tuberculosis News'. This of course includes reference to treatment, but in this, as well as in a number of other diseases, the treatment of the individual is a very

important means of preventing the disease in the community, and it is from this point that the subject has been viewed.

We propose in future to include a public health section in each number of this journal. In it we hope to publish editorial notes, original articles, résumés of papers from other journals, extracts from reports, items of news, etc., on subjects of public health interest, under the headings, nutrition, microbiology, epidemiology, maternity and child welfare, sanitation and sanitary engineering, and public health administration, and on the public health aspects of such diseases as tuberculosis, malaria, and leprosy.

This segregation of the subject of public health may seem contrary to our claim regarding the unity of purpose and indissolubility of medical science. Nevertheless, we feel that it will serve the purpose of focusing the attention of the practitioner on the importance of public health work, and it is for him rather than for the professional sanitarian that this section is

being started. It is however to the latter that we look for assistance to make this section a success, and before undertaking it we assured ourselves of the co-operation of the director and staff of the leading sanitary institution in this country, the All-India Institute of Hygiene and Public Health. They have agreed to help us with the collection and arrangement of material for this section. However, as in the case of the special tuberculosis number, in the publication of which we receive the assistance of a committee of the Tuberculosis Association of India, the final responsibility for the section remains with the editor of this journal.

This new section will be placed in the second half of the journal and will not encroach on the pages devoted to original articles, although original articles will be included in the public health section. Our conservative readers therefore need not feel that they are losing anything, and our progressive ones will, we hope, consider that they are gaining by this change.

Special Article

NOTES ON THE TRAINING OF ATHLETES

By S. A. SUBEDAR, L.C.P.S., R.M.P.
Kutiyana, West Kathiawar

I HAVE read with considerable interest the articles and correspondence in the *Indian Medical Gazette* on doping in sport. The intimately associated subject of training of athletes is one which has not received the attention from medical men that it deserves and I hope that the following résumé of an article in the *Medical Annual* of 1937 by Dr. Adolphe Abrahams, M.D., F.R.C.P., may be of interest to medical men in India. For the sake of convenience of readers, quotation marks have been omitted.

The application of scientific principles to the practice of training of the body for specially severe exertion is of comparatively recent date. Strenuous competitive exercises, i.e., boxing, rowing, walking, were confined to the lower classes as professional exploits. The so-called principles of training were applied with brutality which seems almost incredible to us at the present time.

When athletic enterprises became fashionable, the youths of the period imitated their methods and adopted their system of rules and regulations. For a time the training remained in the hands of the arbitrary professional whose methods constituted an ordeal from which even the bravest might turn with a shudder.

The medical profession claims to have been responsible for a better understanding of the rationale upon which the physical perfection of the human body depends. The medical profession has tried to explain that the laws of physiology apply with particular reference to

the subject of training. With gradual elimination of sheer brute force from many feats of exertion, the introduction of skilled co-ordinated movements has encouraged the aspirants to athletic distinction as highly specialized individuals rather than as crude mass-produced machines upon which almost any sort of system might be imposed. More and more the part which the medical profession is called upon to play is demanded by the increase in the love of sports, in realizing the fact that exercise occupied an important position in modern education and the extension of international competition all over the world.

Diet in training

Prejudice is always difficult to overcome and particularly in regard to dietetics in training; the old-fashioned and well-established fetishes will be the last to disappear. The fundamentals are readily comprehended. They are based upon experiments and investigations. It is easy to understand that no article of food can possess specific properties to produce or increase respiratory power or circulatory efficiency. Energy, stamina, strength and endurance are obtained by efforts. So long as essentials are provided and the food is suitable to the digestive organs and agreeable to the palate, it matters very little in what form they are taken.

Any food which is a source of energy is good for training. During violent exercise much energy is required for the muscular effort. The heart and the lungs should not be embarrassed by improper and injudicious meals at unsuitable times. Our predecessors appreciating that overcooking hardened the fibres of meat, ate it raw. Such injunctions led to a nauseating regime which produced staleness, boils and other

minor illnesses too frequent during the training of the past, and, although rare, not altogether absent at the present day.

Quantity of food.—The only guide to the quantity of food which an athlete should consume is the natural appetite. To eat beyond the requirement of appetite is a gross error. Every particle of food thus eaten becomes an encumbrance, hindrance, and a loss. To consume large quantities of animal proteins, on the mistaken belief that strength is acquired, is a grave error. Long distance cyclists take astonishingly small quantities of food. This leads us to the conclusion that eating is often a matter of habit.

The choice of food.—The more we study the methods of the greatest athletes, the more we are struck with their simplicity. The normal selection is a mixed diet according to the taste, opportunity, or status of the individual. The advantages of animal proteins over vegetable proteins require no emphasis. Yet it is a question whether any virtue is possessed by the proteins of meat over those of milk, eggs, cheese. With ethics we are not concerned. A large number of athletes eat and prefer meat. There are great vegetarian athletes also. It is therefore foolish to assert that all athletes should follow a particular rule in matter of diet.

Recently, the value of carbohydrate as a muscle food has assumed importance and the practice of taking sugar a short time before a contest is harmless. In the case of very prolonged efforts, such as a 100-mile run or a 12-hour cycle race, the athlete will be well advised to take only meat sandwiches of small bulk or a solution of glucose, remembering also that the loss of water from the body should be replaced by common salt solution. Experiments have given support to the impression that vitamin B and fat in small quantity should be included in the diet.

Liquids.—An idea to a certain extent persists that liquid in any form is bad for training. It is very simple to explain that violent exercise is accompanied by considerable loss of water through the skin and unless this water is replaced regularly the athlete will suffer from insufficiency of lubrication. Liquid in training is not only harmless, but a liberal supply is beneficial, provided it is not taken in excess at meal times. Enough should be taken to make the meal enjoyable, but not more. Larger quantities are beneficial when taken on an empty stomach, on rising, between meals and at night.

Alcohol.—Alcohol is quite unnecessary in training. The vast majority of athletes are total abstainers. Alcohol has its limited use as a medicine. It is the practice during the full training of the university crew to allow champagne occasionally to instil a spirit of cheerfulness and to mitigate over-anxiety which prevails in the circumstances.

Tobacco

In training it is inadvisable to change a man's habits; emphasis should not be laid upon the prohibition of smoking. It is not easy to compare the capabilities of smokers and non-smokers. Experiments have been conducted which appear to indicate the baleful effects of tobacco upon physical efficiency, for example the disadvantages of carbon monoxide in inhaled smoke, the effects on the nervous system, or the direct action on the heart. But the restlessness, sleeplessness, irritability and other disturbances which often follow withdrawal of tobacco should not be forgotten. The young athlete should be encouraged to abstain from tobacco as much as possible. It is good to be more tolerant. There are great track athletes who smoke up to the last moment of going to the track. Long distance cyclists are invariably non-smokers, not because they believe they suffered, but because they were not interested.

Sleep

This depends on the individual. The old idea that half of 24 hours should be spent in bed has no justification. Sleep of seven or at most eight hours should be recommended. Injunction to go to bed early should be enforced to avoid late hours which are not good for training. To bed at 10 or 10-30 p.m. rising at six or 6-30 a.m. with a little physical exercise or some mental occupation before breakfast is the best rule.

Drugs

Old time training consisted of strong emetics and strong purgatives. Nowadays drugs are rarely employed. Their use is only guided by the necessity of the moment. Patent medicines are useless. Their benefit is only suggestive. The doping habit which is prevalent in some part of the continent should be condemned.

Physical fitness and staleness

A distinction ought to be drawn between training and coaching. The preparation of an athlete for a contest requires him to be brought to the acme of physical perfection. Co-operation between the coach and the trainer is the best procedure. The condition of physical fitness and that of staleness are associated. When an athlete goes stale, the change is so profound as to lead us to the conclusion that some constitutional disturbance has occurred. His nervous system is deranged. He is dejected, peevish, irritable, sleeps badly, loses his appetite, and loathes the track and anything connected with it. His capabilities deteriorate. He is inferior to an untrained man. This can be attributed to the monotony of life, diet, society, and conversation. In the highly strung athletes this induces 'brain fag'.

If staleness should occur complete rest from the track and from everything connected with it should be advised. This will restore the

mental balance in a few days. Change of food will also contribute to the cure. It is desirable to give rest to the digestive organs by giving invalid diet. A small dose of calomel should be given. Weight is the guide which leads us to the suspicion of staleness. A continuous loss of weight must be regarded as a danger signal. Change in the rate of heart beats is another guide. The athlete should be exerted for a period of 20 seconds. After the cessation of exertion if he does not regain his former pulse rate within 40 seconds, he is unfit. Searching inquiry must be made not forgetting the psychological aspect.

Medical News

INDIAN MEDICAL BIRTHDAY HONOURS, 1941

The following are the names of medical men and others associated with medical institutions in the Indian Honours List of date 12th June, 1941. We offer them our congratulations:—

K.C.I.E.

Lieutenant-General G. G. Jolly, I.M.S., Director-General, Indian Medical Service.

C.I.E.

Major-General H. Stott, I.M.S., Surgeon-General with the Government of Madras and lately Inspector-General of Civil Hospitals, Bihar.

Lieutenant-Colonel C. M. Ganapathy, I.M.S., Director of Public Health, Madras.

Lieutenant-Colonel G. Verghese, I.M.S., Director of Health and Inspector-General of Prisons, Orissa.

Lieutenant-Colonel C. M. Nicol, I.M.S., lately Director of Public Health, Punjab.

Lieutenant-Colonel M. A. Nicholson, I.M.S., Chief Medical Officer in Central India and Residency Surgeon, Indore.

O.B.E.

Lieutenant-Colonel J. M. R. Hennessy, I.M.S., Civil Surgeon, Jubbulpore, C. P. and Berar.

Major F. A. B. Sheppard, I.M.S., District Medical Officer, Madura, Madras.

M.B.E.

Miss Elizabeth Isabel Hamilton-Browne, W.M.S., Lady Assistant to the Inspector-General of Civil Hospitals, Punjab.

P. T. J. Doss, Esq., Medical Officer of Health, Secunderabad Cantonment, Hyderabad (Deccan).

B. S. Parsram, Esq., Medical Officer, R. B. Udhavdas Tarachand Hospital, Shikarpur, Sind.

Kaisar-i-Hind Gold Medal

Mrs. Lydia Torrance Allen, Superintendent, Lady Dufferin Hospital, Calcutta.

Miss Margaret Duncan Salmond, Lady Willingdon Leper Settlement, Tirumani, Chingleput, Madras.

Kaisar-i-Hind Silver Medal

Miss Mary Harding, lately Matron, Lady Reading Hospital, Peshawar, N.W. F. P.

Miss Eileen Spencer Morris, Medical Superintendent, St. Stephen's Hospital for Women and Children, Delhi.

Miss Hope Nicholson, Doctor-in-charge, Jackman Memorial Hospital, Bilaspur, C. P. and Berar.

Miss Aileen Barter Snow, Medical Officer in charge of the St. Catherine's Hospital, Amritsar, Punjab.

Kaisar-i-Hind Bronze Medal

Miss Mary Augusta Beetles, Senior Sister, Patna Medical College Hospital, Bihar.

Diwan Bahadur

Captain Rao Bahadur P. K. Ayyar, Civil Surgeon (retired), Madras.

Sardar Bahadur

Sardar Sahib B. H. S. Grewal, in charge Civil Hospital, Goira, Lyallpur, Punjab.

Rai Bahadur

A. P. Bajpayee, Esq., Civil Surgeon, Bijnor, U. P.
Rai Sahib R. P. Ghosh, Civil Surgeon (officiating), Manblum, Bihar.

Rao Bahadur

G. R. D. Rau, Esq., Principal, Stanley Medical College, and Superintendent, Stanley Hospital, Madras.
Rao Sahib K. V. Chipkar, Civil Surgeon, Bijapur, Bombay.

S. J. Eapen, Esq., District Medical Officer, M. & S. M. Railway, Guntakkal.

Shifa-ul-Mulk

Hakim A. Laatif, Vice-Principal, Tibiyan College, Moslem University, Aligarh, U. P.

Sardar Sahib

Sardar T. Singh, Medical Practitioner, Loralai, Baluchistan.

Sardar S. Singh, Sub-assistant Surgeon, Baluchistan.

Khan Sahib

A. Majid, Esq., Civil Surgeon (officiating), Rajshahi, Bengal.

M. K. Kakarzal, Esq., Municipal Medical Officer of Health, Budann, U. P.

Shaikh A. Karim, Senior Sub-assistant Surgeon-in-charge, His Excellency the Governor's Dispensary, Punjab.

Sayid A. Hasib, Assistant Surgeon, Bihar Sub-divisional Hospital, Patna.

Rai Sahib

R. K. Arora, Esq., District Medical Officer of Health, Jaunpur, U. P.

N. C. Sinha, Esq., Assistant Surgeon, Muzaffarpur, Bihar.

C. N. Banerjee, Esq., Superintendent, Vaccine Depôt, Namkum, Ranchi, Bihar.

K. Singh, Esq., Lecturer in Midwifery and Gynaecology, King Edward Medical School and in-charge of Maternity and Gynaecology Wards, King Edward Hospital, Indore, Central India.

Rao Sahib

W. A. Phaturfod, Esq., Port Health Department (on deputation), Bombay.

STAINS FOR MEDICAL WORK OF INDIAN MANUFACTURE

SEVERAL essential stains of excellent quality used for bacteriological work are now being manufactured in India for the Medical Stores Department as a result of the collaboration of the Department with a Professor in a South Indian University and the Central Research Institute, Kasauli.

These include congo red, chrysoidin, methyl violet, brilliant green, eosin and Leishman's stain.

These stains had hitherto been imported mainly from Germany as specialities of a few well-known manufacturers. With the advent of the war, the Director-General, Indian Medical Service, investigated the possibility of their production in India from commercial dyes of British origin.

INDIGENOUS SUBSTITUTE FOR PARAFFIN MOLLE

AN order for 300 tons of anti-mosquito cream, perhaps the largest order for an item of this kind ever placed, is being complied with by the Medical Stores Department. Paraffin molle, an ingredient of this cream, which was imported and was in the past difficult to obtain, has now been successfully replaced by hardened vegetable oil of indigenous manufacture.

Public Health Section

NUTRITION

DURING recent years there has been a great advance in our knowledge of the science of nutrition. This advancee has been rapid, far reaching, and spectacular, arousing the interest not only of medical men and scientists but of the ordinary citizen, of governments, and of public bodies. The development of this newer knowledge of nutrition, as McCollum has termed it, has upset long-established beliefs and raised questions of great practical importance on the adequacy of diets in common use, on existing food habits, on dietary requirements, on the extent of malnutrition, and on the direct and indirect effect of nutrition, on efficiency, on health, and on disease. The most outstanding feature of this advance has been the upsetting of the orthodox view on the dietary requirements of man. Beri-beri, scurvy, rickets and pellagra, which have been responsible for such ravages in man, have been found to be due to the deficiency of certain essential formerly undefined food factors, the vitamins. The last two decades have seen the mysterious and elusive vitamins becoming definite chemical entities with well-defined chemical and physiological properties.

It is the understanding of these new nutritional factors which has revolutionized our ideas on food requirements and the effect of food on health. More important than the clinical recognition of deficiency diseases has been the fact that much ill-defined ill health and many conditions of obscure aetiology are due to minor degrees of deficiency. The response of these conditions to the administration of nutritional factors has been so striking that therapeutic dietetics has become an important branch of medicine. In the wider field of public health this new knowledge is proving of the greatest value. Dietary and nutrition surveys are repeatedly showing the high general incidence of malnutrition in most sections of the population. Public health measures are being introduced to provide milk, cod-liver oil, and other protective foods for mothers, infants and school children. The provision of adequate nutrition to all people has become perhaps the most important social question of our time.

The development of this nutritional knowledge has been so rapid that the average medical practitioner and the public health worker have not been able to keep pace with this advance. Yet, the importance of this subject is such that neither the physician nor the health officer can afford to ignore the application of this knowledge to their respective fields, without serious loss of efficiency. In this new section on public health, facts pertaining to nutrition will be presented from time to time.

STUDIES ON THE VITAMIN-A CONTENT OF GHEE

By M. C. MUTHANNA *, M.Sc.

and

P. K. SESHAN, M.Sc.

(Department of Biochemistry and Nutrition, All-India Institute of Hygiene and Public Health, Calcutta)

GHEE and butter, in spite of their importance as articles of diet in India, have not received sufficient attention as regards their nutritive essentials, especially vitamins A and D. Wright (1937) after a survey of the ghee industry in India estimated that about seventy crores of rupees worth of ghee are being manufactured in India annually.

Ghee, or clarified butter, is prepared as a cottage industry in the Indo-Gangetic plains, Gujarat and Rajputana. The method of manufacturing ghee differs from province to province and its aroma and keeping quality depend on the mode of manufacture. Ghee sold in the Indian market is grossly adulterated. The ghee merchants manage to circumvent the Food Adulteration Act by adding colouring matter, butyric esters, etc., to the adulterated ghee so as to give the characteristic physical and chemical constants of pure ghee. Purity of ghee is tested mainly by its physical and chemical properties, such as the butyro-refractometer reading, Reiehert-Wollny value, acid and iodine value, fluorescence, etc. There being no standards for vitamin-A and D content of ghee, usually these are not tested. But ghee is the most important source of these vitamins particularly for the vegetarian. The ghee is usually stored in tins in open and warm places. All this causes the consumer to lose much of the nutritive value of the ghee.

It was felt that a survey of the vitamin-A content of ghee from different provinces would be interesting. The stock of animals in various provinces differs and so also their fodder, according to the climatic environment. All this will cause considerable variation in the vitamin-A content of butter and ghee. The survey incidentally would also give a rough index of the state of nutrition of the cattle and the richness of the fodder. The vitamin-A content of ghee sold in Bengal and Sind has been determined. The effects of heat, exposure and storage on the vitamin-A content of ghee have also been studied. Since some merchants sell ghee of high Reiehert-Wollny (R-W) value at an enhanced price, one of the objects of the present study was to determine whether ghee of high R-W value has higher vitamin-A content than those of low R-W value. The present paper gives a

* Public Analyst, Karachi, on deputation to Biochemical Standardization Laboratory, Calcutta.

report on some of the results obtained during the study.

Banerjee (1936) and Banerjee and Sunawala (1936) studied the vitamin-A content of ghee and butter of both cow and buffalo by the antimony trichloride method giving the Carr-Price blue units. Grewal and Kochhar (1938) studied the vitamin-A content of Punjab town and village ghee by the same method. Banerjee and Doctor (1938) also studied the loss due to exposure, irradiation and auto-oxidation of vitamin A in ghee using the same method. It is now established that the Carr-Price method of determining vitamin-A content does not give comparable values and cannot be expressed in absolute quantities of vitamin A. The correct method of estimating the vitamin-A content is by the spectro-photometric method of determining the quantity of absorption of radiations 3280 Å by the substance. This gives very reliable values. Using this method De and Majundar (1938) have determined the vitamin-A content of ghee and butter generally obtained in Madras. They have also studied the loss of vitamin A due to cooking, exposure, etc. The vitamin-A content of Madras ghee was about 25 international units per gramme, or 8.3γ.

A large number of samples of ghee kindly supplied by the Director of Public Services, Karachi, and the Director of the Bengal Public Health Laboratory, Calcutta, were analysed and the R-W values and the butyro-refractometer (BR) values determined. Samples of ghee which had R-W values higher than 24 were selected for the determination of the vitamin-A content. The outfit used for this purpose was Zeiss spectrophotometer fitted with spectrophotometer (Spectrograph). Ten grammes of ghee were saponified and the non-saponifiable fraction of the ghee was dissolved in 25 c.c.m. of cyclohexane and the extinction coefficient was measured by the quartz spectrograph. From this the extinction coefficient of a 1 per cent solution in a 1 c.c.m. column of liquid at 3280 Å was calculated.

This value multiplied by 53.33 expresses the vitamin-A content in microgrammes (1/1000 of a milligramme) per gramme. One milligramme contains about 3,000 international units of vitamin activity.

Result.—The vitamin-A contents of ghee sold in Sind and Bengal are given in tables I and II.

To study the loss of vitamin A, samples of butter were heated to different temperatures and kept for 5 minutes and then the vitamin-A content was assayed. The loss is expressed as percentage in the table. The result of two typical cases are given in table III.

In order to study the loss of vitamin A due to air and sunlight, the following procedure was adopted. Ten grammes of ghee were weighed in petri dishes 4 inches in diameter, so that the surface area was the same. Then these were exposed to direct sunlight and air for known durations. Then the vitamin-A contents were

assayed in the usual manner. Table IV gives the observations of a typical sample.

TABLE IV
Loss due to exposure to sunlight

Time of exposure	R-W value	BR value at 40°C.	Vitamin A γ per gramme	Percentage of loss
Unexposed	31.6	42.6	8.0	Nil
5 minutes	31.6	42.6	8.0	Nil
10 "	31.6	42.6	5.3	34.0
15 "	31.6	42.6	4.0	50.0
30 "	31.6	42.6	0.0	100.0

To study the loss of vitamin A due to ultra-violet radiation similar experiments were conducted by exposing the ghee in open dishes to the ultra-violet radiations of a Hanovia quartz mercury arc kept at a distance of 16 inches from the surface of the ghee. The observations are given in table V.

TABLE V
Loss due to exposure to ultra-violet light

Time of exposure	R-W value	BR value at 40°C.	Vitamin A γ per gramme	Percentage of loss
Unexposed	31.6	42.6	8.0	
1 minute	31.6	42.6	4.5	40.0
2 minutes	31.6	42.6	4.0	50.0
3 "	31.6	42.6	3.0	60.0
10 "	31.6	42.6	0.0	100.0

Twenty samples of ghee (*viz.*, those listed in tables I to III) whose vitamin-A content is known were tested for their fluorescence. On exposure to the quartz mercury arc fitted with an ultra-violet filter all of them fluoresced intense greenish blue. Using a Pulfrich photometer, the fluorescence of these samples was compared, keeping the ghee which contained 17.5γ per gramme of vitamin A as standard. It was observed that the intensity of fluorescence had no relation to the vitamin-A content as all of them showed nearly the same fluorescence.

From the results presented above the following conclusions are drawn :—

(1) The vitamin-A content and Reichert-Wollny values of 10 samples of ghee from Bengal and Sind provinces have been studied. Sind ghee contains on an average 12γ of vitamin A per gramme, while Bengal ghee contains about 8γ of vitamin A per gramme.

(2) There is no relationship between R-W value and the vitamin-A content of ghee.

(3) The study on the loss of vitamin A by heating shows that the loss begins to appear at temperatures higher than 100°C.

(4) Considerable and rapid loss of vitamin A is observed when ghee is exposed to sunlight.

(5) There is no correlation between vitamin-A content and fluorescence of ghee.

Because of the wide prevalence of vitamin-A deficiency diseases in India and the large availability of ghee, the question whether ghee can supply the daily human requirements of vitamin A is important from a nutritional point of view. Unlike the other vitamins, vitamin A is stored in the liver and the daily requirement of an adult has been assessed to be about 1,000γ of vitamin A. It has been observed in the above study that good butter after clarification gives a ghee which contains about 10 to 15γ of vitamin A per gramme. The daily needs of vitamin A will be satisfied only if there is a daily intake of 100 to 150 grammes of ghee (3

MICROBIOLOGY

INCIDENCE OF SALMONELLA INFECTION IN RATS IN CALCUTTA

By S. C. GHOSAL, M.B., D.P.H., D.B. (Lond.)
(From the Department of Microbiology, All-India Institute of Hygiene and Public Health, Calcutta)

Review of literature.—In England and America rats have been incriminated as important reservoirs of salmonella organisms. Savage and Read (1913) examined the liver, spleen, faeces and heart-blood of 41 rats and isolated five strains of *Salmonella enteritidis*. Savage and White (1923) isolated six strains of the same organism from the liver, heart-blood and intestinal content of 96 rats. Kerrin (1928) made cultures of spleen and liver of 100 rats and isolated 11 strains of *S. enteritidis*. Recently Khalil (1938) in a more extended series isolated 45 strains of *S. enteritidis*, 40 strains of *S. typhi murium*, three strains of *S. newport* and one strain of *S. thompson*, respectively, from 750 rats. In America, Meyer and Matsumura (1927) examined 775 rats and isolated 28 strains of *S. enteritidis* and 30 strains of *S. typhi murium*. Verder (1927) also recorded the isolation of five strains of *S. enteritidis* and one of *S. typhi murium* from 114 rats. Furthermore, Salthe and Krumwiede (1924), Savage and White (1925), Jones and Wright (1936) have definitely incriminated rodents (rats and mice) as the source of infection in certain outbreaks of food poisoning. As far as we are aware, no work on the above lines has been done in India. Outbreaks

(Continued from previous column)

to 5 ounces). This however is impracticable. Yet as at present the quantity consumed is but a small fraction of the needs, systematic propaganda for larger consumption of ghee by all classes of people will be valuable, especially as ghee is available in large quantities, and is the only animal fat consumed by the average vegetarian Indian.

Acknowledgments

The authors desire to express their indebtedness to Bt.-Col. Sir R. N. Chopra and to Prof. G. Sankaran for their kind interest in this work. They also desire to thank Mr. K. K. P. N. Rao for help in this work.

of food poisoning due to salmonella organisms are not of infrequent occurrence in Calcutta. A close association also exists between human beings and rats in the city. It was felt worth while therefore to conduct a survey on the incidence of salmonella infection in rats in Calcutta.

Source and species of rats.—The majority of rats for this investigation were collected from the port area. Many were also obtained from residential houses, slaughter houses, markets, and bustees. Fifty per cent of the rats examined were *G. varius*, 30 per cent *R. rattus* and the remaining 20 per cent *R. norvegicus*.

Technique of investigation.—Bits. of liver, spleen and intestine (colon) were put into tetrathionate broth (Jones, 1936) incubated at 37°C. for 18 hours and then plated on MacConkey's plates. In the beginning, both Mueller's broth and Kauffmann's (1935) modification of it were used for enrichment, but the latter was given up later as there was no special advantage in its use. Suspicious colonies were picked up from the plate and slide agglutination with standard O sera (Oxford standard agglutinating sera and sera supplied by Dr. Kauffmann) was done for preliminary identification. Strains giving positive agglutination were subcultured and examined morphologically, and biochemically in the usual manner. Final diagnosis was made by macroscopic agglutination with H and O sera, separately. On fresh isolation many strains gave cross agglutination with both *typhi murium* and *enteritidis* O sera; this was due probably to the presence of common antigen XII, but after a few subcultures this feature was not noticed.

Results.—In all, 364 rats were examined and the results are given below:—

TABLE I
Showing the number of positive rats and the strain isolated

Organisms	Number of rats positive	Number of strains isolated	Percentage of positive rats
<i>S. enteritidis</i>	13	22	3.57
<i>S. typhi murium</i>	36	59	9.89
TOTAL	49	81	13.46

Showing the distribution of infection in different organs

Organisms	L	S	I	L	S	I	L	S	I
	Only	Only	Only	and S	and I	and I	and L	and S	and I
<i>S. enteritidis</i>	4	2	1	3	2	1	1		
<i>S. typhi murium</i>	7	5	3	10	4	2	2	4	

L = Liver.

S = Spleen.

I = Intestine.

TABLE III
Showing the number of strains isolated from each organ

	<i>S. enteritidis</i>	<i>S. typhi murium</i>
Liver	..	10
Spleen	..	7
Intestine	..	5
	27.2%	72.8%

TABLE IV
Infection rate in the different species of rats

Species of rats	Percentage of infection
<i>G. varius</i> ..	12.2
<i>R. rattus</i> ..	14.1
<i>R. norvegicus</i> ..	13.9

Discussion.—It will be seen from table I that 13.46 per cent of the rats examined were found infected with salmonella organisms (*vide* also table IV). This figure is much higher than the results of any previous worker who has dealt with a large number of rats. For example, Meyer and Matsumura isolated salmonella organisms from 7.5 per cent of the rats examined, while Khalil found only 7.3 per cent positive. As regards the species of salmonella isolated, it will be noticed that there was a great preponderance of *S. typhi murium*. While the infection rate for *S. enteritidis* was only 3.57 per cent the rate for *S. typhi murium* was 9.89 per cent. Also of the 81 strains isolated 27.2 per cent were *S. enteritidis* and 72.8 per cent *S. typhi murium*. Most investigators outside India have found *S. enteritidis* as the predominating organism and a few *S. enteritidis* and *S. typhi murium* equally common. In Calcutta infection with *S. typhi murium* appears to be more frequent.

From tables II and III it will be seen that 18 out of 49 positive rats were found to be harbouring the organisms in the intestine. This works out to an intestinal infection rate of 5 per cent in the total rats examined. This is a very high figure and it is unnecessary to emphasize the danger of contamination of food with the infected faeces of these rodents in the city, especially as the hygiene sense of the population is not too well developed and as the rodents live in intimate association with human beings. It is suggested that in future all outbreaks of food poisoning be investigated with a view to finding out (a) the causal agent, and (b) its source. It may also be necessary to start an anti-rat campaign in the city.

Summary

(1) Three hundred and sixty-four rats were examined for salmonella infection and 49 or 13.4 per cent were found positive.

(Continued at foot of opposite page)

VALUE OF EIJKMAN TEST IN THE DIFFERENTIATION OF AEROGENES ISOLATED FROM MILK

By R. BANERJEA, M.B., D.T.M., D.P.H.

(From the Department of Microbiology, All-India Institute of Hygiene and Public Health, Calcutta)

THE Eijkman test (1904) was originally introduced for the differentiation of 'faecal coli' from 'aerogenes'. The experience gained in the last few years has however shown that the test is not as valuable as it was at first supposed to be. Wilson (1935) has introduced important modifications in the technique and has claimed that the modified test is of very considerable value in differentiation. In India however even Wilson's modification has not proved very helpful in all cases. Raghavachari and Iyer (1939), working with several strains of aerogenes isolated from water, found that about 60 to 70 per cent of the strains were Eijkman-positive instead of negative. The writer, in the course of his work on the bacteriological analysis of milk samples in Calcutta had used the Eijkman test for differentiation of faecal coli from aerogenes, found that positive Eijkman tubes also showed presence of aerogenes in fair numbers. Although this observation preceded the observations of Raghavachari and Iyer quoted above it was not published.

The present work was therefore undertaken to corroborate the above finding and to find out

(Continued from previous page)

(2) Of the positives 72.8 per cent were infected with *S. typhi murium* and 27.2 per cent with *S. enteritidis*.

(3) In 5 per cent of the rats the organisms were being excreted through the intestine.

Acknowledgment

I wish to thank Dr. K. V. Krishnan, M.B., B.S., M.R.C.P., D.B., D.Sc., Professor of Microbiology, All-India Institute of Hygiene and Public Health, for the help and advice received in the course of the work.

the true value of Eijkman test in the differentiation of aerogenes isolated from milk. From 50 samples of milk obtained from various sources a total of 153 aerogenes strains was isolated and tested by Eijkman's method as modified by Wilson. MacConkey broth tubes were inoculated with a loopful of a young peptone water culture of the organism and incubation was done in an electrically-heated covered water-bath made of copper, set exactly at 44°C.; and the temperature recorded was of the MacConkey broth medium and not the water in the bath. The results obtained are given below:—

TABLE

Number of aerogenes examined	Number of aerogenes giving positive Eijkman test at 44°C.	Percentage positive	Number of aerogenes giving negative Eijkman test at 44°C.	Percentage negative
153	106	66.28	47	30.72

It will be seen from the table that about 70 per cent of aerogenes obtained from milk isolated in Calcutta gave a positive Eijkman test. As the strains of aerogenes used were all citrate-positive, the above result also shows that in 70 per cent of cases there was no negative correlation between Eijkman test and citrate test. This is contrary to the results of Clegg, Sherwood and Dodgson (1939) who obtained in England almost a perfect negative correlation between 44°C. Eijkman test and citrate test. A possible explanation for this discrepancy may be in the differences in the climatic conditions of the two countries—England and India. If it is recognized that the environment can influence the behaviour of bacteria then we can understand why the tropical aerogenes behave differently from the aerogenes of temperate climates. Because of higher atmospheric and soil temperatures in India, the aerogenes may have developed the capacity to live and multiply at higher temperatures. If it is so, then the differentiation by the Eijkman test is not valuable under Indian conditions.

BACTERIOPHAGE AS AN INDEX OF WATER CONTAMINATION

By C. L. PASRICHA
MAJOR, I.M.S.

Professor of Bacteriology and Pathology
and

A. J. H. DEMONTE, I.M.D.

(From the Department of Bacteriology and Pathology,
School of Tropical Medicine, Calcutta)

BECAUSE of technical difficulties of isolating pathogenic bacteria from waters (even from waters known to be contaminated fairly recently), the presence or absence of *Bacterium coli* in water supplies and the relative numbers of this organism if present are recognized as indications of the presence and degree of faecal pollution. This is based on the assumption that the more bacteria of intestinal origin there are in water, the more likely are pathogenic species to be amongst them.

The presence of *Bact. coli* type I is accepted as the most delicate index of recent faecal contamination and the practical value of the 'coli test' in establishing the standards for drinking water is accepted by all those concerned with the bacteriological examination of water supplies. It must, however, be remembered that the evidence at best is circumstantial and conclusions drawn from it cannot be considered as unequivocal as conclusions based on direct evidence. Further the usual method of bacteriological examination of water gives no indication whatever of the source of any contaminating bacilli found in it. They may be from animals other than man. In addition there are many problems, connected with the multiplication of coliform bacilli which may cause difficulties in the bacteriological examination of water supplies perhaps of great significance under tropical conditions.

In order to collect more direct evidence of the presence in water of contamination with excreta of human origin, a search was made for

comparatively easy, employing appropriate methods, to isolate bacteriophages active against these organisms. The methods employed are outlined below:—

(A) The collection of water samples.—Samples of water collected in clean and sterilized bottles are satisfactory. The usual great care must be exercised to secure the samples representative of the water to be tested and to see that no contamination occurs at the time of filling the bottles. Many of the samples of water were collected in sterilized vacuumized 25-c.c.m. ampoules which had been scratched with a file at the tip of their long necks. The tip was broken under the surface of water either with a pair of forceps or by a gentle tap against a stone or other object. The vacuumized ampoule fills and the tip is either sealed on the spot with a spirit lamp or closed with wax, to be sealed later. In this way extraneous contaminations are avoided. This method of collection is particularly useful when samples are to be transported any distance or when they are sent through the post.

(B) The demonstration of bacteriophages in water.—Bacteriophages active against *Vibrio cholerae*, *Bacterium typhosum*, *Bact. shigæ* and *Bact. flexneri* were tested for in each sample. These organisms were chosen as representing the main group of organisms responsible for intestinal infections in man and because these organisms give rise to disease in man alone.

The sample of water in the ampoule is transferred to a flask containing 50 c.c.m. of nutrient broth or peptone water to which are added 1 c.c.m. each of young cultures of smooth strains of *V. cholerae*, *Bact. typhosum*, *Bact. shigæ* and *Bact. flexneri*. The cultures used must be free from any contaminating bacteriophage. The flasks are incubated for 48 hours, N/10 NaOH added, if necessary, to maintain an alkaline reaction as shown by the indicator (phenol red) previously added to the broth. The contents of the flask are filtered through Pasteur-Chamberland L₃ candles and the filtrates tested

TABLE

bacteriophages active against organisms which cause disease in man. Whereas it is difficult to isolate pathogenic bacteria from waters it is

for the presence of bacteriophage by the drop method, using young test cultures on nutrient agar plates.

Five hundred and sixteen samples of water collected from four main sources were examined for the presence of bacteriophages active against the causative organisms of typhoid, dysentery and cholera. The results of these examinations are summarized in tabular form.

It must be stressed that the results from different places are in no way comparable nor of equal significance. The samples from Calcutta were collected from river and certain tanks throughout the year, whereas samples from other sources were collected during short periods. The samples from Hardwar were collected during and for a short period after a Kumbh Mela when the place was literally packed with pilgrims from all parts of India. Samples from the hill station were collected during the summer when there were many visitors from the plains. The number of samples examined are far too few for the results to have any real significance. It is interesting to note that stored spring waters gave the best results.

Unfortunately, it was not possible to carry out parallel bacteriological examinations of these samples. These results show that bacteriophages active against the causative organisms of typhoid fever, dysentery and cholera are present in approximately 50 per cent of the samples examined.

Summary

A method of examination of waters for evidence of contamination with human excreta is suggested. This is based on the assumption that the presence of bacteriophages active against human intestinal pathogens indicates that the particular sample of water has been contaminated by excreta of individuals who harbour such bacteria. The more definite information obtained by the bacteriophageic examinations of water it is suggested should lead to the inclusion of this method in the routine examination of water.

THE TUBERCULOSIS ASSOCIATION OF INDIA

*The Lady Linlithgow Tuberculosis Sanatorium,
Kasauli*

HER Excellency the Marchioness of Linlithgow, the President of the Tuberculosis Association of India, performed the opening ceremony of this all-India institution on the 21st May, 1941, in the presence of a distinguished gathering. This sanatorium will have accommodation for 112 beds to begin with, which, it is hoped, in course of time will be increased to 250 beds.

The sanatorium is to some extent a co-operative institution as regards its maintenance, the system providing a lien on one or more beds in return for an annual contribution. Apart from

an annual grant of Rs. 20,000 by the Government of India, support for the maintenance is received from the Punjab and United Provinces Governments, the States of Chamba, Gwalior, Jind, Jodhpur, Lunawada, Patiala and Travancore, from the Pasteur Institute Association of India, and also from the Tuberculosis Association of India, Bengal, Delhi and Sind.

An alternative contributory system is by endowment of beds at a cost of Rs. 20,000 each. This system has been adopted by Lala Shankar Lall of Delhi, two beds, and by Nabha and Tehri (Garhwal) States, one bed each.

In addition to these contributions, Sir Shri Ram has made a generous unconditional donation of Rs. 5,000 a year for ten years.

At the opening ceremony two munificent donations were announced to the funds of the sanatorium, one from Her Excellency Lady Linlithgow, the President of the Tuberculosis Association, of Rs. 20,000, and one from the Patron, His Excellency the Viceroy, of Rs. 10,000.

Dr. T. J. Joseph, formerly medical superintendent of the Pendra Road Sanatorium, has been appointed medical superintendent of the Lady Linlithgow Tuberculosis Sanatorium, and Dr. H. N. Sahgal has been temporarily lent by the New Delhi Tuberculosis Clinic for the post of second doctor for the sanatorium.

In Her Excellency's opening speech she remarked :—

'I want now to give you a true picture of the scheme. It would be a complete misunderstanding of the objects of the scheme if it was thought that this sanatorium was established only for the treatment of 100 patients. It, therefore, will not be out of place to explain that, apart from the benefit which will accrue to the individual patients, the scope of the institution is a far wider one. This sanatorium is to be a teaching institution where practical demonstration of the various up-to-date methods of diagnosis and treatment will be available to doctors from all parts of India. This is very necessary in a country where in the majority of sanatoria and tuberculosis clinics the level of efficiency is far below what it should be.'

It is necessary to emphasize that the greatest difficulty in the tuberculosis campaign in India is not, as generally supposed, lack of money, but the lack of a sufficient number of doctors properly trained in modern methods of diagnosis and treatment. It is a hopeless task to try and fight tuberculosis in India without having doctors who have specialized not only in diagnosis and treatment but also in the prevention of the disease and in the care and after-care of the tuberculous patient. The difficulty facing us is not the lack of doctors willing to take up special training, but that there are in India too few places where all the facilities exist for the proper training of such doctors. This training requires at least nine months' residence in a fully-equipped modern sanatorium, such as this

one, where doctors can gain experience in the wards, in the operating theatre, the x-ray and the laboratory. Research work will also be carried out there, without which no teaching institution can be complete. By research I don't mean only bacteriological research, but research necessary with regard to the development of the disease and the various treatments.

While bacteriological research can be carried out in a comparatively small institution, the other kind of research can only be effectively carried out in a sanatorium or hospital with a large number of patients.

The object of the Kasauli scheme is a very wide one and it is intended that the institution should serve the whole of India by effective co-operation with those sanatoria and clinics which have not got the facilities necessary. From institutions where patients are not able to have the modern chest operations, it is proposed that they should be sent to Kasauli where these operations could be performed and where possibly they need not be detained for more than two months after which they would return to the institution which sent them, for further treatment. This co-operation is of the utmost importance to get the full value out of the Kasauli scheme as in this way hundreds of patients each year could take advantage of the facilities to be obtained here.

New tuberculosis institutions

Bengal.—The Government of Bengal have approved the proposal to establish a tuberculosis sanatorium at Peshok in the Darjeeling district. Steps for acquisition of land are already under way and provision has been made in the budget for 1941-42.

Assam.—There is only one chest clinic in the province situated in Shillong, attached to the Civil Hospital. Some special equipment was supplied by the Tuberculosis Association and some was presented by Major R. A. Haythornthwaite. Two home visitors are attached to it. An x-ray department has also been opened.

Jhalupara on the border of Shillong town has been selected for the location of a tuberculosis sanatorium for the province.

A comprehensive programme has been drawn up by the Assam Provincial Tuberculosis Association and the Assam Government, it is learnt, has provided a sum of Rs. 90,000 in their budget for capital expenditure in connection with the scheme.

The United Provinces.—The first of the chain of tuberculosis clinics in the United Provinces has been opened in the King Edward VII Hospital. The Provincial Tuberculosis Association has granted Rs. 8,000 to the clinic and the Benares Municipal Board has sanctioned an annual grant of Rs. 1,200.

N. W. F. P.—(1) The Government Tuberculosis Sanatorium, Dadar, Hazara district, was built at a cost of Rs. 1,84,000 and was

equipped at a cost of Rs. 20,000. The maintenance expenses come to Rs. 36,228 per annum. Two medical officers trained in tuberculosis are attached to it.

(2) In Haripur there is a four bed tuberculosis ward attached to the Civil Hospital. This ward cost Rs. 3,212 and was equipped at a cost of Rs. 1,538. A part-time medical officer is attached to it.

(3) The Tuberculosis Ward, District Jail, Abbottabad, was built at a cost of Rs. 19,917. One full-time sub-assistant surgeon is engaged and the annual maintenance expenditure comes to Rs. 4,000 per annum.

(4) The Tuberculosis Clinic in the grounds of the Lady Reading Hospital, Peshawar, was built at a cost of Rs. 10,000. One full-time medical officer trained in tuberculosis and three health visitors are attached to it. The annual maintenance expenditure comes to Rs. 8,000.

Baluchistan.—A tuberculosis clinic has been opened in Quetta, as a vital necessity to the Baluchistan Tuberculosis Sanatorium.

Cochin State.—As a result of the campaign against tuberculosis initiated by Her Excellency Lady Linlithgow, a new tuberculosis clinic has been opened in the middle of February 1941, at Trichur in the compound of the Civil Hospital. The total expenditure on the clinic has been Rs. 30,000 inclusive of Rs. 17,000 spent on its equipment. Mr. Thattil Koehuvaried, a merchant of Trichur, gave a donation of Rs. 10,000 for the construction of the clinic, the balance being met from the subscription of the State to the King Emperor's Anti-Tuberculosis Fund. The clinic has an accommodation for 14 patients.

The clinic has been placed in charge of a doctor whose services have been lent to the Cochin State by the authorities of the Arogyavaram Sanatorium.

The clinic has become very popular within the first few days of its opening. Already over 200 patients were attending every day by the beginning of March.

PUBLIC HEALTH REPORTS

ANNUAL PUBLIC HEALTH REPORT OF THE PROVINCE OF ASSAM FOR THE YEAR 1939.
BY LIEUT.-COLONEL A. M. V. HESTERLOW,
M.B., Ch.B. (EDIN.), B.Sc., P.H. (EDIN.),
D.T.M. & H. (EDIN.), I.M.S., DIRECTOR OF
PUBLIC HEALTH, ASSAM.

The climatic, agricultural and economic conditions during the year were on the whole satisfactory. Rainfall was in deficit till the month of May but from that time onwards—except in the month of August when it was again in deficit—it left no room for complaint. Agricultural operations proceeded apace and, in the absence of any setbacks in the form of floods or prolonged droughts, resulted in a fair harvest. Prices of agricultural produce showed a slight rise owing, apparently, to the tense international situation which prevailed in the earlier part of the year and which later culminated in the outbreak of war in September. The sum total of all these factors is reflected in the general well-being of the people.

The agency for collecting the vital statistics remained the same as before and the figures representing vital occurrences in the different areas may be presumed to

be as reliable as those of the previous years. In the working out of ratios, on the other hand, a change has been made this year; the ratios have been worked out not on the basis of the census population of 1931 as hitherto but on what is termed the 'estimated population'. As the estimated population has apparently taken no account of the increase of population by immigration, the ratios pertaining to areas such as Kamrup, Nowgong, Darrang and Lakhimpur where immigration is active should be accepted with caution.

The statistics show that, like the North-West Frontier Province and Sind, Assam had a lower birth rate and death rate than the remaining provinces in India. The birth rate (28.44) compares well with the quinquennial average (28.40) and the death rate (19.25) with the quinquennial average (19.63). Infantile mortality was lower than in any other year during the last ten years but even so the rate, *viz.*, 149.73 per mille, is high. The table showing mortality according to sex and age shows that wastage of life is higher among the males till the age of 15 is reached after which till the age of 40; at any rate, the wastage is markedly larger among the females. It is perhaps safe to assume that this larger wastage of life among the female population is in some way connected with the strain of child bearing. This appalling loss of young mothers and children brings into prominence the need of expansion of maternity and child-welfare work.

The saving of young life is, however, only a part of the bigger problem of protecting human life in general by preventive means. Of the diseases accounting for deaths during the year, the chief ones are fevers, dysentery, diarrhoea, cholera and small-pox.

The head 'Fevers' includes not only malaria and kala-azar but also various diseases having fever as their predominant symptom. It may not be possible to state the proportions of deaths occasioned by the various diseases falling under this head. But it is common knowledge that malaria accounts for by far the largest number. The amount of sickness due to malaria is even larger and the importance of carrying on an incessant fight against this scourge which literally saps the vitality of the population has constantly been before the mind of the Government. Apart from the anti-larval operations carried on in various places under the supervision and guidance of the Assam Medical Research Society, quininization is being extended to the limit of the provincial resources, in spite of the stoppage of free supply of quinine hitherto made by the Government of India and the increase in price of the anti-malarial drugs due to the war.

There is probably room for more consumption of the anti-malarial drugs and as it would be impracticable to purchase all the amount needed, Government are directing their attention towards the cultivation of cinchona within the province.

Kala-azar continued to show signs of recrudescence. An increase in the staff and intensification of surveys led to a greater number of cases being detected and treated than in the previous year. Goalpara, Nowgong and Sibsagar between them accounted for the greater part of the increase. New treatment centres were opened wherever necessary and in Golaghat (Sibsagar district) arrangements were made for in-door treatment of cases which were either too ill to travel or showed complications requiring closer medical observation.

Typhoid fever is a difficult disease to diagnose and statistics even from town areas cannot be said to be reliable. It is suspected that contaminated water-supply is a contributory cause and Government would like to draw the attention of those municipal bodies which have not yet provided uncontaminated sources of water-supply to their responsibility in the matter.

Cerebro-spinal fever which claimed 235 victims in the Naga Hills and Manipur State during the preceding year claimed only 11 during the year under report.

Cholera, dysentery and diarrhoea.—As against 11,907 deaths from cholera in the preceding year the number of deaths in 1939 was 3,020, out of which 1,470 occurred in January and represented the end of the previous year's epidemic. The death rate was less than half of

the decennial average and the year in question must be regarded as having been remarkably free from cholera. The department was on the whole prompt in sending medical aid but there is still room for improvement in the prompt reporting of first cases from out-of-the-way places. The question of effecting an improvement in this matter and in diffusing general knowledge as regards first steps which the villagers can take before medical aid reaches them is engaging the attention of Government.

Small-pox.—This was the only disease, the number of deaths from which was greater in 1939 than in the preceding year. Considering that vaccination is a sure protection and that, if the statistics of vaccination appended to the report year after year are to be believed, the entire population should have been vaccinated long ago, it would be well for the director to find out whether and how far the failure is due to (1) the insufficiency of the staff and vaccine, (2) failure or reluctance of the staff to visit out-of-the-way places and (3) reluctance of persons to undergo vaccination.

Maternity and child-welfare work.—Mention has already been made about the importance of maternity and child-welfare work. Progress has been difficult for various reasons; for one thing, neither the Government nor the local bodies nor the Red Cross Society have sufficient funds; for another, trained staff is limited. Nevertheless, further progress is being planned. With the growing appreciation of the work of trained *dais* the demand for training of *dais* is increasing. Facilities for informal training of a sort exist in various hospitals as well as at the Berry-White Medical School. The question of prescribing a formal course of training together with a suitable curriculum is under consideration. A Bill for registration of *dais* along with nurses and others is also under preparation.

Leprosy.—Government acknowledges with thanks the part played by the missions and the British Empire Leprosy Relief Association in the relief of leprosy. Among the leprosy colonies run by missions and deserving of special mention are those in the districts of Sibsagar and Goalpara, while the British Empire Leprosy Relief Association has assisted by providing funds for the construction of several centres for outdoor treatment and the training and entertainment of a special leprosy officer for the purpose of co-ordinating effort. It is hoped that the visit of Dr. Santra, Propaganda Officer of the Association in the cold weather, will lead to the formation of a comprehensive policy and plan. Local enthusiasm would need to be kindled if steady progress is to be achieved.

Food adulteration.—This is unfortunately a growing evil. The administration of the Assam Pure Food Act has been far from satisfactory. Except in municipal areas with health officers, there is hardly any attempt to enforce the Act. One of the difficulties probably is to enlist the co-operation of a sufficient number of local persons with the requisite spirit of public service and leisure. The procedure for sending samples for analysis strikes the average person as being unduly elaborate but it cannot be over-simplified if the accused is to have a fair trial and his guilt definitely established. Government propose to investigate the suggestion that a substantial reduction in the rate of fees charged for analysis will help to mend matters.

Propaganda.—Public-health exhibitions which have an enormous propaganda value seem to have already fallen into disuse. Apart from the treatment of epidemics as they arise the main function of the department lies in a wide diffusion of the science of healthy living. This diffusion has to be not of abstract ideas but of concrete shape into which these ideas are translated and presented in a form suited to easy assimilation by the people. The department has to be ready with type plans of model houses, latrines, uncontaminated water-supply, etc., suited to the means and conditions of the villagers. Balanced diet, causation and prevention of diseases, and first aid are also matters on which the public needs constant advice. It is only when solutions have been found in these matters and presented to the villager in a manner calculated to

enlist his active co-operation that the department will be able to look with satisfaction on its work.

ANNUAL REPORT OF THE MYSORE STATE DEPARTMENT OF PUBLIC HEALTH FOR 1939

Two thousand three hundred and fifty-two deaths from plague were reported as against 5,196 in the previous year. As a preventive measure, in addition to the 132,536 anti-plague inoculations, rat destruction by means of cyanogas fumigation was carried out in nearly 27,000 houses in various parts of the State, including the cities of Bangalore, Mysore and the Kolar Gold Field. There were only 533 deaths from cholera. It is gratifying that this disease is not endemic in the State and that if timely measures are taken to prevent infection from outside, it is quite possible to control it.

Vital statistics.—The new system of compiling vital statistics introduced in the State in 1938 was adopted as a model for the other Provinces and States of India.

Public health institute.—Sixteen thousand five hundred and twelve samples in the Bacteriological section, 2,543 samples in the Chemical section and 312 cases with 1,141 articles in the Medico-legal section were examined. During the year 11,010 c.c.m. of anti-cholera vaccine and 31,531 c.c.m. of T.A.B. vaccine were issued for use. Biological methods of investigation of the nutritive value of foodstuffs were continued.

Bureau of health education.—During the year, 173 cinema shows were given in 103 places in all the districts to an audience of about 105,000, compared with 190 shows in 94 places to an audience of 114,000 in the previous year. The permanent Health Museum in Mysore was kept open to the public throughout the year. Two models of a bore-hole latrine and a bore-well, respectively, were added to the exhibits during the year and another of a rat-proof house was under construction. Health exhibitions were also held in Bangalore City and the Kolar Gold Field on the occasion of the 75th anniversary celebrations of the Red Cross Society. Village improvement works on a health league basis were carried out in the Health Training Centre, Clospet, in 40 villages.

Bureau of epidemiology—malaria control.—Among the several anti-malaria measures sanctioned during the year may be mentioned the permanent anti-malaria engineering works at Hiriyur, the anti-malaria work at Belur, the malaria control work around the Princess Krishnammanni Sanatorium, Mysore City, and the starting of itinerant dispensaries at Krishnarajnagar and Pavagada.

Malaria control was continued during the year in the Bhadravati old and new towns, and at Marconahalli, Shimshapur, Chikmagalur, Belur, J Half-yearly spleen and parasite surveys of the ten control and the four comparison villages of the Mandya Malaria Unit were made. The permanent anti-malaria engineering measures under execution at Bevinahalli, Kyatanagere and Sundahalli were in progress during the year.

The staff deputed for guinea-worm control visited 672 villages, examined 570 wells and restocked fish in 266 wells, while that engaged in hookworm control work visited 97 villages in the Periyapatna Taluk, also making a spleen survey in these villages and distributing 4,821 totaquina tablets to persons actually suffering from malaria.

Bureau of sanitary engineering.—The work of this bureau was divided into five sections, viz, Water-supply, Drainage, Town Planning and Surveys, Sanitary Fitings and Installation, and Bore-wells. A separate division was created during the year for the Bangalore city drainage works. The bureau maintained the water-supply installations of twenty-five places and completed ten out of the twenty-one drainage works under execution. It also prepared plans for the improvement of junctions and extensions and for slaughter houses and mutton stalls and designs for dwelling and farm houses, rat-proof dwellings and cattle pounds.

Bore-wells.—The total number of bore-wells drilled for local bodies up to the end of December 1939 was 156. In the year under report, twenty-one bore-wells were completed and ten were in progress.

Bore-hole latrines.—Three hundred and forty-nine bore-hole latrines were constructed during the year.

Among the important measures carried out during the year may be mentioned (1) the constitution of a Combined Local Health Committee for the consideration of health problems in which the civil, the military and the railway authorities are concerned and for the solution of which the co-operation of all these bodies is required; (2) the constitution of a Central Health Committee with the Member of Government in charge of the Public Health Department as Chairman and the Director of Public Health as Secretary; (3) the training of thirty-nine students in the Sanitary Inspectors' Training Class; (4) the deputation of Dr. V. Narasimha Murthy to Bombay for training in the manufacture of plague vaccine and (5) the delimitation of the areas of operation for the respective agencies of the Bangalore City and the Civil and Military Station authorities to avoid overlapping of activities in respect of malaria work.

REPORT ON THE PUBLIC HEALTH ADMINISTRATION OF THE PUNJAB FOR THE YEAR 1939

The estimated mid-year population of the province for 1939 was 27,231,113 representing a further increase of half a million over the figure for the preceding year and an increase of nearly 16 per cent over the census figure. The birth rate was 40.8 *per mille* compared with 43.7 in the year 1938, the decline being more marked in the districts of the Ambala division where famine conditions prevailed. Famine conditions also accounted for more deaths in the south-eastern districts, except in Gurgaon; but the total number of deaths in the province was less than in the preceding year and the death rate was lower by 1.2 *per mille*. More than half the deaths occurred amongst children of not more than five years. The infantile mortality rate was 167.57 which is still very high, although lower than the average of the last ten years and indicates that a great deal yet remains to be done in the domain of child welfare work.

As in the preceding year two-thirds of the total number of deaths were recorded as due to fever of some kind, such as malaria, enteric, measles, etc. But little significance can be attached to these figures, as the primary reporting agencies are prone to describe the cause of death as fever without taking the trouble of obtaining accurate information. That the figures cannot be regarded as reliable or of any real value is clear from the fact that in the Amritsar district where 2,760 deaths were reported under the group 'Fever', 82 per cent of them were found on investigation by the medical registrars to have been due to some other cause. It is, however, known that malaria was not unduly prevalent during the year under report. More than 4,000 lb. of quinine and cinchona febrifuge were distributed free. Other anti-malaria measures were also carried out, so far as was possible with the limited personnel and funds at the disposal of the Public Health Department.

Of 4,311 deaths which were due to small-pox more than 50 per cent occurred amongst children under five years of age. Over 4½ million vaccinations were performed during the season 1939-40; but a vigorous vaccination campaign on a widespread scale can achieve full results only when all births are registered and the outbreak of the disease is promptly reported. It is gratifying to note that some improvement has already become evident in certain districts as a result of the action taken on the report of the district medical officers of health against village headmen and village watchmen for neglecting to furnish information in regard to the appearance of an epidemic disease.

Only 19 deaths occurred from cholera and no case of plague was reported. As a precautionary measure

nearly 200,000 anti-cholera inoculations were carried out and over a million rats were destroyed. Survey work in leprosy has been carried out systematically and 21 districts have now been covered. In order to discourage lepers belonging to other provinces from coming to the Punjab, Government have decided that a leper home will not be entitled to a grant in respect of a non-Punjabi patient admitted in future, unless at the time of his admission he was certified by the civil surgeon of the district to be in a dangerously infective condition. Anti-hookworm survey was conducted in certain talukas of the Sialkot and Amritsar districts; and 118,636 patients were treated as compared with 87,863 in 1938 and 49,423 in 1937.

The outstanding event of the year was the commencement of work on the Lahore Drainage and Sewerage Scheme which, when completed, will effect remarkable improvement in the health of the capital of the province. In four other towns drainage schemes were in progress and in five towns they were completed. Water-supply schemes were completed in nine towns. For sanitary works in villages, such as the construction of proper platforms for wells to prevent the water from contamination, the sinking of new wells and the paving and drainage of village streets a sum of Rs. 2 $\frac{1}{2}$ lacs was allotted by Government. A condition was imposed that the villagers would contribute in labour, material or money one-third of the cost of any work financed under the scheme. The cheerful acceptance of this condition is a heartening sign that the villager is not indifferent to environmental hygiene and is anxious to live in healthy surroundings.

Eight new maternity and child-welfare centres were organized during the year bringing the total to 102.

Refresher courses were held at most of the centres for certificated *dais* in order to prevent any deterioration in their knowledge or standard of work. The number of *dais* under training was 2,593 and certificates after completion of training were obtained by 627 *dais* as compared with 563 in the preceding year.

The Public Health Department is to be congratulated for its excellent work in the Hissar district where, owing to the prevalence of scarcity conditions, new and difficult problems arose which required special energy and imagination. The resistance to disease was low and health conditions in general were a matter of deep concern. The food which was available to the famine-stricken population was not only scarce, but also lacking in the necessary vitamins with the result that deficiency diseases, such as scurvy and night-blindness, appeared and had to be combated. In order to secure co-ordination in preventive and curative measures all rural dispensaries in the district were transferred temporarily to the control of the public health department. Special treatment centres were established and arrangements were made for the visiting of the sick in their villages by medical officers. Vaccinations and anti-cholera inoculations were carried out vigorously; while deficiency diseases were brought under control by the free supply of germinated grain.

It was stated last year that Government were engaged on the consideration of a proposal that vegetable *ghi* should be allowed to be sold only if it bore a distinctive colour. Legislation to this effect has now been passed and a rule has been made that no artificial *ghi* shall be sold, or offered or exposed for sale, or kept in possession for the purpose of sale, unless it is coloured with Oil Orange E in the prescribed degree.

Current Topics

Methods Used for Improving Athletic Performance

(From the *Journal of the American Medical Association*, Vol. CXV, 12th October, 1940, p. 1281)

THE term 'doping' was originally used to describe methods designed to increase the functional efficiency of athletes by means of highly active drugs. Now it is employed to describe any method of improving athletic performance temporarily either during training or in connection with competitive events. Boje has classified such substances into four groups: food preparations, oxygen, artificial sunlight and pharmaceutic substances.

Most of the food preparations, especially dextrose or sugar, which provide calories in a readily acceptable or otherwise suitable form are unobjectionable medically, Boje feels. The evidence for the use of lecithin is not convincing and there seems to be no reason why it should be recommended for improving athletic performance. Similarly there is no experimental basis on which to recommend the use of yeast, although it does not appear to be deleterious. Conclusive evidence on the rôle of liver preparations in muscular work and its efficacy for increasing physical energy is also lacking.

Phosphates which have been employed can often cause a purely subjective feeling of freshness and zest for exercise which may amount to a condition of euphoria. Boje concludes that phosphates taken in quantities exceeding the amounts found in a normally varied diet can probably increase the output of the organism. Although there is considerable loss of salts in heavy physical effort, this is probably insufficient to warrant administration of salts except in prolonged contests. Alkalies, usually in the form of sodium carbonate, have also been employed. Before deciding to administer them, attention should be given to the fact that the change produced by exertion in the pH of the blood and its carbon dioxide tension influences

among other things the regulation of respiration. Further, the administration of alkalies by mouth constitutes such a violent interference with the whole pH regulatory system that it is as likely to be detrimental to the maximum physical output as the reverse. For a small group, such as aviators and mountaineers, ammonium chloride can be considered as an agent capable of increasing functional capacity. Other than for occasional slight local irritation, there can be no medical objection to its use.

The use of pure oxygen as a 'dope' has been discussed from time to time. It may be granted that if it is administered immediately before the start of a contest, especially in the case of underwater swimming, it may exert some favourable effect. Nevertheless Boje feels that most athletes and sports leaders have a fanciful and confused idea about the meaning of 'oxygen priming' and that it is highly questionable whether the inhalation of oxygen is of any advantage in ordinary sports events.

Much has been said recently about the value of ultra-violet rays in connection with athletic training. Certainly if administered in suitable doses ultra-violet radiation should not produce any dangers, although athletes who are not used to ultra-violet rays should refrain from exposure immediately before taking part in competitions.

Pharmaceutical substances have been used in athletics based on their influence on the nervous system either as stimulants or as soothing agents. The toxic action of alcohol so overshadows its other effects that its rôle as a source of energy is of little athletic importance. Ether has been included by some as a 'doping' agent but its use does not appear to assume any real importance in connection with sports. 'Smelling salts', usually consisting of a solution of ammonia and of ammonium carbonate combined with ethereal oils, is popular in the prize ring and can be pronounced harmless.

Cocaine is one of the oldest known forms of 'dope', although the extent to which it is now used by athletes is unknown. Leaving aside the question of whether or not it affects metabolism favourably, its influence on the central nervous system, which constitutes the motive for its use as a stimulant, cannot be questioned. Cocaine is effective in removing the sensation of fatigue and can in this manner undoubtedly raise the level of performance in the course of prolonged effort. This mechanism, however, is dangerous; it may have acute intoxicating effects when used in large doses. Its repeated use engenders addiction. Cocaine should never be used in connection with athletics.

Caffeine and other purine derivatives, although widely used as stimulants in connection with physical and mental effort, do not appear to have any established effects in connection with brief physical effort. Definite conclusions cannot be derived from the few available experiments on extended exercise. Furthermore, it is difficult to gauge how far coffee, chocolate and cocoa given to athletes in normal therapeutic doses as a physical stimulant can endanger their health. It seems likely that any substance capable of stimulating the body to exertion beyond the normal limits of fatigue set by the body will prove injurious.

Amphetamine sulphate is much more capable than caffeine of eliminating the sensation of fatigue; the overwhelming evidence of its toxicity, together with the fact that it is not definitely established that performance is improved, indicates that this substance should not be used in connection with athletics. Moreover, the application of extra stimuli or a weakening of natural powers of resistance in organisms undergoing a severe strain must involve risks.

The group of drugs including valerian, bromides and barbituric acid derivatives can be included, but there seems to be no danger of abuse among athletes since every one of these substances has powerful fatiguing properties. Digitalis and glyceryl trinitrate likewise can be readily eliminated both because of insufficient evidence of their 'doping' properties and because of their toxic effects. Nikethamide and metrazol have been employed by athletes because of their stimulating influence on the circulation and the central nervous system, which produces a definite subjective feeling of freshness in the tired organism. There is, however, nothing to show that recovery is improved and there are deleterious effects, especially in the convulsive properties of both substances. The use of such products by athletes should be definitely avoided. Finally, although various endocrine products have been tried the evidence on this subject is so flimsy that their use should be avoided, since it may involve dangers the extent of which cannot be evaluated.

Medical advisers must naturally strictly forbid the use of any agent suspected in any manner of being deleterious or any substance which may cause the least direct danger of whipping up the organism to extreme exertion. Although there can be little objection to the use of nutrient agents, of vitamins and of oxygen, the medical adviser should also do everything he can to discourage the use of costly and ineffective substances.

Treatment of Bronchial Asthma

By C. H. EYERMANN, M.D.

(From the *Mississippi Valley Medical Journal*, Vol. LXII, July 1940, p. 119)

By bronchial asthma is meant an affliction marked by recurring paroxysms of wheezing dyspnoea more pronounced in the expiratory phase, cough, and a sense of constriction in the chest due to pathology of the bronchioles. The conception of allergy has brought about better clinical differentiation of those who wheeze so that bronchial asthma can be divided on the basis of aetiology and, perhaps, mechanism into two broad classes: allergic in which specific sensitization can be proved and non-allergic in which the patient corresponds symptomatically to the allergic group but in

whom no specific factor can be discovered. The advantage of the classification is that it indicates the application of logical therapeutic measures which have resulted in increasing the therapeutic efficiency in bronchial asthma by 5 to 50 per cent during the last three decades.

The treatment of both types of bronchial asthma resolves itself into the subjective relief of the paroxysmal wheezing dyspnoea and the removal, or modification, of its cause. The plan of treatment depends upon the phase of the disease at the time of observation, the aetiological agent and upon what kind of a patient has the disease.

The successful management of the acute paroxysm of bronchial asthma can be undertaken without knowledge of its aetiology and is dependent upon the subcutaneous injection of epinephrine hydrochloride 1 : 1,000, probably better known as adrenalin. Except in those who have developed a tolerance for it, doses up to 0.3 c.c.m. are as effective and without the unpleasant and sometimes alarming side actions of the larger doses. A satisfactory method of using the drug is to fill the syringe with 0.5 c.c.m. more or less, and with the syringe remaining in place, to inject one minim or 0.1 c.c.m. a minute until the attack begins to subside or until beginning physiological effect is noted by pallor, which is often first seen about the nose by tangential light, by fibrillary muscle tremor, or by palpitation. When physiological effect is obtained, there is no need to administer more epinephrine even if there has been no improvement in the attack. In an emergency, however, one need not be concerned with overdosing, and enough should be given to produce the desired effect. In instances of extremely severe bronchospasm it is possible to give by slow continuous subcutaneous administration several cubic centimetres of epinephrine without inducing side effects.

Ephedrine and the oral inhalation of adrenalin 1 : 100 solution by means of an all-glass nebulizer are useful only for mild attacks; attacks which are more a discomfort than a paroxysm of bronchospasm. When these are not at hand, hot strong black coffee sipped slowly, emetics and measures to induce belching, inhalation of the fumes of burning stramonium leaves, and enemata will also bring about relief. Acetyl salicylic acid is used by many, is often helpful but is treacherous. The frequency with which it induces severe bronchospasm forbids its indiscriminate use and it should not be employed until one is certain beyond a peradventure that it will not induce of itself or increase an already existing bronchospasm. In these mild attacks, sedatives of the hypnotic series will be of help. They, too, should be used with discernment because they have been known to induce bronchospasm. More often they are combined with ephedrine to overcome its side effects and so there is a small measure of safety, if idiosyncrasy to them exists, as well as the advantage of their possible synergistic action.

MANAGEMENT OF PATIENT

The management of the patient with frequently repeated paroxysms of bronchial asthma revolves about the drug treatment of the paroxysm, the maintenance of nutrition, and the search for the causative agent. Experience has shown that this type of case becomes free of bronchospasm more rapidly in a hospital when the usual extrinsic causes (feather, orris root, wool, cottonseed, insecticides, animal pets, house dust) can be avoided; the nutritional status more readily maintained, and diagnostic measures employed without effort to the patient. Rapid improvement under such circumstances is presumptive evidence of an environmental factor. Some cases require, in addition, short periods of starvation or some type of trial diet before relief is obtained. In these instances, one assumes that an ingestant may be an added aetiological factor.

Generally, the asthmatic paroxysm responds to these symptomatic measures. In a small percentage, the patient remains in a constant asthmatic state despite environmental change, dietary manipulation, and subcutaneous administration of epinephrine. Soon the effect of epinephrine is transitory, even with increasing

dosage and shorter intervals of administration. Finally even large doses fail to relieve, while at the same time they increase the nervous irritability and produce palpitation, tremor, weakness, and pallor. Now one has the clinical condition which is called status asthmaticus or intractable asthma. The slightest exertion, as well as eating, drinking, or coughing increases the already existing discomfort. Anoxæmia, exhaustion, fear, and overdosage with epinephrine are the factors which aggravate the condition.

On physical examination, there is pulmonary dilatation as shown by great hyper-resonance and absence of downward expansion at the bases, with diffusely distributed inspiratory and expiratory wheezing upon easy breathing. When the patient has had a great deal of epinephrine there is also tachycardia, occasionally with extrasystoles, cold, clammy extremities, anxious expression, a certain amount of hyperkineticism, and some degree of cyanosis of the lips and nail beds. Such patients are dehydrated and undernourished because their dyspnoea does not allow sufficient amount of drink or food and usually that which is swallowed increases their discomfort so that the will to swallow is weakened. All of this goes to make up a clinical situation suggesting a fatal outcome.

The therapeutic indication for this situation is the absolute minimum of physical activity, control of the cough, correction of the anoxæmia, and liquefaction of the sputum, and can be treated by one, by a sequence, or by a combination of several therapeutic plans. Irrespective of the plan employed, discontinuance or great reduction in dosage of epinephrine should be part of the treatment.

MEDICINAL THERAPY

One of the best methods of interrupting the cycle of attacks in status asthmaticus is by means of the continuous inhalation of a mixture of 80 per cent helium and 20 per cent oxygen through the specially designed mask of Boothby, Lovelace and Bulbulian. This method decreases the amount of effort required to breathe, but there is no immediate effect upon the bronchial spasm, œdema, or secretions. It requires from 12 to 48 hours of constant inhalation to bring about improvement—the time required seemingly dependent upon the length of time the patient has been in status. As in all other types of therapy which interrupt the cycle of attacks, small doses of epinephrine again become effective during the ensuing improvement.

Aminophyllin, in dosage of 4 to 8 grains in 10 c.c.m. of glucose or normal saline, given very slowly intravenously by means of a 22-gauge needle, gives prompt relief in some instances. When the relief is temporary it can be repeated. The manner in which it induces relief is not known.

Anesthesia with ether and olive oil by rectum will break the cycle in status asthmaticus in about 50 per cent of cases. The average adult dose is 5 to 7 ounces of a mixture of equal parts of pure olive oil and surgical ether. It should be given without the usual pre-anesthesia medication because of the frequent harmful effects of the ordinary dosage of morphine, and can be given without preliminary cleansing by gravity or by a syringe, a few cubic centimetres at a time until anæsthetized. The duration of the anæsthesia is usually several hours, and after one-half to one hour of anesthesia, epinephrine in small doses again become effective. It should not be used as a matter of last resort and only in conjunction with supportive measures.

In lieu of these methods or as auxiliary measures, drugs that will control cough or induce rest will help the patient to survive until the status asthmaticus terminates. When cough is not a prominent part of the symptomatology, sedatives of the hypnotic series are helpful when given to physiological effect. Chloral hydrate, chlortone, and the bromides are the safer drugs to use because they have not in my experience nor have they been reported as inducing bronchospasm. Barbital and its derivatives are valuable but should not be given in full dosage until one is certain that hypersensitivity to them does not exist because

they frequently induce and thereby increase already existing bronchospasm. In those who have a short, frequently repeated, unproductive cough, when all other methods fail, morphine is useful in small doses provided no idiosyncrasy exists. The cough reflex is depressed by doses which are too small to exert hypnotic action so that one should use the smallest dose that will serve the purpose. It should not be employed more frequently than is necessary to maintain the required degree of control of coughing. The repetition of the single effective dose should not be at stated intervals but according to the needs of the patient and, to avoid accumulative effect, the dose should be reduced as soon as there is alleviation of symptoms. It should never be given in a customary dose of 0.015 gm. ($\frac{1}{2}$ grain) and never combined with atropine. The exact initial dose necessary for relief of cough cannot be stated because it varies with the individual and with the intensity of his symptoms, but lies between 1/32 and 1/12 of a grain of morphine for the adult; if idiosyncrasy exists even this dosage is dangerous. If the cough is not allayed by several injections at three or four-hour intervals a small increment in dosage can be tried. During the period of morphine administration the respiratory rate must not fall below 20 per minute. It is unusual to require $\frac{1}{2}$ grain (0.015 gm.) morphine during twenty-four hours as a total dosage. In some, better results are obtained by combining the morphine with small doses of epinephrine.

As a rule status asthmaticus terminates successfully when large amounts of sputum, usually purulent, are coughed up so that adequate treatment of the dehydration serves the purpose of correcting deranged metabolic processes and liquefying the sputum, and should be instituted simultaneously with, and be a part of, whatever therapeutic plan is being used. Fluids should be given parenterally and orally, if possible, the amount, type, and method of administration being determined by the exigencies of the clinical situation. Co-existing abdominal distension should be relieved by a small catheter left in the rectum to allow of the easy expulsion of gas and by enemas as soon as the condition of the patient permits. Cyanosis, when present, should be corrected by oxygen inhalation.

AETIOLOGICAL FACTOR

When the cause of the allergic bronchial asthma has been determined, all that is necessary to bring about a clinical cure is the absolute and complete avoidance of the offending substance. If an ingestant, it should not be eaten and, if an inhalant, it should not be inhaled. There is no drug which will permanently alter or prevent the effect of the absorbed allergen in the hypersensitive individual. If the causative food is essential to the maintenance of nutrition, oral hyporesensitization should be tried. Occasionally it is successful and it is more often, than by hypodermic injection. One begins by feeding minute amounts daily and increasing the amount by small increments at intervals of five days until a satisfying amount is eaten. Recurrence of symptoms from one of these increments necessitates reduction of the dose to the one at which no symptoms were produced, followed by gradual approach with smaller increases in amount to the dosage which had previously induced the symptoms. If the inhalant cannot be avoided, hyposensitization injections will be of benefit in the majority of instances, and it is emphasized that specificity is the all important determinant for success with these injections. No amount of injections of house dust will help a patient hypersensitive to orris root.

When the asthma has induced pulmonary emphysema or there is an associated infection of the bronchi or paranasal sinuses, the diagnostic problem is confused by the occurrence of bronchospasm unassociated with demonstrable absorption of allergen and the therapeutic problem is complicated by the necessity of appropriate therapy for the associated conditions. Such therapy, whether medicinal, climatic, psychic, or mechanical, is only to alleviate the effects of specific hypersensitivity and will vary with the experience, ingenuity, and enthusiasm of the therapist.

The therapeutic problem in those who appear to have non-allergic asthma is difficult. While one is treating the usual accompanying complications, one is bewildered by the diverse stimuli that induce the bronchospasm and tormented by the thought that hypersensitivity exists despite negative cutaneous reactions, such being due either to our failure to test with the proper allergen or to immunologic vagaries. Successful therapy in these cases requires a thorough knowledge of internal medicine and its diagnostic handmaiden allergy, with an expanding experience with asthmatic patients and their psychology. Practically, one decides as to the care of foci of infection, the use of vaccine, either stock or autogenous, the employment of non-specific desensitization with peptone, with milk, with typhoid or colon bacilli, with tuberculin, and such miscellaneous forms of therapy as autohaemotherapy, exposure of the various portions of the body to the roentgen ray, physiotherapy, light therapy, hydrotherapy, climatherapy, endobronchial treatment with bronchoscope, and breathing exercises—all of which have enthusiastic proponents but none of which improve all cases. The multiplicity of therapeutic plans for this type of bronchial asthma mirrors the difficulty in obtaining consistent satisfactory therapeutic results.

SUMMARY

One now has enough knowledge of the development of the allergic state and the various symptoms of hypersensitivity to advise prophylactic measures and to practise preventive medicine. This knowledge allows us to advise that the child of parents with allergic manifestations be prevented from absorbing the inhalant, ingestant and contactant allergens most frequently causing clinical allergy; to be alert to the possibilities of allergy, explaining the cause of symptoms which ordinarily might not arouse the suspicion of allergy; perhaps even having a voice in the choice of household furnishings, cosmetics, clothing, drugs, and occupation. As far as the adult is concerned, such advice is part of the active treatment, and his prophylactic treatment is the " " ic manifestations during childhood his chronic illness and its inevitable sequelae.

While one indicates methods of therapy and medicinal formulæ, it should be realized that excepting methods of hyposensitization, there is no standardized treatment—that one treats an individual influenced by the distress and the fears incident to a disease reputed to be incurable. The best therapeutic results are founded upon a study of the patient as a whole, considering his heredity, his environment, his peculiarities, and his reactions to discomfort; correcting the abnormalities found by physical and laboratory examinations, evaluating the influence of controlled environments; interpreting the observed reactions of cutaneous testing, of the ingestion of foods, and the administration of drugs in the light of past experience and applying treatment guided by the integration of this knowledge.

The Present Position of Sulphonamide Therapy

By W. R. THROWER, M.D. (Lond.), M.M.C.R.
(From the *Lancet*, Vol. I, 18th January, 1941, p. 67)

SOME two years have elapsed since the synthesis of any new sulphonamides with striking therapeutic activity, and it is now possible to say with some certainty what particular compounds will do in actual practice and what is the best procedure for tackling infections by organisms within their range of activity.

The beginning of chemotherapy in its present form was the synthesis by Jacobs and Heidelberger in 1917 in New York of a number of azocourein sulphonamides which were highly bactericidal *in vitro*, and it is something of a medical tragedy that no further study of these and allied compounds was undertaken until 1933. In this year, after experimental work had demonstrated that sulphonamido-chrysoidin was likely to be of value,

this compound was used in clinical medicine and proved to be effective against streptococci of the β -haemolytic type, meningococci and gonococci. In some respects the ease with which different agents may be tested against β -haemolytic streptococci in mice has been unfortunate, inasmuch that attention has continually been focused on infections with this organism to the exclusion of the staphylococcus, a much commoner and at present a more lethal organism when it invades the blood-stream. Danger lies in arguing that the same compounds administered in the same way will be required in the treatment of both streptococcal and staphylococcal infections simply because both organisms happen to be cocci. The different course of infections by the two organisms in the human subject shows how distinct they are.

While interest was centred on the action of sulphonamido-chrysoidin on certain streptococci came the fundamental discovery by Tréfouél and others that the activity of this compound lies in its sulphanilamide nucleus, this type of compound being long known to chemists working in the dye industry for its mordant properties. The observation that sulphanilamide was a therapeutically active drug made possible most of the chemotherapeutic research of recent times. Sulphanilamide, while less toxic than sulphonamido-chrysoidin, is a powerful drug, and its indiscriminate use may be fraught with the well-known unpleasant side effects common to all sulphonamides. The benzyl derivative of sulphanilamide (Proseptasine) is active against streptococcal infections, and seems to be less toxic than sulphanilamide. Sulphonamido-chrysoidin, the red compound presented in tablet form as Prontosil Rubrum, is held by some to be a more active streptococcidal agent than sulphanilamide. Possibly because the dye compound is less readily soluble and therefore more slowly absorbed than sulphanilamide its action is more constant, but for this reason in fulminant disease sulphanilamide is the better compound to use. A soluble dye (disodium 4'-sulphanaminophenylazo-1-hydroxy-7-acetylaminonaphthalene-3 : 6-disulphonate), marketed as Prontosil Soluble, is also available for therapeutic use. The risk of toxic reactions with these red compounds, apart from the inconvenience of dyes, limits their sphere of usefulness, and new and better drugs have largely superseded them. It has moreover been found possible to prepare a compound of sulphanilamide with a solubilizing group which is suitable for parenteral administration. This drug, whose formula is disodium-para-(γ -phenyl-propyl-amino)-benzenesulphonamide- α - γ -disulphonate, and which is marketed under the name Soluseptasine, has high antistreptococcal and antimeningococcal potency.

The therapeutic range of the earlier compounds examined is thus limited, and continued search has been made for derivatives of sulphanilamide with wider activity. In 1937 and 1938 there was synthesized a new class of compounds in which one hydrogen atom of the sulphonamide group (SO_2NH_2) was replaced by various substituents. Four compounds produced in this way deserve detailed attention: Uleron, which is para-aminobenzene sulphonamidobenzenesulphon-dimethylamide; Albucid, which is para-aminobenzene-sulphon-acetamide; M. & B. 693 or sulphapyridine, which is 2-(para-aminobenzene-sulphonamido) pyridine; and Thiazanide or sulphathiazole, which is 2-(para-aminobenzene-sulphonamido) thiazole.

Uleron, originally introduced as an antistaphylococcal agent, has also been used in the treatment of gonorrhœa, but this drug has proved disappointing in the treatment of early infections. A considerable number of cases of severe peripheral neuritis have followed its exhibition, and outside Germany its use in gonorrhœa has largely been abandoned. Albucid has the advantage of seldom causing unpleasant side effects, but it is generally regarded as a less powerful gonococcicide than the other and more popular sulphonamides. The synthesis of sulphapyridine by Ewins and his co-workers was the first outstanding advance after the demonstration by Tréfouél and his colleagues of the properties of sulphanilamide. The outstanding merit of sulphapyridine is its activity against pneumococcal infections

of all types, but it also appears to be the most potent remedy yet available for gonorrhœa and meningococcal meningitis. The fact that it is active against certain streptococcal infections is not surprising, but its routine use for these infections does not seem to be justified when other equally potent and better tolerated drugs are available. Certain cases of staphylococcal infection have responded to the use of sulphapyridine when high concentrations in the blood have been obtained.

The thiazoles are capable of further substitutions in the thiazole ring, to produce methyl and phenyl derivatives. The thiazoles as a class are moderately active against the common pathogens and detailed study of them in the clinical field was deferred until recently when reports from the United States suggested that they were of value in the treatment of staphylococcal infections. These somewhat optimistic reports have not been wholly confirmed in England, but the clinical trials have focused attention on staphylococcal infections as a whole, and on the possibility of using existing sulphonamide compounds in their treatment.

NEW APPROACH TO ACUTE INFECTIONS

To obtain the best results from these new remedies it is important to pay less attention to the conventional names of particular conditions than to the underlying organisms. For example, in the past the terms lobar pneumonia and broncho-pneumonia have been arbitrarily used, and little importance has been attached to their bacteriology; nowadays, however, the treatment as well as the prognosis is seen to turn on the nature and type of the organisms, and not on whether the lesion is alveolar or peribronchial in distribution. Fortunately many acute respiratory infections respond to treatment with one or other of the sulphonamides, but when a case is encountered which appears refractory to treatment it is good practice, if this had not already been done, to examine the flora of the sputum and see whether the predominant organism is one likely to respond to chemotherapy at all and, if so, which of the various compounds available is most suitable. In the same way the infecting organism should be determined whenever possible when treating acute infections of the skin or subjacent tissues by chemotherapy with or without the help of surgery. The kind of treatment successful in, say, a streptococcal infection is very different from that necessary in one due to staphylococci, for the latter organism is only acted on to any extent by two compounds—sulphapyridine and sulphathiazole—and then only when they are present in high concentrations in the blood conveyed to the affected part.

The haphazard exhibition of these new drugs to all and sundry infections is most undesirable, for there are still a number of infective processes which prove irresponsible to chemotherapy and in these prolonged administration may be not only useless but actually harmful.

BACTERIA INFLUENCED BY SULPHONAMIDES

The organisms affected by chemotherapy can be divided into two groups—those which are highly susceptible, and those on which the drugs exert only a moderate activity. In the first group are β -haemolytic streptococci, all types of pneumococci, meningococci, gonococci and certain strains of *Escherichia coli* and *Bacillus pestis*. These organisms are the principal causes of illness commonly attended by a high case-fatality rate. In the second group are a large number of micro-organisms which show a greater or less response to the sulphonamides depending partly on the location of the infection in the body and partly on the manner in which treatment is carried out. An instance of the effect of location is the typhoid bacillus; the typical general disease due to this organism is uninfluenced by any drug, but in the 'carrier state' with persistent infection of the urinary tract sulphapyridine acts almost as a specific. Experimental work provides an explanation of this difference. The typhoid bacillus is only slightly affected by sulphonamides in therapeutic concentrations both *in vitro* and *in vivo*, but is killed by the concentrations

attained in the urine, often amounting to 10 or 20 times those in the blood. With infections due to low-grade streptococci a different process operates, for many strains are fairly responsive to treatment but the lesion they cause has the peculiarity of shielding the organism from effective concentrations of the drug, as in subacute bacterial endocarditis, and a somewhat similar mechanism may operate in pneumonia caused by the same organisms.

The common organisms of respiratory catarrhs, with the exception of *Haemophilus influenzae* and the Friedländer bacillus, exhibit only a sluggish response to chemotherapeutic agents and the diphtheria bacillus not at all. Scarlet fever is not influenced materially by sulphonamides, but they may be strikingly effective when complications arise. Gas gangrene, tetanus and anthrax are often successfully treated with sulphapyridine, but particularly in gas gangrene variations in strains of the organisms make results inconsistent; steps must also be taken to combat the exotoxins circulating. In staphylococcal infections treatment is influenced by the nature of the lesions commonly present and also by the fact that the organism is only influenced by certain sulphonamides in high concentrations. Local lesions in the acute febrile stage respond sporadically to sulphathiazole but there is still doubt about the best way of maintaining an effective level in the blood. For bacteræmic cases both sulphathiazole and sulphapyridine are valuable when given by intravenous drip of the sodium salt in normal saline, the dosage being controlled by periodic estimation of the blood concentration.

Virus infections, except that causing lymphogranuloma inguinale, are unaffected by existing sulphonamides, although of course they may control concurrent microbial infections.

USE OF SERA

The advances of chemotherapy have been entirely in the antibacterial direction, and none of the new compounds affect toxins except in so far as they eradicate their source. On theoretical grounds it is desirable to employ antitoxic sera as adjuvants to chemotherapy, but practical considerations with regard to their administration, apart from the factor of availability in the right place at the right time, do not make combined therapy easy. With the exception of some cases of gas gangrene and acute staphylococcal infections the results of chemotherapy alone are so consistently good that little harm results from failure to administer serum. Much of the danger from infections with gas-producing organisms of a severe type is due to the exotoxins present, the effects of which may be mitigated by good antitoxin. In acute staphylococcal infection there is increasing evidence that the early use of antitoxin with chemotherapy is beneficial.

DOSAGE

Chemotherapy has revolutionized the treatment of certain acute infections but the method is still subject to many limitations and it is important that enthusiasm for new things should not exceed knowledge of their application. One patient cured somehow is worth any number of fully investigated dead ones, but patients will always have better prospects of recovery if treated scientifically than by rule of thumb. A methodical approach to the treatment of acute infections is not difficult now that laboratory facilities are readily available for doctors who have neither the time nor the inclination to undertake clinical pathology. If the infecting organism can be identified with precision the appropriate compound can be selected for treating it, but treatment should not be unduly delayed for laboratory reports; the doctor must rely on his clinical acumen to decide the most likely nature of the infection, and make any necessary adjustments later when pathological reports are ready. Close liaison between the clinician and the pathologist is particularly important in the control of obscure or resistant infections, since it is possible to determine by direct test whether a particular organism is influenced by any compound.

Another direction in which clinical pathology can help is by periodical determinations of the sulphonamide content in the blood of patients undergoing chemotherapy. The concentrations of different compounds necessary to attain the optimum effect have been determined, principally by clinical experience, but modifications may be required to meet changing circumstances. When using sulphamamide a blood level of 10 mg. per 100 c.c.m. is required, and with sulphapyridine a level of 5 to 10 mg. per 100 c.c.m., except in acute staphylococcal infections when at least 15 mg. per 100 c.c.m. seems desirable. Agreement about the levels needed with sulphathiazole has not yet been reached, but in pneumococcal and meningococcal infections they must, it seems, be rather higher than those required with sulphapyridine, and in staphylococcal septicaemia about 20 mg. per 100 c.c.m. should be aimed at.

It is a fundamental rule in deciding on the dosage of any sulphonamide that an effective level should be attained in the blood as rapidly as possible and then maintained by regular four-hourly administration. This may be done by giving two or three initial loading doses, consisting of twice the amount considered necessary of maintenance. If oral therapy is impracticable because the patient is vomiting or too ill some form of parenteral therapy must be given. The choice of soluble compounds is more or less limited to three—solusceptasine and the sodium salts of sulphapyridine and sulphathiazole. There is considerable discussion about the best way of giving these compounds. The difficulties do not arise solely over the question of their pH but also over the best way to get them into the circulation. In severely ill or collapsed patients the peripheral circulation is inactive, so that intramuscular injections may be sluggish in action and be attended by local necrosis, a situation which cannot arise if the intravenous route is adopted. Provided that only one or two injections are necessary little harm is likely to be done by giving them intravenously in the ordinary way, but if prolonged parenteral therapy is required a continuous intravenous drip of the compound dissolved in normal saline is the ideal technique, and has in my experience never been attended by untoward results. Intrathecal injections must never be given.

Clinical practice has shown that the giving of somewhat arbitrary quantities of the various drugs by mouth or injection is on the whole attended by good results. A common cause of failure is that, owing to irregularities in absorption or over-rapid excretion, effective blood levels have not been attained, so that the periodic determination of blood concentrations is an important aid to treatment in many infections. No patient is ever the worse for intensive treatment at the beginning of an infection and a few subsequent days of high dosage. Troubles arise through so-called moderate doses being given, which are usually ineffective and have to be continued for longer than would otherwise have been necessary. If the organism is or has become drug-fast a change to another compound known to be active against the particular infection concerned should be made. A total dosage of between 20 and 30 gm. is sufficient to control most infections.

ADJUVANTS TO TREATMENT

The success of sulphonamide therapy in difficult circumstances must not detract from the importance of ancillary methods which will help to overcome the general effects of an acute process. One point particularly requires emphasis—the value of recumbency throughout treatment. As a rule the acuteness of the illness decides this automatically but many less ill patients do take these remedies while walking about. There is a higher incidence of side effects among these people, and it is questionable whether the drugs do much good in the doses given to ambulant patients except in gonorrhœa, where the causal organism is highly susceptible to sulphonamides; even here results are much better when the patients are hospitalized.

SIDE EFFECTS

We must distinguish between complications due to the disease and those due to treatment, and must

recognize that many patients now live to develop complications who without chemotherapy would have died before they became apparent. Of the true side effects of chemotherapy a particularly troublesome one is nausea with or without vomiting, and considerable attention has been directed to its causes and prevention. Existing evidence suggests that there is a local action probably in the stomach combined with a central action in the medulla. The local action may be prevented to some extent by suspending the drugs in milk or better still in certain mucilages; with sulphapyridine the regular administration of dilute hydrochloric acid seems to be of value, although just what the significance of variations in the acidity of the gastric juice may be is as yet undetermined. The sulphonamide content of the blood must be a factor in the causation of general reactions, but on present evidence it seems that fluctuations in the blood levels are a more potent cause of trouble than the absolute amount present, since high levels which are constant are better tolerated than irregular lower ones.

WOUND SEPSIS

The principles involved in the treatment of wounds are no different from those of the control of acute infections elsewhere in the body by the same types of organism. Interest at the moment centres on the value of applying sulphonamides locally to wounds, but it must be remembered that they are at the same time being submitted to constantly improving surgical technique, and it is impossible to say whether the good results claimed come from the drugs or the surgery. The feeble activity of sulphonamides on micro-organisms in albuminous fluids demonstrated by Fleming makes it questionable whether better results could not be obtained by surgery combined with the administration of chemotherapeutic agents in sufficient amounts by the blood-stream. There is, moreover, growing evidence that various compounds applied direct to a wound produce a local foreign-body reaction in the tissues. The whole question is one requiring much critical study.

Reviews

ABDOMINAL OPERATIONS.—By Rodney Maingot, F.R.C.S. (Eng.). Volumes I and II. 1940. D. Appleton-Century Company, Incorporated, New York and London. Pp. x plus 806 in volume I and pp. vi plus from 807 to 1385. Illustrated

MR. RODNEY MAINGOT is already well known to us in the sphere of medical literature as editor of *Post-Graduate Surgery*. In that book his contribution to the section on abdominal surgery was small, but now he has produced a two-volume work of his own on abdominal operations.

The first volume begins with a section on abdominal incisions, and the most important types are described in detail with the aid of illustrations.

The author's strong criticism of the Battle incision will be endorsed by many. More than one general method of closure of abdominal incisions is given. They are elaborate, if not laborious, the sort of technique one sees employed by a surgeon who has been dogged by a succession of burst abdomens or post-operative hernias.

The main part of this volume, and the best in the whole book, describes the surgery of the stomach and duodenum. The reader is given a wide selection of operations for chronic duodenal ulcer, including six modifications of the Billroth I method, the standard Billroth II operation and three modifications, the Polya operation, and the modern version of Finsterer's operation of pyloric exclusion combined with partial gastrectomy. The selection appears at first sight to be bewildering, but justice is done to each method in turn. The technique of gastro-jejunostomy is to be found in the chapter on pyloric obstruction. *Sic transit*

gloria....! The description follows the usual lines, with the exception that a triple suture line is used.

Parts 3 and 4 are devoted to the surgery of the spleen and pancreas. Volume I ends with part 5, which contains the surgery of the gall-bladder and bile ducts. It is, as one might expect, an excellent and authoritative description.

In volume II the first three parts deal with the liver, appendix and peritoneum. Then come chapters describing hernia. The chapter on strangulated hernia is particularly helpful. A long section on the intestine then follows. It is interesting to note that no method of primary anastomosis has yet supplanted the Mikulicz procedure in colonic resection.

Indeed, the position of the Mikulicz operation has recently been strengthened by the introduction of improved clamps for restoring the continuity of the bowel.

The last chapter of the book is on the subject of post-operative chest complications and is written by Dr. Sleigh Johnson. He reminds us that 10 to 14 per cent of cases of abdominal section suffer from post-operative lung complication, and deplores the lack of progress in respect of this problem. He discusses the aetiology, prevention and treatment of lung complications, the use of heparin being of special interest.

The book has been published and printed in the U. S. A. It has been splendidly done, as befits its importance. Most of the illustrations have been executed by Miss Pauline Larivière, and they are so good that it seems rather unkind to point out that in three figures she has drawn lines transverse crossing the rectus muscle midway between the umbilicus and the symphysis pubis.

W. McN. N.

POULSSON'S TEXTBOOK OF 'PHARMACOLOGY AND THERAPEUTICS'.—By Stanley Alstead, M.D. (Liverpool), M.R.C.P. (Lond.). Third English Edition with new appendix. 1940. William Heinemann (Medical Books), Ltd., London. Pp. xi plus 557. Price, 21s.

Poulsson's *Pharmacology* needs little introduction; it is one of the best books on the subject, it is written with lucidity and precision, and contains numerous invaluable practical hints.

The present edition contains the second *Addendum* to the *B. P.*, issued in June 1940, and gives an account of the new preparations of vitamins and hormones. A special chapter on the sulphonamide compounds, their different preparations, posology, mode of action, and therapeutic indications have made the book very up-to-date and immensely useful, both for students and practitioners. The classification, though not pharmacological, is very ingenious and original.

The book, though suffering from some minor limitations in its scientific and experimental aspects, as also in explaining certain technical things in the light of modern drugs standardization which students are supposed to know nowadays, will definitely prove to be a good addition to our pharmacological library.

J. C. G.

THE MANUFACTURE OF COMPRESSED YEAST.—
By F. G. Walter, A.A.C.I. 1940. Chapman and Hall Limited, London. Pp. viii plus 254. Illustrated. Price, 15s.

The discovery of yeast as one of the most potent sources of several essential nutritional factors has greatly increased the importance of this substance, already indispensable as a leavening agent and in the fermentation industries. Until the great war yeast was only a by-product of the alcoholic fermentation, but during the last twenty years the manufacture of yeast has developed into a great industry by itself. In spite of vast literature on the chemical transformations brought about by yeast, there has been little mention of yeast production in scientific literature. This book therefore supplies a distinct need.

The book presents a comprehensive description of various processes in the cultivation of yeast, the

principles underlying those processes, and the application of these in practice. The usefulness of the book has been greatly enhanced by inclusion of a description of the plant, together with the specifications of the important units, vessels and fittings. A chapter is devoted to dried yeasts and yeast foods, but unfortunately the quality of yeast from the point of view of its content of various vitamins finds little mention. The book however represents a valuable volume on the subject of the cultivation and manufacture of commercial yeast.

DEBATABLE TUMOURS IN HUMAN AND ANIMAL PATHOLOGY.—By W. F. Harvey, E. K. Dawson and J. R. M. Innes. 1940. (Cancer Research Memoirs No. 1.) Published for the Cancer Control Organization of Edinburgh and South-East Scotland by Oliver and Boyd, Edinburgh (Tweeddale Court). Pp. vii plus 124. Illustrated. Price, 10s. 6d.

THIS is the first volume of the cancer research memoir series published by the joint efforts of the research laboratory of the Royal College of Physicians of Edinburgh, the cancer control organization of Edinburgh and South-East Scotland, and the Institute of Animal Pathology, University of Cambridge. In this volume they have taken up seminoma, granulosa-cell tumour, mixed parotid tumour, melanoma, lymphoepithelioma, giant-cell tumour, endothelioma, lymphosarcoma and meningioma.

The choice of the title of the book is befitting the neoplasms which the authors have selected for the purpose of discussion, as their real nature has always remained a subject for speculation. The memoir is the outcome of the study of more than 15,000 tumours in the laboratory of the Royal College of Physicians, Edinburgh. The authors have dealt with nine varieties of tumours in the present volume. They have first given a short but clear-cut definition of the tumour, then a detailed description of its gross anatomy and microscopic structure after which a full discussion of their own views, as well as of the views of notable workers of Great Britain and other countries of the world. After this, they have given a conclusion in which the most modern and accepted ideas have been summarized.

The descriptions and discussions have been lavishly illustrated with innumerable pictures and excellent and convincing photomicrographs. A very commendable feature of the volume is that, although the writers have to some extent dogmatically pushed their own views as well as the views of their own school of thought, they have not forgotten to take other schools of thought into consideration. In this way, the book, though small in volume, is thorough and comprehensive. A very valuable portion of the book is the inclusion, at the end, of a chapter containing an exhaustive literature which the authors have chosen to call 'directional literature'. This will enable the student of tumour pathology to increase his scope of study without having to spend time to search in the literature. This book is full of original ideas and should be possessed by everyone who is interested in neoplastic diseases, surgeon, physician, or laboratory worker.

M. N. D.

THE MICROSCOPIC ANATOMY OF VERTEBRATES.—
By James I. Kendall, Ph.D., D.Sc. Second Edition. 1940. Henry Kimpton, London (263, High Holborn, W.C.). Pp. 342. Illustrated with 197 engravings. Price, 17s. 6d.

THIS is an excellent monograph which is packed with valuable information regarding histological problems and will be of great help to microscopists and embryologists. The writer has avoided too much emphasis on mammalian and human materials as the latter are available in a large number of excellent textbooks. In this book one will find exhaustive microscopic anatomy of important non-mammalian tissues.

In biology the conception of cellular independence is a necessity and this has been very well tackled with

stereo-diagrammatic figures. Various tissues originating from germinal layers are grouped separately amongst type specimens of all important classes of vertebrates. The cytomorphosis, histogenesis and organogeny of the mammalian and other vertebrates have been explained in a manner which will be found very interesting and stimulating. The book also contains original touches which enhance its value. Very useful facts are to be found in the chapter on technique in which all the important histological methods are incorporated. For the microscopist this chapter is invaluable.

All the diagrams are very illustrative and other descriptions are convincing. The book is up to date and free from any errors of fact. It is also very easy reading. In conclusion, the book is an admirable one which clarifies a difficult portion of comparative anatomy. The author is to be congratulated for making a very intricate subject so easy to remember and to reproduce.

M. N. D.

**PRINCIPLES OF THE ART OF ANAESTHESIA
(BEING THE LECTURES DELIVERED TO THE STUDENTS OF THE ROBERTSON MEDICAL SCHOOL, NAGPUR).**—By S. A. Sharma, B.Sc., M.B., D.T.M. (Cal.). 1941. Published by A. D. Mani, Hitavada Press, Nagpur (India). Pp. 148. Illustrated. Price, Rs. 2

AFTER a careful analysis the most generous critic will find difficulty in pointing to any merit in this

book. The reader is unavoidably driven to the conclusion that the personal experience of the author in any but the most elementary forms of anaesthesia is extremely limited. The casual dismissal in four lines of the technique of administration of an endotracheal anaesthetic does not suggest practical knowledge of the subject.

The book abounds with gross inaccuracies such as the statement that the corneal reflex should never be lost in surgical anaesthesia (this, incidentally, is contradicted three pages later). Nitrous oxide is described as an explosive gas. Again, it is said that exhaled nitrous oxide cannot be rebreathed. Has the author never heard of the carbon dioxide absorption technique? In the introduction the author announces that the book has been written for the enlightenment of his students. In which case some of his statements are frankly dangerous. For example, he says blandly that a double dose of avertin may be given in cases of toxic goitre.

The book is almost devoid of any real practical advice even in the simple administration of ether and chloroform by the open method. A student, knowing nothing of how to set about giving a general anaesthetic, will still know as little when he has read the book.

Apart from the subject-matter, the misprints and spelling mistakes are so numerous as to make the text scarcely readable. At the end of the book there are three and a half pages of errata, which cover only a small proportion of the total mistakes.

An unfortunate addition to the already swollen ranks of medical literature.

Abstracts from Reports

THE PASTEUR INSTITUTE OF SOUTHERN INDIA, COONOOR. ANNUAL REPORT OF THE DIRECTOR TOGETHER WITH THE THIRTY-THIRD ANNUAL REPORT OF THE CENTRAL COMMITTEE OF THE PASTEUR INSTITUTE ASSOCIATION, 1939-40

DURING the year certain important changes were made in the medical personnel of the Institute. An arrangement was made with the Government of India for a Medical Research Department Officer as Director, and for a specially trained officer of the Indian Medical Department as Assistant Director. The services of two sub-assistant surgeons of the civil medical cadre of the Government of Madras were withdrawn. The special rabies research officer appointed in 1937 was taken on the permanent staff of the Institute as senior medical assistant, and a junior medical assistant was recruited.

At the request of the Director-General, Indian Medical Service, the Central Committee agreed that the Pasteur Institute, Coonoor, should be included in the list of Training Centres for I.M.S. officers on condition that no expenditure to the Association would be involved.

The reorganization of the laboratories which was commenced in 1938 was completed during the year. Equipment essential to the proper functioning of the laboratories was provided in so far as funds permitted, but additional equipment will have to be furnished as funds become available.

Numerous additions were made to the library by purchase, gift and exchange.

The standardized system of antirabic treatment which was introduced at the Pasteur Institute, Coonoor, in 1933, was reviewed after five full years' working. Analyses of the data collected during this period indicated the advisability of adhering to the practice of giving larger doses of antirabic vaccine to human patients estimated to be at greater risk of contracting rabies. At the same time, sufficient evidence became available to justify the adoption of a simpler classification of patients with a corresponding reduction in the number of graded courses of treatment hitherto

employed. In consultation with the directors of other institutes in India a revised and simplified system of treatment was introduced which allowed of the classification of patients into three classes.

The revised system of antirabic treatment was introduced with effect from 1st December, 1939.

The antirabic vaccine employed for the treatment of human patients was a 5 per cent suspension of sheep-brain (Paris strain of fixed virus) in carbol-saline prepared by Semple's method. A total of 1,455,556 c.cm. was manufactured during the year.

During the period under review, 425 patients received a complete course of antirabic treatment at the Institute (398 Asiatics and 27 Europeans). Incomplete courses of treatment were also given to 56 patients of whom 27 were absolved from further treatment after the possibility of rabies in the biting animal had been excluded. The remainder absconded.

The treatment given at the various subsidiary centres was similar to that administered at the Pasteur Institute, Coonoor. The various centres returned 10,374 case cards for patients treated during the period under review. Of these, 8,021 received a complete course of treatment and 2,184 were incompletely treated. The remainder were absolved from further treatment as the possibility of rabies in the biting animals was excluded.

Only 21 deaths were recorded among the 10,205 patients who received complete or incomplete courses of treatment giving a mortality rate of 0.2 per cent. All of the 21 deaths reported during the year occurred among Asiatic patients. Death followed dog-bite in 20 cases and fox-bite in one case.

General laboratory work

In response to the demand for the services of a general medical laboratory in this part of India, the Institute has continued and extended facilities for work of this kind. Routine laboratory examinations were carried out on a large scale for the benefit of hospitals, dispensaries and practitioners.

Diagnostic tests carried out during the period under review covered a wider field than ever before.

Research work in rabies

The antirabic vaccine at present in use at this Institute is a 5 per cent suspension of the brains of sheep inoculated with the Paris strain of fixed virus prepared by Semple's method (phenol vaccine). This vaccine while satisfactory from the point of view of a low associated mortality among treated cases necessitates the administration of large doses over prolonged periods—patients exposed to the risk of rabies infection may receive as much as 10 c.c.m. daily for 14 consecutive days. The large amount of nerve tissue (foreign protein) which the vaccine contains is believed by some workers to be the cause of the rare, but serious, complication of post-treatment paralysis (paralytic accident). It would obviously be desirable to produce a vaccine of at least equal efficacy which would be as free as possible from foreign protein and which could be administered in smaller doses over a shorter period of time.

Preliminary experiments were undertaken to investigate whether the excess of sheep-brain protein could be eliminated from the vaccine without impairing its antigenic value. It was found possible by precipitation at the isoelectric point to eliminate a large proportion (about 80 per cent) of the foreign protein present in suspensions of sheep brain. For this purpose suspensions of fixed virus brain were prepared in buffer solution adjusted to pH 4.4.

The immunizing properties of (1) the clear supernatant (clear vaccine) resulting from isoelectric precipitation of sheep brain suspensions of varying strengths after adjusting to pH 7; (2) the precipitate remaining after isoelectric precipitation in buffer solution the virus being rendered avirulent by incubation at 37°C. for 24 hours at pH 5, and the precipitate resuspended in the volume of saline necessary to give a resultant total protein content equal to that of 5 per cent phenol vaccine, and adjusted to pH 7; (3) 5 per cent phenol vaccine was investigated in a large series of experimental animals. Results so far obtained have shown that the clear vaccine had an immunizing value at least equal to that of 5 per cent phenol vaccine when the total protein content of the clear vaccine was equal to, or half, that of the phenol vaccine. The resuspended precipitate, however, gave very inferior results.

The clear vaccine prepared by the method described above appears to be relatively non-toxic. Large doses have been administered to experimental animals both intravenously and subcutaneously without producing toxic manifestations. It has been administered to human patients in large doses by the intravenous and intrathecal routes without producing any untoward effects.

Attempts have been made to produce hyperimmune serum in sheep by repeated injections of rabies virus. Serum has been obtained which is capable of neutralizing rabies fixed virus *in vitro*. Antibodies were detected in the euglobulin and pseudoglobulin but not in the albumin fractions of this serum. The effects of large doses of serum concentrate from hyperimmune serum on early cases of rabies is under investigation.

A research unit known as the Protozoal Parasites Enquiry was attached to the Pasteur Institute, Coonoor, at the end of 1938. This unit is entirely financed by the Indian Research Fund Association.

The initial activities of the enquiry were directed to establishing colonies of experimental animals, strains of parasites, etc., but some interesting investigations have already been completed. Much attention has been given to a study of the mechanism of defence against malaria.

Nutrition research laboratories

An independent enquiry financed by the Indian Research Fund Association has been working on nutrition problems at the Pasteur Institute, Coonoor, almost continuously since 1918. This organization is now known as the 'Nutrition Research Laboratories', a brief account of the history, development and achievements of which is given below.

The first investigations on nutrition to be carried out at the Pasteur Institute, Coonoor, were begun in 1918 when Lieut-Colonel R. McCarrison, I.M.S., commenced work with one assistant and scanty equipment.

In the earlier days of nutrition research in Coonoor McCarrison discovered that monkeys fed on deficient diets showed striking pathological changes in the walls of the intestine. In a series of experiments on groups of rats fed on diets resembling those consumed by various Indian peoples, McCarrison showed that the growth rate of the animals corresponded with the physical development of human beings living on similar diets. McCarrison's experiments on the vitamin content of Indian cereals, with reference to the problem of beri-beri in India, were of considerable value, as were also his observations (with Norris) that the washing of rice causes considerable loss of vitamins and mineral elements. McCarrison's book *Food*, published in 1928, achieved wide circulation and did much to stress the importance of nutrition in relation to public health in India. On Colonel McCarrison's retirement in 1935 the directorship was taken over by Dr. W. R. Aykroyd.

In 1935, a systematic survey of the nutritive value of Indian foodstuffs was commenced as this was considered an essential preliminary to the satisfactory development of public health nutrition work. The practical results obtained have been incorporated in a popular bulletin entitled *The Nutritive Value of Indian Foods and the Planning of Satisfactory Diets*.

In recent years special attention has been given to diet surveys. The main object of diet surveys is to discover the defects of Indian diets and to indicate desirable changes and improvements in the dietary of the people within their economic resources. As the result of these surveys it has become apparent that the diet of the poor rice-eater is essentially the same all over India. In addition to his staple cereal he consumes only very small quantities of other foods, such as pulses, vegetables, fruit and meat. Milk and milk products are taken in negligible quantities, or not at all. In most parts of India the production and consumption of pulses could with advantage be increased. The intake of leafy vegetables is everywhere below the desired level.

In addition to these activities in the field, many laboratory investigations on various aspects of the science of nutrition have been carried out in Coonoor. Numerous experiments have been carried out on rats and other animals to discover the best methods of improving poor Indian diets. Considerable attention has been given to the study of the pathological changes caused in man and laboratory animals by defective diets. The cause of one of the commonest deficiency diseases in India—stomatitis—has been investigated and it has been shown that milk is a valuable curative agent. Much attention has been given to the rice problem in India. A chemical method for assaying the anti-beri-beri vitamin (vitamin B₁) in rice and other foods was adapted for routine use, and applied to a large number of food samples. It was shown that parboiled rice, unlike raw rice, retains vitamin B₁ and other vitamins after milling and this fact was correlated with the geographical incidence of beri-beri in India. Beri-beri is rare amongst parboiled-rice eaters, and is a serious public health problem only in areas in which raw rice is the staple food. The economic factors underlying the abandonment of the practice of home-pounding rice in the Madras Presidency have been studied by questionnaires and field surveys. The results of these investigations have been incorporated in a monograph entitled *The Rice Problem in India* which has been published this year.

A chemical test for nicotinic acid in foods has been devised in Coonoor and has been extensively employed in this and other parts of the world. The test facilitates the investigation of a common and serious food deficiency disease—pellagra—which can be cured by nicotinic acid.

An important part of the work of the Nutrition Research Laboratories has been the holding of training classes for health workers, the issue of popular bulletins, and the distribution of posters and other propaganda

material. A museum containing exhibits of an educational nature has been established at Coonoor, and popular lectures have been delivered and press notes issued from time to time. The work of the Nutrition Research Laboratories has been closely associated with that of the Nutrition Advisory Committee of the Indian Research Fund Association which is concerned with the development of nutrition work in India, and which has already made pronouncements on various subjects of national importance. The laboratories also collaborate with the Technical Commission on Nutrition of the League of Nations and act as a link between the technical commission and nutrition research organizations in eastern countries.

Malaria investigations

During the year, an independent research organization known as 'Malaria Investigations' established its headquarters at the Pasteur Institute, Coonoor. This organization is financed by the International Health Division of the Rockefeller Foundation, and in addition to the laboratories and office in Coonoor a field station is maintained at Pattukottai, Tanjore District.

The main objects of malaria investigations are to conduct research on malaria in selected areas in the Madras Presidency, to discover cheap and adequate measures of controlling malaria in these areas, and to demonstrate the economic feasibility of employing them.

Plague enquiry in the Nilgiri District

At the request of the Director of Public Health, Madras, the Pasteur Institute provided facilities for the conduct of a special enquiry into the epidemiology of plague in the Nilgiris.

The results obtained by the enquiry have shown that the commonest field rodent, the mole rat, and its fleas are a potential danger in regard to the transmission of plague. This species of wild rodent infests the local areas of potato cultivation but the enquiry observed that they appeared to flourish equally well in gardens under other types of cultivation, and it seemed doubtful whether restriction of potato cultivation in and around municipal areas, such as Coonoor and Ootacamund, would be an effective anti-plague measure.

ANNUAL REPORT OF THE HENRY LESTER INSTITUTE OF MEDICAL RESEARCH FOR THE YEAR 1940

DURING 1940, the work of the Institute has been maintained along the lines indicated in the previous report, but owing to war all activities have had to be restricted.

A great deal of work continues to be carried out with reference to the special problems and opportunities in China. In the Division of Physiological Sciences our interests are centred in nutrition. This involves two main aspects, an analysis of Chinese diets and ancient Chinese remedies on the one hand and the application of modern knowledge in regard to vitamin and mineral deficiency and chemotherapy. In all the work clinical and laboratory investigation go hand in hand and we are indebted to the Lester Chinese Hospital for its co-operation.

In the Division of Pathological Sciences the same guiding principle is at work, namely, Chinese problems in relation to local opportunities. Owing to military occupation of the surrounding country, field research has had to be curtailed and we are becoming more dependent on our own resources for maintaining the hosts and parasites which constitute so important a condition of this work.

In the Clinical Unit a great deal of time is being spent in carrying out for the whole hospital routine laboratory investigations necessary for diagnosis and treatment. At the same time an attempt is being made by careful records to establish the range of normals as well as the disease incidence in a hospital population, while every opportunity is taken of cases of nutritional deficiency

These reflections naturally lead to a brief review of the evolution of the Institute and some indication of our hopes for the future.

Having decided in 1932 to establish a Medical Research Institute in which teaching would be subsidiary to research and not designed for degrees or diplomas the organization of the institute naturally fell into three divisions of Physiological, Pathological and Clinical Sciences the latter with special relations to the Lester Chinese Hospital. Our relations with the hospital have been more intimate than with any other institution and this is appropriate since it was undoubtedly Mr. Lester's interest in the Shantung Road Hospital which led him to provide not only for the hospital but also for a medical institute. The organization of clinical research has come relatively late in the development of the biological sciences and this is due to the difficulties inherent in the fact that the interests of the patient who becomes a subject for research and of the hospital organization surrounding him, must be safeguarded at all costs. In the case of the Lester Chinese Hospital it was thought that these difficulties might be overcome if the institute controlled one floor of the hospital for research purposes, but the purposes of a mission hospital and of a research institute, both excellent in their way, are hardly compatible with use of the same nursing staff and hospital organization, with the result that some modification in the original plan has become necessary.

The new arrangement whereby the institute makes itself responsible for all laboratory services leaving clinical co-operation to the goodwill of the hospital appears to be more economical for both parties. It is essential however that the results of laboratory research should be clinically tested and that the laboratory programme should be determined by clinical needs. This does not necessarily mean that all laboratory research must be *ad hoc* research. It is very desirable that it should be fundamentally biological but the ultimate purpose of medical research must be kept in view. However, in spite of these difficulties advances in our knowledge of clinical science have been made by members of the Clinical Unit. Dr. Platt was instrumental during his five years' work in definitely adding to our knowledge of nutritional deficiency diseases more especially in regard to the diagnosis and successful treatment of acute beri-beri, a disease previously fatal in a large number of cases.

On the surgical side, Dr. Gordon Thompson and Dr. Gray carried out a full programme of surgical work, contributing to the relief of a large number of patients with advances more particularly in the field of urology.

Correspondence

ON THE COMPOSITION OF BUFFALO MILK AND THE DETECTION OF ADULTERATED SAMPLES PASSED AS COW MILK

Sir.—Ghosh and Datta in their communication in your May number recorded analytical results for fat, non-fatty solids and lactose content of a number of samples of buffalo and cow milk obtained in Assam. According to them the lactose content of buffalo and cow milk 'varies within a similar and narrow limit', an observation which led them to suggest that the estimation of lactose would help the detection of water adulteration in buffalo milk which is passed as cow milk.

If water alone happens to be the adulterant it can be detected without having recourse to lactose estimation. But, as pointed out by the authors, it will be found helpful in cases where starch emulsions and the supernatant water from boiled rice which do not contain lactose are used as adulterants.

Milk sophistication, unfortunately, has left the realm of primitive methods and is now claiming to be scientific. The receiver of cow's milk starting with buffalo

milk which is a by-product of the creameries. More recently reconstituted milk which is even cheaper than fresh separated liquid milk is being extensively used in some Indian cities (*vide Report of the Director, Public Health, Bombay, for 1939, p. 59*). Since such a case of adulteration involves no reduction in the level of lactose, the suggested legislation to prescribe a minimum standard of 4 per cent for lactose amounts to legalizing the crime cited above.

A second point of interest in the said study is concerning the standard for the fat content of buffalo milk. It was suggested that the present minimum of 6 per cent prescribed in some Pure Food Acts should be reduced to 5 per cent, because the analytical data they presented would justify this.

This suggestion involves a generalization which is contrary to the experience of other analysts. There are a host of factors that control the fat content of milk, and one may not be far from truth if it is pointed out that what holds good in Assam may not hold good elsewhere in India. This suggestion therefore lacks the backing of experience. As it is want of uniformity, where it is possible, in the standards prescribed for certain foodstuffs in Indian Pure Food Acts is well known to all that are connected with their working. In a large measure such a state of things is the outcome of lack of sufficient effort to consult the analytical profession prior to legislation and also due to dependence on the opinion of those who are on the spot. In the circumstances, one would ask if there is any point in suggesting standards which do not achieve the object with which they set out, or propose an alteration to old ones based on incomplete evidence.

G. NARASIMHAMURTY, M.Sc., A.I.C.

PUBLIC HEALTH LABORATORY,
BOROUGH MUNICIPALITY,
SURAT,
25th June, 1941.

IDEAL MARRIAGE

SIR.—The letter you have published from Dr. John Lowe in this month's *Indian Medical Gazette*, in which he complains bitterly of my review of Th. Van de Velde's book *Ideal Marriage*, makes me think that it is to Dr. Van de Velde that I owe an apology in that I did not indicate sufficiently clearly the advantages to be gained by reading his book. Shortly, they appear to me to be these, namely the studied clarity of his style, his knack of knowing what it is that youth needs and wants to know about sexual intercourse, and, lastly, the absence of irrelevancies which are so common in textbooks on sexology.

I cannot see Dr. Lowe's point in comparing the number of languages into which this book has been and is still being translated with the number of languages into which the *Bible* has been translated. But if this comparison interferes with his peace of mind let him read for *Bible*, *Uncle Tom's Cabin*.

As an admirer of the teachings of the founder of Islam, I have always been disappointed when reading the *Koran* to note how little Mahomed has been reported to have preached on sex. This is all the more astonishing since Arabs of Arabia are, as a race, the world's sexual athletes.

I am sorry if my review of *Ideal Marriage* gives any reader of it the notion that I regard sexual intercourse as the main, if not the only important, thing in life, for I do not think so. At the same time, as a practising psychiatrist, I am, even at my age, perpetually being shocked by the results that come to my notice through sheer misunderstanding or wilful ignorance of men and women as to their sexual lives. Without a sane attitude towards and a far fuller knowledge of sex, no man can claim the title of 'sapiens', no matter what else he knows.

OWEN BERKELEY-HILL,
LIEUTENANT-COLONEL, I.M.S. (Retd.).

STATION ROAD, RANCHI
(BIHAR).

Service Notes

APPOINTMENTS AND TRANSFERS

LIEUTENANT-COLONEL H. K. ROWNTREE, M.C., I.M.S. (Retired), has been appointed Director of Production, Instruments and Appliances, with effect from the 17th April, 1941, vice Major R. I. Reid, appointed Additional Assistant Director-General, Indian Medical Service (Stores).

On return from leave, Lieutenant-Colonel R. V. Morrison assumed charge of his duties as 1st Physician, Rangoon General Hospital, on the forenoon of the 13th May, 1941.

Lieutenant-Colonel M. L. Treston, Medical Superintendent, Dufferin Hospital, Rangoon, was appointed as Inspector-General of Civil Hospitals, Burma, with effect from the afternoon of the 31st May, 1941, vice Lieutenant-Colonel H. S. Cormack, M.C., Officiating Inspector-General of Civil Hospitals, Burma, transferred.

On his reversion to military duty, Lieutenant-Colonel P. D. Chopra, Deputy Inspector-General of Prisons, Punjab, made over charge of his duties on the afternoon of the 16th June, 1941.

The services of Lieutenant-Colonel S. N. Makand, Director of Public Health, C. P. and Berar, have been placed at the disposal of the Government of India, Defence Department, with effect from 21st June, 1941.

Lieutenant-Colonel J. B. Hance, C.I.E., O.B.E., V.H.S., has been appointed as Director of Public Health, C. P. and Berar, in addition to his own duties as a temporary measure, with effect from the afternoon of the 21st June, 1941, vice Lieutenant-Colonel S. N. Makand, transferred.

Major W. Scott, Civil Surgeon, Hoshangabad, with headquarters at Pachmarhi, has been re-posted to Amravati.

Major R. I. Reid is appointed Additional Assistant Director-General, Indian Medical Service (Stores), with effect from the 17th April, 1941.

Major R. I. Reid, Additional Assistant Director-General, Indian Medical Service (Stores), is appointed to officiate as Assistant Director-General, Indian Medical Service (Stores), vice Lieutenant-Colonel M. K. Kelavkar, granted leave.

Captain H. B. Wright, Deputy Assistant Director-General (Medical Stores), Karachi, is appointed to officiate as Additional Assistant Director-General, Indian Medical Service (Stores), vice Major R. I. Reid.

Major A. M. Sheridan, Civil Surgeon, is transferred from Cawnpore to Naini Tal.

The services of Major E. S. S. Lucas, Civil Surgeon, Dehra Dun, have been placed at the disposal of the Government of India, Defence Department, with effect from 10th April, 1941.

The services of Major W. D. B. Read are placed temporarily at the disposal of His Excellency the Commander-in-Chief, with effect from the 12th April, 1941.

The services of Major R. A. Wesson, Civil Surgeon, Meerut, have been placed at the disposal of the Government of India, Defence Department, with effect from 28th May, 1941.

Major E. A. R. Ardesir made over charge of the Rajshahi Central Jail to Dr. Abdul Majid in the afternoon of 11th June, 1941.

On his reversion to military duty, Major Ilahi Baksh, Professor of Pharmacology and Therapeutics, K. E. Medical College, Lahore, made over charge of his duties to a non-I.M.S. Officer, on the 14th June, 1941 (afternoon).

On his reversion to military duty, Major B. S. Nat, Professor of Operative Surgery, K. E. Medical College, Lahore, made over charge of his duties to a non-I.M.S. Officer on the afternoon of the 14th June, 1941.

Major G. B. W. Fisher, 1st Resident Medical Officer, Presidency General Hospital, Calcutta, is appointed to do the duties of the 2nd Resident Medical Officer of the same institution, in addition to his own duties, during the absence, on leave, of Captain W. M. Niblock.

Captain H. S. Maini, A.I.R.O. (Medl.), to be acting Major whilst holding the appointment of Officer Commanding, No. 1 Indian Convalescent Depot. 1st March, 1941.

The services of Captain G. F. Harris, an officiating Agency Surgeon, are temporarily replaced at the disposal of His Excellency the Commander-in-Chief, with effect from the forenoon of the 20th April, 1941.

To be Captain (on probation)

Edward John Crowe, 23rd April, 1941, with seniority as Lieutenant from 23rd April, 1936, and as Captain from 23rd April, 1937.

The undermentioned officers are called to army service, with effect from the dates specified:—

ARMY IN INDIA RESERVE OF OFFICERS

Medical

Captain P. B. Sen. Dated 10th June, 1940.
 Captain S. S. Apte. Dated 18th June, 1940.
 Captain L. R. Wagholkar. Dated 18th June, 1940.
 Captain S. J. Sane. Dated 18th June, 1940.
 Captain S. K. Wakade. Dated 19th June, 1940.
 Captain H. K. Ambike. Dated 20th June, 1940.
 Captain P. Papatha. Dated 21st June, 1940.
 Captain D. R. Sharma. Dated 24th June, 1940.
 Captain Damodar Singh. Dated 24th June, 1940.
 Captain K. L. Malhotra. Dated 26th June, 1940.
 Captain D. N. Basu. Dated 27th June, 1940.
 Captain K. C. Virmani. Dated 27th June, 1940.
 Captain W. A. Mirza. Dated 28th June, 1940.
 Captain P. D. Kapur. Dated 1st July, 1940.
 Captain J. N. Vasudeva. Dated 5th July, 1940.
 Captain H. S. Maini. Dated 8th July, 1940.
 Captain C. L. Malhotra. Dated 9th July, 1940.
 Captain R. S. Seagat. Dated 9th July, 1940.
 Captain D. C. Lahiri. Dated 9th July, 1940.
 Captain C. S. Ahluwalia. Dated 10th July, 1940.
 Captain Ram Sarup. Dated 10th July, 1940.
 Captain M. A. R. Khan. Dated 12th July, 1940.
 Captain N. C. Das Gupta. Dated 12th July, 1940.
 Captain R. K. Laroia. Dated 12th July, 1940.
 Captain D. N. Kumar. Dated 13th July, 1940.
 Captain R. M. Bharthiae. Dated 14th July, 1940.
 Captain G. L. Singh. Dated 14th July, 1940.
 Captain M. A. N. Meezuddin. Dated 16th July, 1940.
 Captain S. M. Pathak. Dated 19th July, 1940.
 Captain Parduman Singh. Dated 19th July, 1940.
 Captain D. S. Bhatia. Dated 2nd September, 1940.
 Captain R. N. Mitra. Dated 5th September, 1940.
 Captain A. A. Bhambhani. Dated 8th September, 1940.
 Captain S. N. Paul. Dated 9th September, 1940.
 Captain Munshi Singh. Dated 10th September, 1940.
 Captain D. R. Chandihok. Dated 13th September, 1940.
 Captain B. L. Sahi. Dated 16th September, 1940.
 Captain S. W. Palsikar. Dated 17th September, 1940.
 Captain P. N. Sathe. Dated 1940.
 Captain M. L. Blaggana. Dated 1940.
 Captain M. N. Gupta. Dated 3rd October, 1940.
 Captain S. N. Mittra. Dated 5th October, 1940.
 Captain N. L. Mukherji. Dated 5th October, 1940.
 Captain J. N. Phala. Dated 7th October, 1940.
 Captain A. K. Banerji. Dated 8th October, 1940.
 Captain G. S. Babbar. Dated 12th October, 1940.
 Captain Harmam Singh. Dated 12th October, 1940.
 Captain M. H. Palnitkar. Dated 13th October, 1940.
 Captain C. T. Rangaswami. Dated 14th October, 1940.
 Captain N. Sriniwasan. Dated 14th October, 1940.
 Captain S. C. Bannerjee. Dated 11th November, 1940.
 Captain A. H. Mallick. Dated 13th November, 1940.

1940.

Captain D. N. Chakravorty. Dated 15th November, 1940.
 Captain V. N. Khare. Dated 15th November, 1940.
 Captain T. H. Talwalker. Dated 15th November, 1940.
 Captain K. Satyanarayana. Dated 16th November, 1940.

Captain K. Raghavachari. Dated 16th November, 1940.

Captain P. N. Sen. Dated 19th November, 1940.
 Captain G. C. Tandon. Dated 22nd November, 1940.
 Captain K. T. Thadani. Dated 1st December, 1940.
 Captain C. P. Shahani. Dated 5th December, 1940.
 Captain S. P. Maitra. Dated 7th December, 1940.
 Captain K. L. Aich. Dated 7th December, 1940.
 Captain K. K. Sirker. Dated 7th December, 1940.
 Captain P. V. R. Murty. Dated 12th December, 1940.
 Captain N. G. Patwardhan. Dated 15th December, 1940.

The undermentioned Lieutenants (on probation) are confirmed in their rank, with effect from the dates specified.

LEAVE

Brevet-Colonel A. M. Dick, C.B.E., V.H.S., Principal, and Professor of Ophthalmology, K. E. Medical College, Lahore, proceeded on leave, preparatory to retirement, from the afternoon on the 2nd June to 29th July, 1941 (both days inclusive).

Captain W. M. Niblock, 2nd Resident Medical Officer, Presidency General Hospital, Calcutta, is granted leave for 6 weeks, with effect from the 16th June, 1941, or the date of availing.

PROMOTIONS

The undermentioned officer is granted the local rank of Colonel, whilst specially employed:—
 Lieutenant-Colonel G. Covell, C.I.E. Dated 31st May, 1941.

Lieutenant-Colonel to be Colonel

J. B. Hance, C.I.E., O.B.E., V.H.S. Dated 16th December, 1940, with seniority from 27th January, 1935.

The undermentioned Indian Medical Service Officer is advanced to the List of Special Selected Lieutenant-Colonels:—

Lieutenant-Colonel H. E. Shortt, C.I.E. Dated 14th February, 1941.

Major to be Lieutenant-Colonel

R. McRobert. Dated 10th June, 1941.

Major M. G. Saincher to be Acting Lieutenant-Colonel whilst holding the appointment of Officer Commanding, Training Field Ambulance. Dated 16th February, 1941.

Captain A. G. Miller to be Acting Major whilst holding the appointment of Officer Commanding, Indian Convalescent Depot. Dated 15th April, 1941.

LAND FORCES

(Emergency Commissions)

Lieutenant to be Captain

E. Fletcher. Dated 12th March, 1941.

Lieutenant (on probation) to be Captain (on probation)

L. R. Flowers. Dated 19th May, 1941, with seniority from 1st September, 1940.

RETIREMENTS

Lieutenant-Colonel J. H. Smith. Dated 15th March, 1941.
 Lieutenant-Colonel H. S. Cormack, M.C. Dated 6th May, 1941.
 Lieutenant-Colonel J. H. Hislop, M.C. Dated 9th June, 1941.

Notes

BEWARE OF IMITATIONS

THE physicians and members of the allied professions throughout India usually see to it that the layman is warned against buying so-called 'substitutes', but sometimes a doctor will take the chance of prescribing unknown products because he wants to save the patient's money.

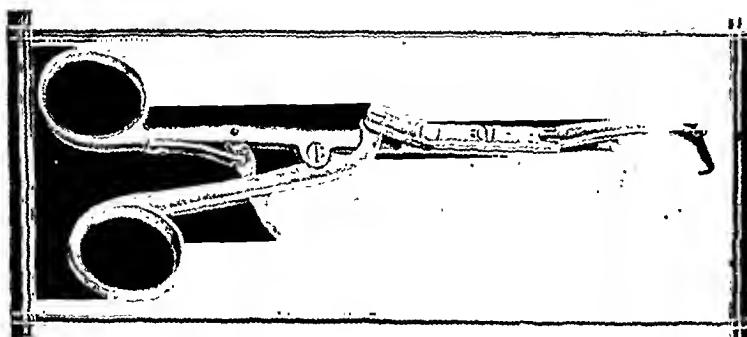

It is during times of unrest and disturbance that the makers of these unknown inferior preparations derive the greatest amount of profit at the expense of the public health. The reliable and ethical practitioner will not deviate from prescribing Antiphlogistine because he has the interest and welfare of his client at heart and will make it his business to discourage the practice of using imitations.

Antiphlogistine has been ethically and scientifically compounded for over 50 years and from time to time it has been imitated, but never has it been duplicated. The silicate of aluminum base used in its manufacture is obtained from private owned mines available only to the Denver Chemical Manufacturing Company.

In acknowledging the confidence which the medical profession has shown towards Antiphlogistine, we suggest that, when prescribing or ordering a kaolin cataplasm for pneumonia, bronchitis or pleurisy, physicians should specify the original genuine product.

TETRA-TOWEL HOLDING FORCEPS

THESE tetra-towel holding forceps have been designed for me by the Times Surgical Company according to my indications. They are made so that they bite vertically and yet the handles lie flat. In this way the annoying towel forceps handle which continually catches in the surgeon's suture and interrupts work is eliminated.

They are also made with a slight curve in the shaft so that they lie snugly to the curve of the patient's body on either side of the incision. This curve is a further factor in keeping the handles out of the way.

I am extremely pleased with them, after nearly a year's constant use. They are made in stainless steel.

A. T. ANDREASEN, F.R.C.S.,
CAPTAIN, I.M.S.,
Civil Surgeon and Principal,
Orissa Medical School, Cuttack.

BOVRIL, LIMITED

Everybody a food specialist

I DARE say you will remember the witty doctor's definition of the difference between the general practitioner and the specialist—the G. P. being a man who knows less and less about more and more, while the specialist knows more and more about less and less.

In this sense I think it can be said that we are all becoming food specialists nowadays.

The quantity of some of our foods may be growing less and less, but—thanks to the experts of the ministry of food and others—we know more and more about making the most, and the best, of the still very ample supplies that the merchant service and the navy risk so much to bring us.

One of the points on which the experts through the press and B. B. C. lay great stress is the importance of making meals tempting to the appetite, as well as satisfying from the purely nutritional point of view. Indeed it is being increasingly realized that the nutritional value of food is to some extent dependent upon its flavour. For a tasty appetizing meal is undoubtedly more easily digested and better assimilated than a meal of equal food value but dull and unattractively served up.

Value of Bovril

It is here that Bovril is proving of real and unique service on the kitchen front. For present conditions give added point to a fact familiar to generations of housewives—that there is no better or simpler way of adding the necessary relish and flavour to an otherwise uninteresting dish than by adding a small quantity of Bovril.

Bovril, the body's ministry of supply

Though it is both true and important that Bovril adds variety and interest to restricted fare and that 'a little of what you fancy does you good', it must not be forgotten that its effects are valuable physiologically as well as psychologically. I refer, of course, to its action, well established by scientific experiment, to stimulate the flow of digestive juices and so to assist the physical processes of assimilation. It would perhaps be not too fanciful to liken its functions to those of the ministry of supply in the body politic, which does not itself undertake the production of the sinews of war but sees to it that this production proceeds with the greatest possible efficiency and dispatch.

Bovril in air-raid shelters

In all its long history of public service Bovril has never proved so valuable or been so much appreciated by so many people as it is to-day. This is partly due to the fact that at all times of stress and strain people instinctively turn to Bovril for stimulation and support. But a special reason is to be found in the conditions under which the populations of our great towns are living. Literally millions of cups of Bovril have given warmth and encouragement to those who, night after night, uncomplainingly put up with the inconvenience and discomfort of long hours in air-raid shelters. As a measure for combating the cold, and sometimes the damp, of shelters, and for brightening the spirit of shelterers, our product has proved of the very greatest value, and the public have quickly come to regard it as an essential part of shelter equipment.

NUNAL

To obtain a prolonged anti-epileptic, hypnotic and analgesic effect, it is essential to use a preparation that

is absorbed evenly, and the body provided with a fairly steady supply of the preparation over a considerable period. For this prolonged therapy, Nunal has been prepared, as the result of an extensive research in our laboratories.

Chemically Nunal is phenyl-ethyl-malonyl-urea.

Indications.—The main indication for Nunal is epilepsy. It has a strong hypnotic action and induces sleep even in cases of insomnia due to pain. It can therefore replace morphine in suitable cases. Nunal is suitable for conditions of excitement, mania and alcoholic delirium and is also recommended in the treatment of eclampsia, tetanus, hyperemesis gravidarum. In fractional doses excellent results have been obtained in relieving spasms. For this reason it has gained noteworthy success in bronchial asthma, whooping cough, migraine, etc.

Dosage.—It is always advisable to begin treatment with small doses and when the individual dose is once found it should be maintained. Generally in adults of average constitution per oral dose of 0.05 to 0.3 gm. (gr. $\frac{1}{2}$ to gr. 4) daily is sufficient. The initial dose should not be more than 0.05 gm. (gr. $\frac{1}{2}$), and, when this is well tolerated, higher doses may be given. Women and delicate men receive correspondingly smaller doses. The dosage for children and infants vary according to age and constitution from gr. $\frac{1}{2}$ to gr. $1\frac{1}{2}$ per diem. When Nunal is given continually, the dosage after a few days should be interrupted for 24 to 48 hours in order to ensure excretion and minimize cumulative effects.

Contra-indications.—In cases of asthenia and great debility Nunal should be used with caution and only in small doses. In patients with marked diseases of the liver, heart or kidneys, use of Nunal is not advised.

Original packing:—Tube containing 10 tablets of gr. $1\frac{1}{2}$. Supplied by the Union Drug Company, Limited, 285, Bowbazar Street, Calcutta.

CALCIUM LÆVULINATE

THERE has been a need in calcium salt therapy for a calcium carrier that was stable in solution, gave a high concentration of calcium ions in the ampoule solution, and was not irritating to the tissues. Oral administration of calcium is often slow while intravenous and intramuscular injections sometimes result in inflammation or ulceration. These and other deficiencies have been observed with the calcium salts of inorganic acids and also, though to a lesser extent, with the salts of those organic acids that have as yet attained much employment in medicine. In recent years studies of the safety and clinical effectiveness of the normal calcium salt of lœvulinic acid have drawn attention to this salt and to its many advantages over other calcium compounds.

Calcium compounds can be used in tetany, in tuberculosis, in various types of urticaria and angio-neurotic oedema, in certain types of intestinal and gall-bladder pain, as adjuncts of vitamin D in the treatment of rickets, and to lessen certain transudation phenomena. Calcium lœvulinate has been used successfully in effecting rapid but temporary increase in the blood calcium content of tuberculous patients by the intravenous route; reduction of oedema and lowering of clotting time have been observed. It is reported to have been used successfully as an adjunct of gold therapy for tuberculosis, serving to combat concomitant diarrhoeas.

Advantages

(1) Its high calcium content (13.1 per cent) compares with that of calcium lactate (13.0 per cent) and more favourably with that of calcium gluconate (8.9 per cent).

(2) Because of its high solubility, stable solutions can be obtained with concentrations as high as 30 per cent or over at room temperatures. Calcium gluconate, in contrast, tends to precipitate even in 10 per cent solution in ampoules.

(3) The solutions are stable at 100°.

(4) The solutions are neutral.

(5) Although it leaves an alkaline ash it does not produce alkalosis. It does not cause acidosis except when used in excessively large doses.

(6) It often assists in the reduction of oedemas.

(7) The ill effects often observed with other calcium salts, such as nausea, loss of appetite, ulceration or inflammation, or diarrhoea, are either entirely absent or markedly reduced.

This product is manufactured by Messrs. Paul Lewis and Company, Inc., 918 N. Fourth Street, Milwaukee, Wisconsin.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints gratis; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributor should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19.8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

UNUSUAL RHINOSPORIDIAL INFECTION IN MAN

By R. G. DHAYAGUDE, M.B.

*Department of Pathology and Bacteriology, Seth G. S.
Medical College, Parel, Bombay*

RHINOSPORIDIAL infection is not uncommon in Bombay. During the course of the last ten years 1931—1940 inclusive, 45 cases of this infection came under my observation. They have been mostly polypoid growths occurring in the nose, or naso-pharynx. Two of these were uncommon in regard to their anatomical distribution and are likely to be of general interest. The first originated in the urethral mucous membrane; while the second showed generalized rhinosporidial granulomata all over the body.

Rhinosporidiosis of the urethra.—Case 1, Mohamedan male, aged 45 years, presented himself at the surgical out-patient department of King Edward VII Memorial Hospital, Bombay, with a complaint that a small mass protruded out of the external urinary meatus while micturating. He did not complain of any bleeding or retention of urine. He had noticed the swelling for about a month.

A pedunculated small polypoid growth was seen protruding from the external urethral meatus for about half a centimetre (plate XXVII, figure 1). On pressure it came out (figure 2) nearly 2 to 2.5 cm. more, and another small growth similar in appearance and feel was seen by its side, the whole appearance being like the bifid tongue of a serpent. By means of a probe it was ascertained that the base of the growth was about 3 cm. above the external urinary meatus. The penis was normal and the lymphatic glands in the inguinal region were not affected. A specimen of urine taken at the time of examination did not show any abnormality.

While attempting to cauterize the growth by diathermy, it snapped before it could be diathermized. The portion of the growth thus obtained was sent for examination.

Histological examination.—The growth showed typical features of papillomatous growth of rhinosporidial origin. It consists of a connective tissue core covered over with squamous stratified epithelium. The connective tissue is infiltrated with a large number of sporangia with a thick wall and pinkish hyaline matrix in different stages of degeneration. Underneath the epithelium are seen a few mature sporangia with violet-stained spores on the point of bursting. One or two of them have burst and scattered the spores on the surface and in the adjacent connective tissue. A few early trophic forms of the parasites are seen here and there. The epithelial lining is thinned out in areas in which the sporangia are well developed. The connective tissue in the core is strewn with reactionary inflammatory cell infiltrate consisting of polymorphonuclear cells, lymphocytes, eosinophiles and plasma cells and an occasional

foreign body giant cell disposed around disintegrating sporangia.

The patient was further examined to find out whether he had any primary growth in the nose or naso-pharynx. No lesions could be discovered in these situations.

Generalized rhinosporidial granulomata.—Case 2, patient, Hindu male, aged 40 years, was admitted to King Edward VII Memorial Hospital, Bombay, for multiple swellings all over the body, of six months' duration.

The patient was working on a farm about three months ago, but at the time of admission was out of employment. A swelling first appeared on his left lower extremity and from that time on gradually a large number of swellings appeared on his body. He did not remember having suffered from trauma at the site where the first swelling appeared, nor at any other situation where the subsequent ones developed. To begin with the swellings were small, firm nodules in the subcutaneous tissue but as they grew bigger some of them ulcerated, suppurated and broke down. They varied considerably in size. Some of them were only a centimetre in diameter while others were elongated and measured 10 cm. × 5 cm. Some of them were soft and fluctuating while others were firm and well circumscribed. All the swellings were painless and situated in the subcutaneous tissue and were not attached to any deeper structures. None of them showed any connection with nerves. The swellings were situated on the face, thorax, abdomen, back, gluteal region, and particularly large ones on both the superior extremities. As will be seen from the photographs (figures 3 and 4) those situated on the thorax, hypogastrium, back and right shoulder had ulcerated and formed pedunculated masses. Those on the face, right forearm and the gluteal region were just breaking through the skin. The rest and especially those that formed large masses on the arms had an intact integument. The hind view shows them well marked on the dorsal aspect of the left arm and forearm. One such large mass situated in the right arm was excised and sent for microscopic examination. It showed typical structure of a rhinosporidial granuloma (figures 5 and 6).

The patient was further investigated to see if there was any primary growth in the nose or nasopharynx. No lesion could be discovered.

Investigations.—His blood was taken for Kahn reaction and was found to be positive ++++. The cytological examination of the blood showed the following picture:—

Red blood corpuscles	4,400,000 per c.mm.
Hæmoglobin	69.55 per cent.
Colour index	0.87
White blood corpuscles	13,000 per c.mm.
Polymorphonuclears—		
Neutrophiles	65 per cent.
Eosinophiles	13
Basophiles	Nil.
Mononuclears—		
Large mononuclears	1 per cent.
Lymphocytes	21 "

In order to find out whether spores or sporangia were present in the circulation, on two occasions 10 c.c.m. of blood of the patient was taken and laked with distilled water. It was then centrifugalized and the deposit was carefully examined for spores or sporangia. The result on both occasions was negative. A blood culture was not attempted because there was no satisfactory method available for growing the organisms from blood; indeed it is a question whether the organism has been cultivated.

Cultivation and inoculation.—As a large amount of material free from any contaminating microbe was available one of the nodules

was cut out aseptically and the material was emulsified and planted on all the routine media employed in the laboratory, i.e., (1) nutrient agar, (2) blood agar, (3) ascitic agar, (4) Endo's medium, (5) Löwenstein's medium, (6) Sabouraud's medium, (7) Löffler's serum medium, (8) glucose broth, and (9) potato-water medium. The cultures were grown aerobically and anaerobically at 37°C. and at room temperature, and were observed for nearly three months before they were discarded. In Löwenstein's and potato-water medium the organisms were seen in a well-preserved state for over two months, but at no time during the fortnightly examinations was there any evidence of the growth of the fungus. The attempt at cultivation was thus disappointing. So also was an effort to transplant the growth into the subcutaneous tissues of guinea-pigs and dogs. Three guinea-pigs and two dogs were used. Sections cut out from sites where bits of tissue were planted after a period of about two months showed only degenerating sporangia and a chronic inflammatory reaction which appeared to have successfully encapsulated the material. There was no evidence of invasion on the part of the parasite into the surrounding tissue. In one guinea-pig a few apparently healthy-looking sporangia were seen in a biopsy taken from the site of implantation after about a month. The animal was further observed and the mass progressively diminished in size until ultimately nothing could be felt at the site of injection except a small scar of the biopsy.

Comment

A case of rhinosporidial infection in connection with the penis has been described by Ingram (1910). In his case there was a cauliflower-like growth which covered the whole of the glans penis which was enlarged to the size of a baby's fist. The external urinary meatus and probably the contiguous portion of the urethral mucous membrane was involved. In the case described the growth originated a little way up in the urethra and formed polyoid masses which protruded from the urethral opening. Karunaratne (1939) has given a summary of 104 cases studied by him and a synopsis of 280 human cases recorded up to 1939 and apart from the case described by Ingram there is no other report of an infection in connection with the penis. Kurup (1931) mentions that Mohammedans are especially liable to rhinosporidial infection. In this particular case the patient happens to be a Mohammedan, but in my series of 45 cases the Hindus and the Mohammedans are more or less equally affected.

The second case appears to be unique. In the synopsis by Karunaratne referred to above, there is no record of a case of a generalized infection as was seen in this case. In a previous article Karunaratne (1936) makes a statement that the infection remains localized to the

original site though nearby sites may become infected but there is no evidence of generalized haematogenous dissemination. In this case a few swellings had ulcerated on the surface and a few areas in the contiguous portion did show the presence of a fungus which might be ascribed to contact infection. But a large number of swellings scattered on the legs, thorax, abdomen, back and the superior extremities could not possibly be accounted for by a contact infection. Besides many of the large swellings had an intact skin covering them. Lymphatic spread cannot explain such a wide anatomical distribution. The only process by which such a generalized dissemination could be explained is by the haematogenous route. The failure to demonstrate the fungus in the blood by microscopic examination does not militate against the possibility of haematogenous spread, for it is well known that a cultural examination becomes necessary to demonstrate micro-organisms in septicaemic conditions, unless the infection is very massive. Unfortunately a suitable method of cultivation of the parasite has yet to be described. Except for a single reference quoted below there has been no record of a successful culture of the fungus.

Even when such rich material was available for the cultivation of the fungus, all attempts to grow them have failed. Tirumurti (1914) attempted unsuccessfully to cultivate the organism and to produce infection in animals. Duggan (Karunaratne, 1939) mentions that successful growth of the organisms was obtained by Iyer on Sabouraud's medium. In my experiments Sabouraud's medium was employed, but I have failed to obtain a growth. The organisms were seen in a state of relatively good preservation for some time, but the best medium from that point of view in my experience was potato-water medium. The positive Kahn reaction appears to be accidental. It might be of interest to add that the patient was given large doses of potassium iodide for a period of three weeks but the swellings were not in any way affected by the treatment.

BULLOUS EMPHYSEMA OF THE LUNG

By T. K. RAMAN, M.D., D.T.M. (Cal.)

(From the Department of Medicine, Andhra Medical College, Vizagapatam)

ALTHOUGH emphysema of the lung has been described by Lannaec the condition of bullous emphysema has come into prominence only recently. Kerley (1931) reported a case with two large bullæ, one at the left apex and the other at the right base. The clinical findings suggested spontaneous pneumothorax and the radiological diagnosis of bullous emphysema was confirmed post mortem. Kerley (1936) described bullous emphysema as a clinical entity. Wiese *et al.* (1939) described a case of multiple bullous emphysema in a male aged 38 years. Radiological appearance suggested bullæ on either side. Twenty large and small emphysematous bullæ were seen post mortem. The condition was associated with anthracosilicosis, and was under observation for several years. Illingworth (1938) reported a case of congenital emphysematous bullæ (air-containing cyst) at the base of the right lung in a girl aged 1 year and 3 months. Paracentesis showed positive pressure and 100 and 76 c.cm. of air was withdrawn on two successive days. The patient was discharged and subsequent examination showed the same signs without any improvement. The condition is extremely rare and the literature on bullous emphysema during the last four years contains only a few papers. Description of four cases met with in Vizagapatam are given below.

Case 1.—Hindu male, aged 34 years, cloth merchant, was admitted on 8th August, 1936, with a history of fever and dyspnoea of seven years' duration. He gave a history of breathlessness 16 years back, an attack of haemoptysis eight years ago and frequent attacks of dyspnoea for the last four years. He had an attack of gonorrhoea but denied any history of syphilis.

(Continued from previous page)

Summary

1. Two unusual cases, one of rhinosporidial infection of the penis and the other a generalized infection, are described.

2. The spread in the latter case must have been haematogenous.

3. Attempts at cultivation and inoculation into animals were unsuccessful.

Acknowledgments.—For the clinical notes of the first case my thanks are due to Dr. R. N. Cooper, Honorary Surgeon, King Edward VII Memorial Hospital, Bombay.

 TIRUMURTI, T. S. (1914). *Practitioner*, 93, 704.

Physical examination showed a moderately nourished individual with slight oedema of the legs and a condition of dyspnoea.

Respiratory system: chest barrel-shaped, movements equal on both sides but diminished, markedly hyper-resonant note all over, vocal fremitus and resonance slightly increased on both bases, respirations prolonged and rhonchi were heard on both sides.

X-ray of chest showed two emphysematous bullæ, a big one at the apex of the left side and a small one in the middle of the right side.

Circulatory system: cyanosis of the lips, prominent jugular veins, blood pressure 90/68, and radial arteries slightly thickened. Heart boundaries could not be made out on account of hyper-resonance. Heart sounds normal but feeble. Liver palpable three fingers below the costal margin. Blood showed eosinophilia.

Sputum negative for tubercle bacilli.

The patient was running a temperature between 99°F. to 100°F. He was transferred to the tuberculosis department on 18th August, 1936. An exploratory puncture caused extreme dyspnoea and the patient died a few hours later, probably as a result of spontaneous pneumothorax by a rupture of emphysematous bullæ.

Case 2.—Hindu male, compounder, aged 37 years, was admitted on 23rd February, 1939, with a history of cough and breathlessness of ten months' duration. He gave a history of dysentery for ten years and cough and heaviness in the chest of nine months' duration. Treatment gave no relief and dyspnoea was marked for the last four months, especially after exertion. His father died in 1913 with chronic lung disease.

Physical examination: a poorly nourished individual with slight clubbing of fingers and slight oedema of the legs.

Respiratory system: respirations 20 per minute, laboured, chest symmetrical but expansion diminished. Vocal fremitus and vocal resonance normal at both bases. Percussion note slightly hyper-resonant at both apices; a few crepitations were heard on both sides.

Circulatory system: blood pressure 94/60, heart sounds normal but feeble.

Liver palpable three fingers breadth below costal margin, spleen not palpable.

Urine: trace of sugar present.

Blood: haemoglobin 70 per cent, red blood corpuscles 3.9 millions, polymorphonuclears 86 per cent, lymphocytes 8 per cent, eosinophils 4 per cent and mononuclears 2 per cent, anisocytosis, poikilocytosis and a picture of microcytic anaemia. Ancylostome ova in the stools. Sputum—no tubercle bacilli.

X-ray of the chest (figure 1) showed two big bullæ at both the apices. A second x-ray with lipiodol (figure 2) showed that lipiodol did not enter these bullæ.

The patient was discharged on 20th March, 1939. He was re-admitted on 16th June, 1939, with the same symptoms but more severe. Blood pressure 115/90. No further investigation was possible and he was discharged on 20th June, 1939.

Case 3.—Hindu male, aged 25 years, was admitted on 3rd May, 1941, with a history of cough, haemoptysis and slight dyspnoea of six months' duration. He had had recurrent attacks of bronchitis for the last three years and occasional haemoptysis.

Physical examination showed a fairly well-nourished individual with slight anaemia.

Respiratory system: showed diminished movements of the chest, vocal fremitus and vocal resonance present on both sides. Percussion note hyper-resonant on the right side in front and behind, breath sounds were completely absent over the right side, in front and back. X-ray showed bullous emphysema of the right side (figures 3 and 4).

Circulatory system: normal.

He was running a low temperature between 99°F. to 100°F. while in hospital.

Urine: normal. Blood: haemoglobin 80 per cent, red blood corpuscles 3.9 millions, leucocytes 9,000. Repeated examination of sputum did not reveal tubercle bacilli.

He was discharged on 15th May, 1941.

Case 4.—Hindu male, was admitted on 5th June, 1941, with a history of breathlessness on exertion, cough and expectoration of one year's duration. He gave a history of syphilis 20 years ago.

Physical examination showed an ill-nourished individual with slight prominent eyes and slight clubbing of fingers.

Respiratory system: patient in a condition of dyspnoea, expansion of the chest diminished, vocal fremitus and resonance diminished at both apices more at the left apex, percussion showed hyper-resonant note all over, auscultation showed feeble breath sounds at both apices more marked on the left side. Occasional wheezing expiratory sounds were heard.

X-ray showed multiple giant bullæ at both apices.

Circulatory system: apex beat in the 6th interspace just external to the nipple line, systolic and diastolic murmurs were heard in the mitral, aortic and pulmonary areas, blood pressure 105/40. Blood: red blood corpuscles 4.24 millions, leucocytes 9,800, polymorphonuclears 64 per cent, lymphocytes 15 per cent, mononuclears 13 per cent, eosinophils 10 per cent.

Sputum negative for tubercle bacilli. The case is one of multiple bullous emphysema in a patient who has got aortic regurgitation. The multiple giant bullæ might be the result of syphilitic fibrosis of the lung. No further investigation was possible since he refused to remain in the hospital.

Discussion

What exactly bullous emphysema is, is not definitely known. Some are of opinion that the condition is due to a developmental defect and is congenital in origin. Kerley thinks that in the case he described syphilitic fibrosis of the lung was responsible for the formation of large emphysematous bullæ. Fibrosis causes stenosis of the bronchi which leads to the formation of large bullæ. Other forms of fibrosis such as tuberculosis and anthracosilicosis can produce the same condition.

Of the four cases reported here the first case was diagnosed as double pneumothorax and the introduction of a needle into the large bullæ caused death by the production of spontaneous pneumothorax; in the second case diagnosis was made by radiological appearances; in the third the condition was diagnosed clinically by the slight hyper-resonant note and absence of breath sounds on the right side. The question arose whether it was a case of localized spontaneous pneumothorax or bullous emphysema of the right side. Clinical diagnosis was confirmed by radiological observations. The patient had to be discharged and he could not be followed further. In the fourth case the patient had extreme dyspnoea out of proportion to the physical signs. A clinical diagnosis of bullous emphysema was provisionally made; the diagnosis was confirmed radiologically and multiple giant bullæ were seen on both sides. In the second case lipiodol injected into the trachea did not enter these bullæ.

Differential diagnosis arises between localized pneumothorax, congenital cystic disease, and big cavities in the lung.

Positive diagnosis can be made only by x-rays and when the definite outlines of the bullæ are

PANCREATIC CALCULI

By MANGALDAS J. SHAH, M.B., B.S. (Bom.),
M.R.C.P. (Lond.), D.T.M. & H. (Lond.)

Honorary Assistant Physician, K. E. M. Hospital,
Bombay, Honorary Physician to Sir Harkisondas
Hospital, Bombay

CASES of pancreatic lithiasis are rare; this is evident from the fact that so far less than 150 cases have been reported in the literature. To my knowledge only one case has been reported in India, i.e., by Kini (1938). Prior to the advent of x-rays, the case reports came only from the post-mortem rooms. Pancreatic lithiasis was first detected and described by de Graf in 1667. Cawley in 1788 detected pancreatic calculi post mortem in a man, who was a known subject of diabetes during his life time. Thus, Cawley was the first to associate diabetes with pancreatic calculi. Oser in 1903 collected and reviewed 70 cases of pancreatic lithiasis of which 24 cases were suffering from glycosuria during life. In 1904 Robson suggested the use of x-rays for the diagnosis of the condition during life, because of the high calcium content of the calculi. In 1912 Assmann reported a case in which radiological diagnosis was made during life and was confirmed post mortem. In 1928 Seeger reviewed a total of 101 cases including one case of his own; and in 1932 Ackman and Ross reviewed 108 cases. In 1936 Dr. J. G. Mayo reported 25 cases from the records of Mayo Clinic out of which the diagnosis was correctly made prior to operation in 2 cases; diagnosis was incidental in 14 cases during some other abdominal operation; and it was made post mortem in 9 cases. In India, Kini reported a case of

(Continued from previous column)

seen the diagnosis is easy but when indefinite only post mortem will settle the diagnosis.

Summary

Four cases of bullous emphysema are described. In the first case the diagnosis was missed, in the second diagnosis was made by the radiological appearances, and in the third and fourth cases the diagnosis was made clinically and confirmed by x-rays.

Acknowledgments

My thanks are due to Dr. P. Kutumbiah, for the clinical notes and to Dr. P. Kesavaswamy and Dr. C. Benjamin, for the x-ray plates.

multiple pancreatic calculi associated with chronic pancreatitis in 1937. A few cases of successful surgical treatment are recorded.

Herewith 2 cases are reported, one detected at the K. E. M. Hospital and another at Sir Harkisondas Hospital, Bombay.

Case 1.—A male patient, aged 28 years, sought admission to the K. E. M. Hospital on 15th April, 1940, for attacks of colicky pain over the lower part of epigastrium and for symptoms of frequency of micturition, polydipsia, excessive hunger, and loss of weight (50 lb. in 2 years). The pain was described as colicky, severe, shooting across the lower part of epigastrium from right to left, lasting from a few minutes to an hour or more and bearing no relation to food, defaecation or other factors. The total duration of pain was six months. The other symptoms had become marked during last six months.

There was no history of any previous illness, and there was nothing of importance in the personal and family history.

On general examination, the patient appeared markedly depressed, emaciated and asthenic. There was slight diffuse tenderness in the epigastric area. The other systems showed no abnormal findings.

The other investigations were as follows:—

X-ray.—A plain radiogram showed a chain of dense shadows going obliquely across at the level of the lower border of the body of the 12th dorsal and the 1st lumbar vertebrae, extending for about one inch on the right side over the body and for about 2 inches towards the left side (plate XXIX, figures 1 and 2).

Stools.—Loose, large, whitish and showed the presence of fat globules under the microscope.

Fat analysis showed the following:—

Total fat	36 per cent.
Unsoaped fat	12 " "
Neutral fat	4 " "
Free fatty acids	7 " "
Combined fatty acids	13 " "

Urine.—Showed presence of marked glycosuria, and ketone bodies.

Blood sugar.—The glucose tolerance test was as follows:—

Fasting sugar	250 mg.
½ hour after glucose	368.6 "
1 " "	..	333.6 "
1½ hours " "	..	307.6 "
2 " "	..	285.7 "

After a stay of about a week in the hospital the patient went away against advice. He was reported to have died at his residence about a month after leaving the hospital.

Case 2.—A male, aged 44 years, admitted on 16th July, 1940. He complained of abdominal pain in the left half of the umbilical area, loss of weight (20 lb. in 6 months), and of passing oily stools for about seven months. The trouble started with an acute attack of severe colicky pain in the above region shooting towards the back on the left side seven months previously, the attack lasting for four days. He had a second severe attack a month later and a third four days before admission. There was no nausea or vomiting during the attack. He also had a continuous dull aching pain, not related to food or other factors, in the same area, since his first attack. The oily stools were particularly marked after taking a diet rich in fats (ghee). The loss of weight was gradual.

He gave a history of having suffered from dysentery and jaundice ten years ago. There was nothing of importance in personal or family history.

On physical examination, the patient was pale, emaciated and markedly asthenic. There was slight tenderness in the region of pain in abdomen.

The following is a short account of the investigations:—

X-ray.—(a) Plain x-ray in antero-posterior view shows a chain of dense curved shadows, crossing the front of the vertebral column at the 12th dorsal vertebra, extending for about 2 inches on either side, and the lower ends of the curves reaching to the level of first lumbar (figure 3).

(b) In the lateral view the greater part of the shadows lies in front of the vertebra while a few shadows seem to superimpose on the vertebral shadow (figure 4).

(c) Cholecystograms were normal.

(d) Descending pyelography with uroselectan B injected intravenously was done and the urinary tracts were found normal.

Stools.—The stools were large, slightly whitish, foul-smelling, and showed plenty of fat globules under the microscope.

The fat analysis showed the following:—

Total fats	48 per cent.
Neutral fats	27 " "
Free fatty acids	10 " "
Combined fatty acids	11 " "

Urine.—Showed the presence of sugar up to 5 per cent but no ketone bodies. There were no abnormal microscopic findings.

Blood sugar.—The glucose tolerance test showed—

Fasting level	140 mg.
½ hour after glucose	160 "
1 " "	..	160 "
1½ hours " "	..	170 "
2 " "	..	160 "

Enzyme studies.—

(a) Urine diastase index	6.7 per cent.
(b) Blood diastase index	4.2 " "

The blood count showed a moderate degree of anaemia.

The fact that one was able to detect 2 cases of pancreatic lithiasis in a short course of three months can be accounted as pure chance. It will not be out of place to quote Korte's remarks that disease of the pancreas would be far commoner if the doctor would only remember that his patient had a pancreas.

Aetiology and pathology

The exact aetiology of pancreatic calculi is not determined with certainty. It seems to be more frequent in males, since 75 per cent of the reported cases are males. Both the present reported cases are males. Stasis of the pancreatic secretion alone cannot be a causative factor, because the normal pancreatic secretion does not contain calcium carbonate. Also the experimental tying of the main pancreatic duct in animals does not result in stone formation. Infection of the pancreas, through the duct, the lymphatics or the blood, would alter the pancreatic secretion and might lead to formation of calcium stone. Primary pancreatic infection with secondary stasis of the altered secretion seems to be the cause. Biliary disease, e.g., cholecystitis, gall stones, etc., which is associated in many cases might possibly be the source of infection in those cases.

No apparent cause could be found in the first case, while the history of the dysentery and jaundice might be causative in the second case.

Mayo describes two types of pancreatic stones. Those within the ducts are true stones. The false stones are due to calcification of the parenchymatous tissue of the pancreas. The number of stones vary from a single calculus to multiple calculi. The size may be anything from that of a minute sand-grain to one as large as 2 inches in diameter. The shape may be irregular, or faceted. They are pale yellow to light grey in colour. They are very friable—a point of importance for surgical treatment. The main constituent in their composition is calcium carbonate and calcium phosphate.

The effects of the calculi on the pancreas may be *nil*, or they may lead to fatty degeneration, fibrosis, cyst formation, or abscess formation. Usually it is the acinous tissue that perishes first and then the islets of Langerhans. In both the reported cases the calculi are multiple. Both of them showed evidence of affection of both the external and the internal secretions of the pancreas as shown by steatorrhœa, and glycosuria. Steatorrhœa was more marked in the second case, while hyperglycæmia was more evident in the first case.

Symptoms.—There are no symptoms that can be said to be typical of pancreatic lithiasis. The symptoms are mainly of four groups, *viz.*, those due to intermittent obstruction of the pancreatic duct, those due to disorganization and destruction of the pancreas, those due to interference with the bile duct, and finally those of the associated disease.

Pain.—Pain is perhaps the commonest symptom. The situation of pain varies from case to case. It may be in epigastrie, umbilical, right hypochondriac, left hypochondriac or in lumbar areas. In the present series the pain was situated over the lower part of epigastrium in the first case and over the left half of the umbilical area in the second case. Its character may be dull and continuous or colicky and intermittent. The pain was colicky in the first case, while it was both colicky and dull aching in the second case. Ackman and Ross report colicky epigastric pain in 19 out of 29 cases. The pain may radiate to the back, shoulders, scapulae, lumbar area, or iliac fossa, depending on the position of the affected pancreatic area. The pain in the first case radiated across the lower epigastrium from right to left and it radiated to the back in the second case. Nausea and vomiting are frequently present during the acute paroxysms; they were absent in both my cases.

Steatorrhœa and diarrhoea.—The stools are usually oily, large whitish-coloured, frothy, foul-smelling and contain grossly indigested food. The diarrhoea may increase during the attacks of pain. Microscopic and chemical examinations of the stools show the presence of excess of unsplit fat, and partially digested muscle fibres in meat eaters. Very rarely small stones may be detected in the stools. Both the cases showed

increased fat content in their stools, more so the second case.

Glycosuria and hyperglycæmia.—Oser reported association of glycosuria and pancreatic lithiasis in 24 out of 70 cases. Opie (1910) stated that glycosuria came late in the course of the disease when fibrosis and disorganization of the pancreas had become extensive. The first case showed both glycosuria and hyperglycæmia. In the second case, there was glycosuria and the fasting blood sugar level was definitely raised, but the blood sugar curve was a flat one. This might be attributed to lack of proper intestinal absorption of glucose and the appearance of sugar in urine at blood-sugar level of 160 mg. could be explained as due to lowering of the renal threshold for sugar.

Jaundice.—Obstructive jaundice has been reported in 25 per cent of cases, which might be due to obstruction at the ampulla of Vater by the calculus, or pressure on the common bile duct by stones or by inflammatory swelling in the head of the pancreas. In neither of my cases was there jaundice.

Loss of weight.—There is usually a marked loss of weight and asthenia in these cases. In the first case there was a loss of 50 pounds in 2 years. The second patient lost 20 pounds in 6 months.

Physical signs.—There are no physical signs peculiar to the disease. Consequently diagnosis of pancreatic calculi cannot be made on any one physical sign. Both the cases showed only vague tenderness over the areas of pain in the abdomen.

Investigations.—X-ray. As previously stated Mayo Robson was the first to draw attention to the importance of x-rays in making the diagnosis. It is still the best method of making a pre-operative diagnosis of pancreatic calculi. In all cases of pain in the upper abdomen, a plain radiogram without a barium meal is very necessary, since the presence of an opaque meal in the stomach completely or partially obscures the pancreatic site. In a few cases the calculi may be too minute or may contain too little calcium to cast a shadow. A summary of the study from copies of radiograms in 30 cases by Gillies (1939) is given below :—

- (a) **Location**—In 21 cases the shadows were situated in an area below a plane drawn at the upper margin of the first lumbar and above a plane at the lower margin of the third lumbar vertebra. In 9 cases the stones were above the upper plane, but in no case were they below the lower plane.
- (b) **Size**—The size of the shadows varied from that of sand-grains to about 2 inches in diameter.
- (c) **Density**—The shadows were so very dense that they were visible even in front of the vertebral shadows.
- (d) **Number and shape**—Multiple calculi were the commonest, being present in 24 out of 30 cases. The shape was irregular in the majority. The contour of the pancreas was outlined with the calculi in the head being on the right of the spine while those in the neck, body and tail extended across the middle line to the left.

PRACTICAL ASPECTS ON GENERAL ANASARCA, ESPECIALLY IN MALARIAL NEPHRITIS AND HOOKWORM DISEASE*

By ROBERT HEILIG, M.D.

First Physician, Krishnarajendra Hospital, Mysore

THERE are certain periods of the year when Krishnarajendra Hospital cannot provide enough beds for ascites-anasarca cases asking for admission; this periodicity of maximal oedema collection seems to be a problem in itself though

* Read at the XIIIth Annual Conference, Mysore Medical Association.

(Continued from previous page)

The radiograms in both the reported cases are slightly higher, but reach at some points the upper plane of the first lumbar vertebra. Also the contour, shape, density of the shadows together with the symptoms, steatorrhœa and glycosuria, leave no doubt regarding the diagnosis. In the second case care was taken to rule out stones in the gall bladder or kidneys.

The radiograms suggestive of pancreatic calculi have to be differentiated from calcified glands, gall-bladder stones and renal calculi.

Special enzyme studies to show an acute diminution of pancreatic enzymes in the stools, and in material obtained on passing a duodenal tube, and an increase in urinary and blood diastase index may be undertaken.

Summary

1. Two cases of pancreatic lithiasis diagnosed during life are reported.

2. The aetiology, pathology, symptoms and signs, and radiological findings are discussed.

Acknowledgment.—I wish to thank the Dean of the K. E. M. Hospital, Dr. Jivraj N. Mehta, and my chief, Dr. P. C. Bharucha, for permitting me to report the first case. I also thank my other colleagues for helping me in my investigation of both the cases.

many non-medical reasons, such as variations in the intensity and urgency of agricultural work, may be of importance. Most of our anasarca cases belong to one of the three groups:—

- (a) Heart-failure.
- (b) Nephritis.
- (c) Ancylostomiasis.

(a) *Heart-failure.*—The group is the best known and thus the least interesting, here presenting not many differences from heart-failure cases anywhere else. The heart-failure that causes water retention in our patients is either due to a valvular disease or a consequence of essential hypertension; the group of heart muscle degeneration without hypertension, due to atherosclerotic or syphilitic changes especially of the coronary vessels, is in our experience rather rare, whereas it constitutes an overwhelming majority among failing hearts in Europe. To save space for the more detailed description of both the other groups we refrain from discussing our experiences in heart-failure on this occasion.

(b) *Nephritis.*—General anasarca due to kidney disease is seen here sometimes in acute glomerulo-nephritis, sometimes in acute exacerbation of chronic glomerulo-nephritis, but mostly as a wet or nephrotic type of subacute glomerulo-nephritis. In fact, we see about four times more subacute than acute or chronic manifestations of glomerulo-nephritis. During the last 8 months we have admitted 6 cases of acute glomerulo-nephritis; oliguria with high specific gravity, albuminuria, blood and casts in the urine, moderately increased blood pressure, moderately enlarged heart, normal or moderately increased blood urea, absence of fundal changes and the very characteristic distribution of the abundant oedema that started on the eyelids, nearly closing them, and on the face a few days before admission, exclude every other diagnostic possibility. But it is remarkable that 4 of these cases—young girls all of them—suffered from acute malaria, 2 benign, 2 malignant tertian, with regular attack of rigor and fever up to 20 days previous to the appearance of oedema, and along with the acute nephritis. The aetiological importance of the malarial infection for the development of an acute nephritis seems to be made very probable by the fact that all these 4 cases responded excellently to routine quinine treatment, by losing oedema, albuminuria, and haematuria in an average of 16 days, a time sufficient to reduce the pressure from 150, 145, 130 and 130, respectively, to normal and to make disappear the enlargement of the heart in the 3 cases where it was present; I have never seen such rapid healing in fully-developed cases of non-malarial origin; in fact the 2 cases where no sign of malaria could be detected left the hospital after 2 and 3 months, respectively, with albumin and red cells still present, most probably developing lasting kidney damage.

the class or school prizes can be given to the children with the largest number of golden discs earned during the year. Punctuality can be included in the items and it should be remembered that strict punctuality on the part of the teacher is an important requirement.

Care of personal belongings, apparatus and books handled in the school can also be scored in the same way or separately. The children should be taught to maintain their own diaries and to make the entries honestly. This may be said to be the *personal aspect* of health participation.

With regard to the *community aspect*, the task for the teacher is not more easy. This entails developing a correct attitude by the children towards each other's property, books and clothing. The practice of sucking pencils and exchanging clothing, utensils, mugs, etc., is strictly discouraged. Spitting is forbidden and careful wash-room and latrine drill is carried out. The children are themselves made responsible for the proper disposal of paper and refuse in the play-ground and class-room.

As regards the part played by the teacher directly in the community aspect of practice teaching: A daily collection of drinking water should be made, the water being stored in the sun in *chatties* or other receptacles after boiling or disinfecting. The teacher must be responsible for this work, but later it can be left to the children so that no water is drunk by the members of the class other than that prepared for the purpose. The teacher must see that the children wash their hands before drinking or that the children use their individual mugs properly rinsed. The teacher must also be responsible for a daily inspection of wash-rooms and latrines.

If food is eaten in the school, it is very useful if the teacher can keep a small depository where all the food is stored in a cool place, free from flies and dust. She must then supervise the washing of hands before eating, and the disposal of papers and refuse. Later on this responsibility can be made over to the older children so that there is built up a community feeling. In order to prevent flies from collecting in the class-room small dishes of mud containing formalin, sugar and water can be placed in corners or near the food store to entrap flies and insects.

With regard to the lighting and airing of class-rooms, the teacher can train the children to regulate ventilation and light for themselves by airing the room between classes and by opening and shutting windows to avoid overheating and glare. The tidiness of the class-room can also be the responsibility of the pupils under the supervision of the teacher.

In this way the home conditions are to some extent duplicated and the child functions as a unit in a community while the teacher to some extent represents the health authorities.

It is not possible, of course, to neglect instruction or definite lessons in hygiene. Textbooks have to be relied upon. But if we take one of the subjects dealt with in the book, for example water supply, we can see how the textbook instructions can be supplemented by practical lessons in the school and outside.

In the case of water, for instance, one has already mentioned the supervision of the drinking water for the class. In Ceylon, water is boiled and then stored in a cheap galvanized iron can fitted with a tap. The children collect and boil the water every evening before school closes and fill the container so that the water chills overnight for use next morning. Rough earthenware cups and *chatties* can be used to replace more expensive apparatus. Secondly, in the class demonstrations can be given on the effect of adding alum, chlorine, etc., to water. Thirdly, the children can be taken out to inspect the local wells or water supply and a discussion on wastage of water can be held. In towns it is possible to visit the water works and museums where models are shown.

A simple talk on the contamination of water and the diseases which are spread by infected water can be given. This might be a professional talk arranged through the co-operation of the local doctor. Finally, a discussion on the precautions taken to protect water and the water supply in the school can be held. All subjects can be treated in a similar way, supplementing the lessons and practice in the class by utilizing facilities in the community and in the neighbourhood.

There are two further approaches to community health teaching of children, useful both for the teacher and the pupil. The first of these is the holding of safety-first exercises and first-aid drill. Many schools can, and do, develop these schemes on simple lines. The second is school medical inspection.

The school medical inspection is often regarded by the teacher as a time-consuming interruption of little apparent use. But school medical inspection offers three essential contributions to the teaching of civic health:

(1) It provides an opportunity for the teacher to have the doctor's opinion on children whom she suspects need special medical care or dicting or who are a source of infection to the other pupils.

(2) It provides an opportunity to make contact with the parents. School medical inspection can only be of value to the community if the parent is present at the inspection along with the teacher. One may here cite an instance of how often confusion arises with regard to the purposes of school medical inspection. Looking over medical inspection cards in a school for middle class boys in Calcutta, one found against the caption 'Parents present?' 'Yes' was invariably

A NEW AND HIGHLY POTENT TYPHOID VACCINE : A REVIEW

By K. V. KRISHNAN, M.B., B.S., M.R.C.P., D.B., D.Sc.

(From the Department of Microbiology, All-India Institute of Hygiene and Public Health, Calcutta)

AMONG the prophylactic vaccines commonly employed in public health work, typhoid vaccine occupies a place of great importance. In this country, the vaccine is prepared not only by government laboratories, but also by several commercial firms. The results obtained by the use of these vaccines have not been always uniformly good. Complaints have been received from time to time of severe outbreaks of typhoid among recently immunized families and communities, and doubts have been raised as to the protective properties of the vaccine employed. From enquiries into the nature of the vaccines used and their method of preparation, and from the actual testing of some of these vaccines and of the strains of typhoid bacillus used in their manufacture, we are led to believe that some of the manufacturers of these vaccines in this country are not aware of the recent advances in our knowledge of anti-typhoid immunization, and that they are still following the methods of vaccine preparation. This article is specially

(Continued from previous page)

written. Yet at the time of the inspection then being held not a single parent was in attendance. On enquiry it became clear that the teachers were under the impression that the phrase 'parents present' meant 'are the parents alive?'! The interest of the teacher therefore is essential to successful inspection.

(3) The teacher is given an opportunity to talk over with the medical officer some of her problems which may have a medical basis, for example, Atul, who is short-sighted, or Monesh who seems inattentive, but whom the doctor finds is slightly deaf. Aruna who cannot concentrate but is found by the doctor to have worms. Interest for the teacher in her class widens and deepens with such a programme of health education, and each child's home conditions begin to have a meaning.

In small rural schools contact with the parents is easier, but bad transportation and poor communications often interfere with regular attendance and the malaria season in such schools is only too often clearly marked by a great fall in attendance. It is difficult to keep up a sustained programme of health education under such circumstances.

The field of the teacher in health education is largely dependent on the ingenuity, interest and knowledge which she can place at the service of her pupils. The inception of compulsory primary education, however, opens up for us a new era as regards the development of health education in schools.

written with the object of placing the newer knowledge in the hands of interested persons, so that they may prepare or direct the preparation of the new type of vaccine, which recent work has established to be superior in its protective property to the old vaccine. Within the last few years a very large number of valuable contributions pertaining to the subject have been made by different workers (Felix, Perry, Grinnell, Rainsford, Kauffmann and Benstead) and in the March (1941) issue of the *British Medical Journal* a review of the practical advances made is presented (Felix, 1941). This article is only a brief summary of the latest findings and recommendations contained in these publications.

The original method of making typhoid vaccine, as is well known, is that of Kolle, Wright and others, and consists in making a saline suspension of typhoid bacillus (Rawling's strain) grown on meat infusion agar, killing the organisms by heat at 53°C. for 1 hour, and preserving them by the addition of 0.5 per cent phenol. This heat-killed phenolized vaccine is still being employed extensively by many, although recent researches have shown that the immunizing power of the vaccine can be greatly enhanced by the adoption of certain new procedures in the manufacture of the vaccine. These new procedures have been the outcome of studies on the antigenic structure of the typhoid bacillus and the significance of the different antibodies arising from these antigens after immunization.

The old idea was that the typhoid bacillus had only one antigen, that injection of typhoid vaccine gave rise to only one antibody, and that this antibody was protective. The work of Felix in 1924 and others after him soon established the fact that the typhoid bacillus has two antigens—an H or flagellar antigen and an O or somatic antigen, and that O-antibodies were important in protection and not H-antibodies. They also found that after prophylactic vaccination the rise in titre of H-antibodies was far higher than that of O-antibodies, and that the latter was not as high as after recovery from typhoid fever.

The next important advance was made by the discovery that the protection afforded by typhoid vaccine was closely related to the virulence of the culture employed in its preparation and that virulent cultures possessed not only H- and O-antigens but also a Vi-antigen, and that both O- and Vi-antigens represented the essential elements in the vaccine, determining its immunizing capacity. While the function of O-antibodies is to protect the individual against the toxic effects of dead typhoid bacilli, the function of Vi-antibodies is to protect him against the living virulent typhoid bacilli. As these findings have been amply confirmed, it seems justifiable to say that a good typhoid vaccine is one that is made from selected strains of virulent typhoid bacilli rich in both O- and

Vi-antigens. According to the old method of preparation of the vaccine, even when a proper strain is used, the Vi-antigen present is largely lost. The Vi-antigen is remarkably labile and suffers considerable rapid damage by the customary process of making typhoid vaccine—heating and phenolizing. Therefore, special precautions have to be taken to ensure its presence and proper preservation in the vaccine, particularly because it is the most important antigenic component of the vaccine. In the newer method of preparation recommended the necessary safeguards have been introduced.

The so-called 'typhoid vaccine' contains not only typhoid bacilli but also organisms belonging to the paratyphoid group. Studies on the antigenic structure of these organisms have shown that they, like the typhoid bacillus, have H-, O- and Vi-antigens. Paratyphoid A and B possess their own specific Vi-antigens while paratyphoid C possesses a certain amount of the Vi-antigen of the typhoid bacillus. These facts have also to be taken note of.

The first essential in the preparation of any vaccine is to obtain proper strains of the organism concerned and to maintain them in a suitable condition so as to ensure the retention of all antigens present in the organism. In this respect typhoid vaccine is no exception. The strains of typhoid, para A, B and C, selected should contain the maximum amounts of O- and Vi-antigens when tested by agglutination. The strains should also be tested on mice and only the virulent ones used. After the vaccine is made it should be tested for its capacity to stimulate O- and Vi-antibodies in a suitable animal or in man. The ability of these antibodies to confer passive protection to mice against virulent organisms must also be established. Only vaccines conforming to these standards can be considered good vaccines.

In the actual process of manufacture of the new vaccine the organisms are grown on agar and suspended in saline as previously, but are not killed by heat, as heat affects the Vi-antigen. Sterilization is effected by adding alcohol to make a 75 per cent solution. Phenol is not added as a preservative, as that also has a destructive effect on the Vi-antigen. The alcohol employed for sterilization being in itself a preservative is reduced to a 25 per cent strength by the addition of saline and this helps to preserve the vaccine.

This new alcohol vaccine has been found to have very high protective properties. Felix and his co-workers (1941) carried out comparative trials in man with the new and the old type of vaccine and their findings are as follows :—

(1) The Vi-antibody response with the new vaccine was six to seven times greater than the Vi-antibody response with the old vaccine.

(2) The O-antibody response was equally good with both..

(3) The H-antibody response was relatively less with the new than with the old. (This is an advantage.)

(4) The general and local reactions following the injection were markedly milder than those resulting from the use of the old vaccine.

(5) The general and local reactions are of no value as factors contributing to good immunity response.

(6) The immunizing potency of the new vaccine remains undiminished for at least a year.

(7) The doses of vaccine recommended are—

	1st dose	2nd dose
For adult males	.. 0.25 c.c.m.	0.5 c.c.m.
For adult females	.. 0.2 ..	0.4 ..
For children (male and female):—		
From 16 to 18 years	.. 0.2 ..	0.4 ..
" 13 to 15 "	.. 0.1 ..	0.2 ..
" 9 to 12 "	.. 0.05 ..	0.1 ..
Under 8 years	.. 0.05 ..	0.05 ..

(8) The interval between the two injections is three weeks.

(9) Re-vaccination is advisable after a year and a single dose of the size of the first dose is sufficient.

In the city of Calcutta the incidence of typhoid is very high and prophylactic vaccination is widely practised. There are reasons to believe that the vaccine used in some instances is not the best that can be obtained. There is plenty of scope for improving the method of manufacture of the vaccine in the light of the newer knowledge presented in this short review. If the methods of preparation of typhoid vaccine are checked and the new type of vaccine is prepared with due care and attention to every detail a substantial contribution towards a reduction in the incidence and mortality of typhoid in the city would be made. Let us hope it will be done early.

SANITARY ENGINEERING

CEMENT WINDOWS AND VENTILATORS

By RAI SAHIB KASHI PRASAD, M.B., B.S., D.P.H.
Medical Officer, In charge Health Unit, Partabgarh

1. Advantages over windows of other materials

CEMENT structures are elegant, strong and durable. They are proof against fire, rot and white-ants. They neither rust, nor warp. The cost of their preparation is small. Once prepared and fixed into the walls, no further attention or after-care in the way of frequent tarring or painting is required.

For all these reasons cement windows are greatly liked by the village-folk.

2. Specifications

(i) Shape.—These windows may be round, square or oblong in shape. They may look either like a window with a wooden frame and bars of the same material, or like a perforated cement slab or piece of *jali* work seen in verandahs of modern design.

(ii) Size.—The smallest windows or ventilators may be 9 inches in diameter. Others

The two types of cement windows.

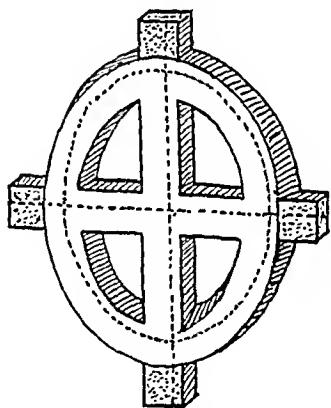

Fig. 1.—Circular with two cross-bars.

may be as large as desired. A good-sized window is 12 inches long, 12 inches wide and one inch deep. It is light, compact and easy to transport. For low-walled huts it will serve as a window; in better class houses it can be fixed as a ventilator.

(iii) Composition.—The windows are made of cement and sand, and are reinforced with iron wire. Where available, coal ashes (from railway engines) may also be utilized. The use of coal ashes reduces the cost of construction.

3. Manufacture

(i) Agency.—They may be manufactured by any intelligent mason who has worked with cement. They may be prepared either at a central place, or actually in the villages by the health leagues, co-operative societies, *gram sudhar sabhas* or rural development *panchayats*.

(ii) Moulds for casting windows.—If a composite mould is used the output is large indeed. A trained and practised mason can cast over a 100 windows (1 foot in diameter) per day. Moulds can be either of cement or of wood of good quality, e.g., teak, which is not easily affected by heat and damp. While moulds can be prepared to cast windows of any size, shape or pattern, it is more economical to have a simple design, such as a circle with two cross-

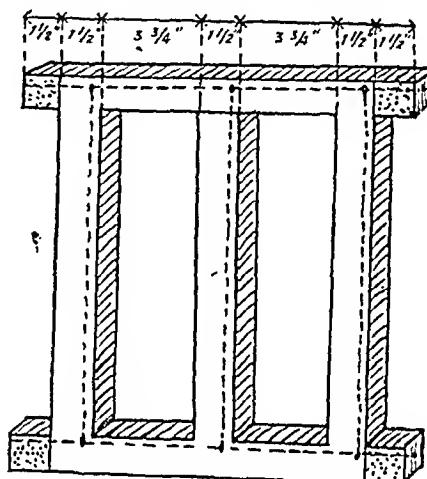

Fig. 2.—In appearance like a wooden window. The dotted lines indicate the reinforcing iron wire. The stippled areas represent the projections which will be embedded in the wall.

bars in it. The edges or walls of the markings (grooves) in the mould should be perpendicular or even bevelled a little, to ensure that the contents slip out easily while the mould is being emptied.

(iii) Materials.—The aggregate may be made with 1 part of cement and 3 to 4 of sand, or 1 of cement with 1 of sand and 3 of coal ashes. Iron wire 1/8th to 1/16th inch in diameter should be used in every limb, bar or curve of the window. Kerosene oil is good enough for lubricating the mould. Moulds should be emptied, i.e., windows cast, on a layer of sand, spread out and levelled, to prevent sticking or distortion of the windows.

(iv) Modus operandi.—Cut iron wire into pieces of suitable size for a 100 windows and bend them properly to the correct shape. Spread out clean sand and level it on a piece of ground. Prepare the aggregate, oil the mould, fill it with the aggregate and insert iron wire in all the grooves in the mould. Then dry the aggregate in the mould by throwing a little dry

mixture (of sand and cement) over it, work it level, and remove the excess. The mould should then be made to stand vertically on one of its sides, and be emptied out. A few taps with a piece of wood may be necessary to loosen the mass and cast it out. After 24 hours a window can be removed, from over the actual place where it was cast, to a trough of water in which it should lie for a week before being used.

4. General hints

An ordinary-sized window should cost about two annas and six pies in all. To ensure that the windows, especially those in which letters or elaborate patterns are incorporated, are fixed properly in the walls, it will be better to have suitable markings to indicate the outer face and the top of the windows. This can be easily arranged while preparing the mould. To have the maximum of air space the number of bars or curves in the framework of the window should be the minimum and their width no more than an inch or so. At the same time there should not be very large holes to admit birds, etc. The windows ought to have projections on the sides and should be fixed not on the outer face of the walls but actually in its thickness so that they cannot be pulled out easily. They should be supplied to the villagers on a contributory basis. It does not require much persuasion to have them fixed in the front or side walls of houses. To admit pure air, windows should be situated away from drains and dung heaps. They should be at a sufficient height so that privacy in the rooms is not interfered with.

A trained mason in Partabgarh will be willing to go to any district if he is paid at 12 annas to Re. 1 per day and actual railway fare. He will be able to cast as many windows as desired and give training to the local *mistris*.

Current Topics

Tonsils and Adenoids

By SIR LANCELOT BARRINGTON-WARD, K.C.V.O.,
CH.M., F.R.C.S., F.R.C.S.ED.

(From the *Practitioner*, November 1940, Vol. CXLV,
p. 309)

IN any children's hospital in this country the condition most frequently demanding treatment and entailing the longest list of patients awaiting operation is 'tonsils and adenoids'. It must therefore be an important problem worthy of constant consideration and re-examination.

At no time in history has preventive medicine attained so powerful a position, and a daily observer of sick children looking back over thirty years appreciates the vast improvement in the general well-being of the child, the better physical condition, the infrequency of certain nutritional disorders, such as rickets, poor dentition, the result no doubt of a higher standard of living, as well as the State care of the child. Yet, during this period, no corresponding reduction in the incidence of 'tonsils and adenoids' has been noted, even allowing for variations of critical standards. In

considering the reason for this, the only constant and unimproving factor has been the British climate, and the only steadily deteriorating one, atmospheric pollution. The former is unlikely to change; the latter is capable of improvement, but it will take time, so that the 'problem of the tonsil' is likely to continue for some generations to come.

The question is often asked, 'What is the function of the tonsils?' Their lymphocytic function is accepted, but they form so small a portion of the lymphatic tissue of the body that it cannot be of great importance. That, with the rest of the lymphoid tissue of the pharynx, they act, when healthy, as a circumoral filter is possible, but the filter tends to get infected. Some consider the tonsils vestigial structures, not of much proven benefit to the individual when healthy, but capable of instituting serious pathological processes. This is no argument for the indiscriminate removal of tonsils; far from it. Ignorance of the function of any organ should make the surgeon doubly cautious in deciding on its ablation. It must be allowed that in the early days, following on the remarkable benefits observed from an improved method of surgical treatment, the attack became too zealous and overshot its objective. Then, not infrequent in therapeutics, the pendulum swung too far in the other direction and an over-cautious policy was pursued. At present the general attitude is intelligent and discriminating, but there is still opposition to the surgical treatment of tonsils on inadequate grounds. Certain objectors are of the conscientious type, which any form of human activity calls into being. They are not open to reason and being small in number are unimportant. Another class, common among laymen holds that the tonsil provides an important but unspecified endocrine substance. It is not possible to deny this absolutely, but all the available evidence is against such a supposition and, if it were true, it is only an argument against removing a normal tonsil. A third class includes the statisticians who, divorced from clinical realities, study figures and produce general statements on the poor results of tonsillectomy. Their attitude is directed against *routine* tonsillectomy, and no sound clinician ever advocates this. Statistics, moreover, include the results of operations performed competently and incompetently, under good surgical conditions and bad.

Too much stress cannot be laid on the high degree of technical perfection that this operation demands. An operation which is incomplete, which inflicts permanent damage on the pharyngeal structures, which, by reason of shock or loss of blood, devitalizes the child for years, should be avoided at all costs. Skill in the performance of the operation can be attained by anyone of surgical aptitude and average dexterity, who is willing to spend some months of observation and practice in a special clinic. It is not to be attempted by the occasional operator after perusal of a book. Those who consider the tonsil an important part of the lymphatic system lay stress on the frequency with which tonsil remnants, products of an incomplete operation, invariably hypertrophy often to an astonishing degree. This, however, is not the effort of nature to replace beneficent tissue that has been lost: it is merely an example of the rule that incomplete removal leads to increased sepsis, and in response to that sepsis the surviving lymphoid tissue hypertrophies. This secondary hypertrophy is not evidence of a protest by nature but only of inadequate surgery. The same reaction to sepsis is seen in the origin of adenoid hypertrophy. Perfection is hard to reach. Everyone, no matter what his experience and skill, has on occasion suffered the ignominy of observing a small piece of lingual tonsil survive the operation to embarrass later both operator and patient alike. It is important therefore to select a method which makes this eventuality as rare as possible, for it is far better to leave a tonsil untouched than to remove it partially.

THE PATHOLOGICAL RESULTS OF THE INFECTED TONSIL

It is now a truism that the size of a tonsil is no criterion of its pathological state. Certain children

SEPT., 1941]

have more lymphoid tissue than others, and a tonsil projecting obviously into the pharynx is not necessarily a menace. Sometimes, however, as a result of infection, the tonsil may so hypertrophy that it interferes with deglutition and respiration. At the same time adenoids may obstruct the nasopharynx, and the picture is striking and unforgettable. The correct treatment, operative removal of the tonsils and adenoids, is dramatic in its results. A child with harsh audible breathing, a fitful and snoring sleeper, constantly vomiting for no obvious reason, without appetite, and a bad doer, becomes at once placid, hungry and thriving. Such a case is obvious. The more dangerous tonsil is moderate or small in size, often not visible unless everted by exciting the pharyngeal reflex.

The appearance of the tonsil on inspection may be quite indistinctive. In adults the presence of pus under the *plica triangularis* or in the crypts, follicles plugged with secretion and concretions, present a recognizable picture, but in children there may only be a little injection or oedema of the anterior pillars to suggest an underlying infection. Many different kinds of pathological organisms are harboured in the tonsil, and their relative pathogenicity is hard to assess, and their bacteriology is often misleading.

By its deeds is the tonsil known. It may be frank, repeated tonsillitis, and here it must be remembered that recurrent pyrexia and malaise (without of necessity any complaint of sore throat for the child often does not complain even with a severe tonsillitis) attributed to a chill from bathing on a cold day or sitting in wet shoes and clothes, may be the only external signs of infection.

Enlargement of the tonsillar lymphatic glands, without any general enlargement of other groups, is presumptive evidence that the source of poisoning is the tonsil. It may be merely a temporary phase following a single infection, but if the enlargement persists it is an indication for radical treatment at the source. It is rare to see tuberculosis of the upper deep cervical glands as a primary condition: the usual history is one of acute adenitis, which subsides to become chronic and finally tuberculous. Another direct result of tonsil infection is otitis media. Excluding the blood stream, the only path of infection to the intact middle ear is by the Eustachian tube. This tube is in close relation to the pharyngeal tonsil, and organisms latent or active in the tonsil can initiate and reinforce an inflammation of the middle ear itself. In children, at least, the first step in arresting chronic otorrhoea is to remove the tonsil. Adenoids also play their part, but their action is more obstructive than infective.

In the operative repair of the cleft palate the importance of the tonsil has only been recognized in recent years. A septic tonsil favours post-operative sepsis of the suture line and menaces the success of the operation. It has been found that enucleation of the tonsils as the first step greatly encourages primary union.

The indications for tonsilleetomy which have been presented so far, especially recurrent tonsillitis, find fairly general acceptance but operation has been advocated from time to time on other grounds which have been more subject to criticism.

Focal sepsis, as an idea, may have suffered from over-elaboration in the adult, and the tonsils, teeth, appendix, and gall-bladder have sometimes been condemned according to fashion rather than to reason. In the case of the child, however, the general surgeon working in an out-patient department is soon convinced of the influence of the chronic septic tonsil on certain general conditions. Slackness of the musculature leading to scoliosis, genu valgum and talipes valgus, and a lethargic state, can often be ascribed to chronic tonsillitis, and the first step in the treatment must be directed to the source of the underlying toxæmia.

Some systematic diseases are believed to be of tonsillar origin, e.g., rheumatism, chorea, nephritis, but here unfortunately the tonsil is too often only the path of entry, and the damage has been done before attention has been directed to this organ. The question

whether or not the patient who has undergone tonsilleetomy is less liable to these catastrophes is difficult to prove, and it is of less importance because no one would advocate the removal of an apparently healthy tonsil because at some period of life the infective agent of rheumatism or nephritis might possibly assail it. It can, however, be suggested with reason that frequent recurrence or exacerbation of the disease, always associated with local signs in the tonsils, is an indication for surgical measures.

TREATMENT

Medical treatment is of temporary, rarely permanent, value in chronic infection of the tonsils. Gargles and paints act superficially and cannot reach the recesses which offer abundant cover for micro-organisms. The infected tonsil has little power of natural recovery and, although the sulphonamides may have an influence on an acute infection, there are obvious objections to too continuous or too repeated administrations.

One of the simpler and most successful prescriptions which will keep infection in a tonsil at bay if, for any reason, radical treatment by removal is contra-indicated, is the potassium chlorate and sodium salicylate mixture. (The dosage given here is suitable for a young child.)

R Potassium chlorate	3 grains
Sodium salicylate	2½ grains
Sodium bicarbonate	2½ grains
Syrup	5 minims
Water to	60 minims

It should not be given for longer periods than a fortnight, but it will often ward off an attack of acute tonsillitis or, in cases of constant relapse, reduce infection so that operation may be safely performed.

Adenoids.—Mild cases of adenoid hypertrophy, sufficient to cause moderate nasal obstruction, should always be given the opportunity of remedial treatment. Many cases improve greatly with corrected diet and habits, and organized breathing exercises. If the condition is advanced, or if it fails to react to physiotherapeutic measures, operation must be performed. Much can be learned from a study of adenoids in cases of cleft palate. Here the precise condition before, during and after operation, can be seen, and it will be observed in adenoid hypertrophy that the lymphoid tissue grows in irregular vertical ridges. If these projections form localized masses, it is possible with a sharp curette to shave them off, leaving the underlying mucous membrane intact: that is the ideal operation. Sometimes, however, the object of the operation is not achieved. The whole mucosa studded with lymphoid follicles is swollen and velvety, and the curette is bound to injure normal tissues, leading to chronic sepsis and adhesions. The removal of adenoids should be performed with the utmost gentleness and the curette should be held as a delicate brush rather than a rake, feeling for the hypertrophied masses and gently sweeping them away.

SURGICAL TREATMENT OF THE TONSILS

From time to time certain methods are extolled for the non-surgical extirpation of tonsils. The electric cautery, diathermy, the application of pastes have been offered to those who shrink from the word operation, as efficient methods of destroying the tonsils. Such agents merely fibrose the tonsil to a greater or lesser extent, usually leaving a septic fibrotic mass behind, and neither protect the patient from recurrent attacks of tonsillitis, nor from chronic septic absorption. They have therefore little to commend them. I have no experience of such methods, save in the increased difficulty of dissecting out tonsils which have unsuccessfully undergone this method of treatment. Radium and x-rays also have their advocates. In the treatment of malignant disease the risks of these powerful agents and the later tissue changes, of which we have no complete knowledge, are no doubt justified: they cannot be in so simple a condition as tonsillitis.

Removal of the tonsils.—I prefer to dissect out the tonsils by the method first introduced by the late

Mr. George Waugh in 1905, and employed ever since by the surgeons at the Hospital for Sick Children, Great Ormond Street, in many thousands of cases. It is a simple surgical procedure which aims at dissecting out the tonsil completely under full vision, with complete control of haemorrhage and without risk of inhalation of blood or foreign bodies. No special gadgets are required and nothing is left to chance, so far as the human factor can control. As in most operations, the beginner must learn the steps in a clinic and perform many operations under skilled supervision until technical perfection is achieved. The inexperienced and the incompetent operator can do great harm.

There is much difference of opinion as to the age at which operation should be undertaken. Provided that the operation is only done when it has become absolutely necessary, it can be performed at any age. There are no grounds for leaving a child even in the first few years of life, to continue to suffer from repeated sore throats, chronic otitis, or persistent glands of the neck, if these conditions can be cured or improved by tonsillectomy. The operation is a very simple affair to the patient under three. There is little complaint or evidence of pain, and little interruption in the normal life of the child. The only objection raised against operation in these early years worthy of consideration is that the tonsils may grow again. If the tonsil is completely removed, as it should be, there is no more likelihood of this occurring in infancy than in the later years of childhood. The older the child the major the operation. Step by step as the years lead through adolescence into adult life, there is an increase in the discomfort to the patient and the technical demand on the operator. This is not an argument for removing a tonsil that is not condemned, but it influences judgment if the postponement of a necessary operation is raised. In general, operation is preferable in the spring and summer months although if need be, if careful post-operative in-patient treatment for several days is insisted upon, the winter months are no absolute bar.

The preliminaries of the operation are important. There should have been no suspicion of acute infection for at least three weeks. Sometimes it is difficult to catch an interval between mild attacks, but a temperature of even 99°F. should cause postponement of the operation. Sometimes a week's administration of the mixture mentioned above is beneficial. If there is any history at all of previous abnormal bleeding, the coagulation of the blood should be tested and, if any abnormality is found, the whole question of operation must be re-examined. No preliminary purge is given before operation and a liberal allowance of barley sugar is provided.

Premedication is of infinite value in children and robs the operation of most of its discomforts. It has been objected that it increases bleeding during the operation, but this has not been my experience. Nembutal given by the mouth is a simple and effective method, if some rules are observed. After administration the child must be kept quiet in a darkened room, preferably without the mother, and anaesthesia should be induced in bed before removal of the patient to the theatre.

Local anaesthesia is sometimes employed for adult patients. Its selection is more often a concession to the wishes of the patient, who fears a general anaesthetic, than to the demands of safety or expediency. Any patient who can tolerate enucleation of the tonsils under a local can equally well, whatever his physical state, survive operation under a skilfully administered general anaesthetic. The benefits of the method are not to be denied. As in most instances of infiltration anaesthesia, the dissection is made rather easier by the opening up of tissue planes, and the uncomfortable effects, nausea, vomiting, and headache, which sometimes follow general anaesthesia, are avoided.

In general surgery fairly heavy premedication is the rule when local anaesthesia is employed, but in throat operations this is inadvisable because of the subsequent delay in the recovery of the normal reflexes. Therefore

the surgeon has to deal with a fully conscious patient and this consciousness may interfere with his detachment and put him to some disadvantage.

The details of the anaesthetic are best left to an expert. Induction with ethyl chloride in the child, and gas and oxygen in the adult, followed by ether and oxygen is a common sequence, but it is well to emphasize that complete relaxation of the pharyngeal muscles must be attained.

During operation exact haemostasis is essential. In children it is rarely necessary to ligate any vessel, but if any bleeding point is active, it should be caught and tied with fine catgut. A suction apparatus is popular with some surgeons, but it is an addition to the armamentarium and is never really necessary. Most operations can be completed with half a dozen pieces of cut gauze.

Complications.—The steps of the actual operation need not be repeated here, but it may be of value to consider some of the possible complications. To check the faults of memory, I have analysed a long series of cases. As hospital notes in so minor a condition are often unreliable, and many diverse operators are included under the name of the chief, it seemed wiser to take private cases for which entire responsibility could be accepted, often performed regrettably under conditions which compare unfavourably with hospital. A consecutive series of 1,078 cases since 1924 when a new system of note-keeping was introduced, has been taken.

In the immediate post-operative course *reactionary haemorrhage*—bleeding within twelve hours of operation—requiring a second anaesthetic has occurred eight times. Should bleeding occur a few hours after operation, dislodgement of the clots and the pressure of a gauze mop, soaked in adrenaline, should first be tried, but if the bleeding persists or recurs, it is wiser to renew the anaesthetic and ligate the bleeding point. Blood transfusion is rarely needed—never in this series—but it should be given if there has been much loss of blood or if the bleeding is due to blood deficiency.

Secondary haemorrhage has been known to occur on the sixth or seventh day. There is often no warning, the whole operation and post-operative course having been most smooth, and the sudden bleeding comes as a disappointing surprise. It is rarely severe and soon ceases, and only once in these records was a ligature considered necessary.

Bronchitis and *pneumonia* have been given as common post-operative complications but there were none in this series, and the risk in properly selected cases has been grossly exaggerated. Recrudescence of an old standing otitis or a septic adenitis are possible sequelæ, but they are understandable in view of the temporary aggravation of the oral sepsis. It is well to warn the patient or parent beforehand that such an event is possible. With the healing of the throat, the activity subsides.

At a recent discussion on the tonsil, *lung abscess* was mentioned but I have never seen a case in which the Waugh method has been employed.

Attention has already been drawn to *incomplete removal* and regrowth of lymphoid tissue. Figures here may be misleading, for a disappointed patient may seek advice elsewhere and the first operator remains ignorant of his failure. Seven in this series are known to have had some degree of recurrence, usually a lingual tag, but for the reasons given the number is probably greater. Nearly 10 per cent of all the cases had had a previous operation on the tonsils. This was more frequent among the early cases, when guillotining was popular and the standard of tonsil operations was generally low. Disappointments occur even after a perfectly performed operation. Soreness of the throat may be felt—probably a rheumatic infection of the pillars—but it is very rare and usually only a temporary discomfort.

The common cold, due to a variety of causes, dietetic, allergic, or associated with chronic sinusitis, is not benefited by tonsillectomy, unless the cold always begins with inflammation of the tonsils. Removal of the tonsils in such a case reduces the frequency and

SEPT., 1941]

shortens the duration of infection, without much altering the underlying pathological state responsible.

CONCLUSION

To sum up, it may be stated that the pathological effects of the tonsil are neither so black nor so white as they have been painted. Absolute indications for tonsillectomy cannot be laid down, and the evidence requires careful sifting before judgment is given. In properly selected cases its performance confers a lasting benefit on the individual.

Lice and Disease

(From the British Medical Journal, Vol. I,
8th February, 1941, p. 199)

BOTH varieties of the human louse, *Pediculus humanus*, were found in England before this war, but whereas the body louse, *Pediculus humanus corporis*, was seen comparatively rarely, the head louse, *Pediculus humanus capitidis*, was much more common. The body louse was usually considered to be restricted almost entirely to vagrants, and although occasionally as much as 5 per cent of a draft of Army recruits has shown signs of infestation, among the general mass of recruits and hospital patients well under 1 per cent have had any body vermin. The head louse, on the other hand, was always exceedingly common. In a recent extensive survey on behalf of the Board of Education and the Ministry of Health Mr. Kenneth Mellanby has shown that in our industrial cities nearly 50 per cent of the girls and 30 per cent of the boys—at least in the poorer sections of the community—had verminous heads during the year immediately before war was declared. The majority of these children had some live lice in their hair and not merely a few nits. In rural districts the situation was much more satisfactory, and it was rare to find more than 5 per cent of any group of country children with head lice, although there is evidence that thirty years ago rural children were as frequently verminous as urban children are to-day. The crab louse, *Phthirus pubis* (often called *Pediculus pubis*), is in peacetime probably about as common as the body louse. Infestation is usually, but by no means always, venereal, and so crab lice may be expected to increase somewhat in wartime. There is probably much less danger of a general infestation throughout the population with *Phthirus* as compared with *Pediculus*, but the possible importance of the crab louse should not be entirely overlooked. The small peacetime reservoir of body lice and the widespread population of head lice might, under conditions favourable to the insects, give rise to practically universal infestation. Unless effective precautions are taken during the war, when so many people are living in shelters and are often unable to change their clothes, and when washing and laundry facilities are among those most easily disorganized, conditions may arise which will be ideal for the louse to increase and multiply.

The life history of both varieties of *Pediculus humanus* is similar: the female lays up to ten eggs a day; these may hatch within ten days, and after a further period of ten days the adults appear. If lice or their eggs are kept away from the body during part of the day their metabolism is reduced and the period of the life history greatly prolonged. At no stage can a louse live more than a month away from man, who is the insect's only source of food. Prof. Buxton has shown that if breeding is not checked a single female might produce 120 daughters and 14,400 granddaughters, and within a short time a small louse population may increase to alarming proportions. The body louse is normally kept in check, except among the few vagrants who are chronically infested, by such simple measures as removing the day clothes at night (this alone will halve the rate of breeding) and by changing underwear, which removes the bulk of both eggs and other stages of the insect. If these things are done regularly, even in the face of frequent

reinfestation, the parasites are unlikely to establish themselves on new host. With the head louse most infestations are fairly light, and the ordinary combing of the hair, though ineffective in exterminating the parasite, serves to keep the population down to fairly small numbers; but if this combing were neglected, even for only a few days, these lightly infested heads would soon bear enormous populations and spread the infestation rapidly elsewhere.

If lice increased greatly their presence and the irritation of their bites would cause a great deal of discomfort, and it is probable that the inability to keep free from parasites might have a dangerous effect on the morale of large sections of the population. The possibility, however, of the appearance of louse-borne disease is of even greater importance. Typhus was formerly not uncommon in England, and if it were reintroduced at a time when lice were common (and transmission by both head and body lice is possible) a disastrous epidemic might occur. It is true that during the last war typhus never established itself on the Western Front, and some workers consider that for this reason it is unlikely to reappear in England, but the risk is one that cannot be ignored. With troops returning from areas where typhus is endemic, the introduction of the disease into England might be difficult to prevent. It must also be remembered that typhus is one of the few diseases that could be introduced by enemy action, for infected lice or infected louse faeces could be spread over our cities from aeroplanes, and the insects would easily survive even if dropped from very great heights. Relapsing fever, transmitted by lice, is also endemic in Eastern Europe, and this disease might similarly be introduced into England. As trench fever disappeared almost immediately after the last war its causation is imperfectly understood, but it is certainly transmitted by lice, and if the insects became common it might well reappear, this time among the civilian population.

If peacetime standards of cleanliness and hygiene can be maintained, then the louse menace will be avoided. It will be necessary to provide abundant facilities for hot baths and obtaining clean underwear for those whose homes have been damaged or where the public utility services have been put out of action. All cities should have ample supplementary disinfection premises available in case of air-raid damage to the usual centre or in case there is a sudden increase in the number of parasites, for it is the disinfection centre that should deal with the very verminous individuals who form the reservoir of body lice. Any measures taken at once to prevent an increase in infestation will be much more effective than those which will become necessary if we wait until the louse population has got out of hand. As well as the simple hygienic measures suggested above, recent research has shown that certain insecticidal powders whose formulae are not yet published may be effective in checking infestation for many days after a single application of the powder to the underclothing. If this work could be put into practice a great advance would be made, and an added protection would be available to those temporarily unable to live under civilized hygienic conditions. But our ideal must always be that such measures, useful as an added protection, should never be considered as the main defence against lousiness.

With regard to the head louse, although this parasite is most common in children, adults are by no means immune, for Mr. Mellanby finds that even in pre-war conditions as much as 10 per cent of adult women may be infested, sometimes very heavily. Even under war conditions these women could keep their heads free from vermin by thorough combing, particularly if this were done by using a specially made fine steel comb; suitable publicity on these lines should prove effective in preventing much increase. Use can also be made of the various liquids available which will easily kill all head lice and their nits: 70 per cent alcohol (made from methylated or rectified spirit and applied so that the hair is kept wet for about an hour) appears quite efficacious and is perhaps the simplest. It seems not unlikely that the war will greatly reduce the incidence

of head lice among children who are evacuated to rural areas. Here they will learn to conform to a new standard of cleanliness by living among people who have come to know that the head louse may be easily dealt with by themselves in the home and who do not therefore feel dependent on a highly organized service provided by the State to deal (as it happens, not very effectively) with such problems. It must be realized that, in the case of both head and body lice, if the people likely to be infested can be made to co-operate in combating possible infestation, then the problem will be far on its way towards solution.

If total extermination is impracticable, it is obviously important that the louse should be kept in check in order to prevent a widespread degree of discomfort, which may be a danger to morale, and to avoid the possibility of louse-borne disease. So far as the body louse is concerned this can be attained by the maintenance of peacetime standards of hygiene. The war may even be made the opportunity for improving the situation by making the nation conscious of the deplorable hygienic standards which allow the degree of infestation by the head louse found even in peacetime.

The Derris Root Treatment of Scabies

By L. SAUNDERS, M.B., B.S.
CAPTAIN, R.A.M.C.

(Abstracted from the *British Medical Journal*, Vol. I, 26th April, 1941, p. 624)

THE varied factors responsible for the prevalence and transmission of scabies are to a large extent unavoidable, but the question of its prevention and control must be faced in the light of present-day circumstances as one of the most difficult public-health problems. New factors have arisen which probably account for the increase in the incidence of scabies seen in civilian practice. For example, many citizens are now huddled together throughout the night in over-populated shelters where sanitary arrangements are inadequate, and some have been unable to remove their clothes for several weeks. Facilities for bathing have in addition become difficult. It is obvious that with the increasing strain thrown on the medical profession to-day scabies assumes an unpleasant but realistic problem, and one which is becoming unduly prevalent in the Army.

The generally accepted method of treatment in civilian practice is the three-day use of sulphur ointment. Other specific drugs which have been used to destroy the parasite are balsam of Peru, beta-naphthol, and benzyl benzoate. Storax ointment, pernol kathiolan, mitigel, and the sodium-thiosulphate-hydrochloric-acid method all have their advocates. It is often left to the patient to arrange the disinfection of his bedding and clothing: little wonder is it, then, that recurrences are so frequent. The disadvantages of sulphur ointment are: (1) its greasy and messy qualities, whereby pyjamas become quickly dirty and uncomfortable to wear; (2) the disagreeable odour of the ointment; (3) the confinement of patients to their own rooms during the course of treatment; (4) the likelihood of sulphur dermatitis arising from prolonged application, and therefore its danger in inexperienced hands.

All the mentioned methods of treatment essentially require baths and disinfection of bedding and clothing. The treatment detailed below will show that neither bathing nor disinfection of clothing is necessary for obtaining a cure.

Thomas and Miller stated that rotenone in a 1 or 2 per cent lotion produced prompt cure in twenty-four unselected cases. I had been in medical charge of a main dressing station where many cases of scabies were seen, and their results induced me to try the treatment. However, instead of using the rotenone solution, which was relatively expensive and difficult to procure, I made a solution of 4 oz. of derris root powder (from which rotenone is extracted) and 1 oz. of soft soap in one gallon of warm water. The powder was of tested strength and was guaranteed to comply with the requirements of the Ministry of Agriculture as a dressing against the warble-fly.

Derris or tuba root consists of the dried rhizome and roots of the *Derris elliptica* Benth and *Derris malaccensis* Prain, climbing plants that are cultivated in the Federated Malay States, Sarawak, Singapore, Sumatra, and Johore. The powder has a slight odour and a bitter taste, and on inhalation produces a feeling of numbness in the tongue and throat. The root contains up to 10 per cent of the crystalline substance rotenone ($C_{22}H_{22}O_6$), which is known as tuba toxin. Three other crystalline substances—deguelin, teplirosin, and toxicarol—have been isolated. The active constituents are soluble in acetone, benzene, chloroform, ether, and carbon tetrachloride. They are insoluble in water, weak acids, and alkalis. Derris is used extensively in horticulture and agriculture as an insecticide, especially against the warble-fly.

The treatment is of great value where water is scarce and baths are difficult to procure, as in severely bombed areas and in the Middle East. By wearing his clothes the patient is able to carry on with his duties, and expense and trouble are avoided. Thus in the fighting forces the problem of scabies becomes a regimental one and not a hospital responsibility. The strength of units would be better maintained and consequently the efficiency of such units would be raised. Those affected with scabies in shelters would be able to carry out the treatment quite simply in them provided space was set aside for such a purpose.

The advantages of this method are as follows: (1) the treatment is non-odorous, non-greasy, and non-messy; (2) the bed-clothes or underclothes are not stained; (3) it is not expensive—each case costs about a penny for a course of treatment; (4) treatment is standardized at two days' duration; (5) it dispenses with the trouble of having clothes disinfected, thereby avoiding hospital treatment; (6) recurrences are few; (7) supervision is unnecessary; (8) baths are unnecessary.

The disadvantage of the method is that some patients complain of a burning sensation in the region of the scrotum and penis after four or five applications. Three or four days after starting the treatment there may be a very mild excoriation of the affected area, particularly the scrotum, and a scaling and slight exudation of serum may appear. This, however, does not incapacitate the patient, and within a week it usually disappears without treatment. The complication is probably due to the strength of the solution. Since using a half-strength solution on a new series of cases the excoriation has been observed in a very much milder form in only 3 cases out of 50.

Reviews

SURGERY OF MODERN WARFARE.—Edited by Hamilton Bailey, F.R.C.S. Part IV—Compiled by Sixty-five Contributors. Section VIII (Continued)—Wounds of Bones and Joints. Section IX—Wounds of the Face and Neck, including those of the Special Senses. 1941. E. and S. Livingstone, Edinburgh. Pp. from 481 to 640. Illustrated. Price, 12s. 6d. Postage, 6d.

THE destruction of the British Empire cannot be going on quite as fast as Hitler hoped, for we have now received part IV of this ambitious work, written and printed within a few hundred miles of Hitler's air bases and then transported safely some eight thousand miles through seas from which, according to Dr. Goebels, the shipping of the empire has long since been driven. This part however did have a slight setback, in that a number of the chapters were completely destroyed by enemy action, and the publication was further delayed because some of the authors of these destroyed chapters had not kept copies of their contributions. We are glad to think that the authors themselves survived and were able to rewrite their chapters.

In this part the section on the wounds of bones and joints is continued and concluded. It is a very

SEPT., 1941]

important section, as on the correct choice of operation under conditions of emergency the future usefulness of the patient to the community will very often depend, even if his life is not also in the balance. It is a subject in which the makers of artificial limbs should have a say; some of the contributors have given this point due consideration, but others have taken the attitude that immediate surgical considerations must be the guide and afterwards the patient must hope for the best. The very well-reproduced coloured plates of cross sections of the limbs add colour to chapters on amputations, though one cannot help feeling that good line drawings would have served as well.

The next section begins with a chapter on wounds of the face and jaws. Some of the triumphs of plastic surgery are illustrated; this chapter is by Mr. T. P. Kilner, a surgical associate of Sir Harold Gillies who achieved such wonders in this field after the last war. The part finishes with three chapters on injuries to the orbit and eyeball; these include injuries by the action of gas, a horror of war that we have so far been spared but we are taking no risks.

THE DIAGNOSIS AND TREATMENT OF PULMONARY TUBERCULOSIS.—By J. B. Hawes, M.D., and Moses J. Stone, M.D. Second Edition. 1940. Henry Kimpton, London. Pp. 260. Illustrated with 75 engravings. Price, 12s. 6d.

THIS little book gives a concise account of the diagnosis and therapeutics of pulmonary tuberculosis with apt observations on the subject. The historical approach is good, and the subject of case-taking is well presented. The sanatorium régime is given in fair detail with up-to-date methods of collapse therapy. The illustrations are good, although some of the legends are not descriptive. The subject of 'follow-up' after the sanatorium treatment does not seem to have received adequate attention; we hope it will be duly considered in the next edition. On the whole, general practitioners and senior medical students will profit by study of this volume.

R. C.

PRINCIPLES AND PRACTICE OF CHROMATOGRAPHY.—By L. Zechmeister and L. Cholnoky. Translated from the Second and Enlarged German Edition by A. L. Bacharach, M.A., F.I.C., and F. A. Robinson, M.Sc. Tech., F.I.C. 1941. Published by Chapman and Hall Limited, London. Pp. xviii plus 362. Illustrated. Price, 25s.

THIS is an English translation of the second German edition and is the first account of chromatography published in the English language. The book is divided into two parts. The general section deals with the fundamental principles of the method, the scope of the method, the chromatographic separation of stereoisomers and also of related compounds, and finally an account of the actual procedure, the adsorption media, the solvents and eluents, and a description of the various types of apparatus used for the purpose. The special section, which occupies more than two-thirds of the book, describes with full experimental details, the chromatographic separation or purification of a large and representative class of compounds. The usefulness of this new method is vividly illustrated by the wide scope of its applications. Not only has this been applied to coloured substances such as chlorophyll, haemin, porphyrins, bile pigments, carotenoids, naphthaquinones, anthraquinones, flavins, anthocyanins and other natural and synthetic dyestuffs, but also to colourless substances such as terpenes, sterols, alkaloids, vitamins, hormones, and enzymes. The method has also been applied for the separation of inorganic ions. A bibliography at the end of the book gives all the references collected up to the summer of 1938.

The English translation of a book so valuable for biochemists, analytical chemists, and research workers on a large variety of subjects should be welcome in all the English-speaking countries of the world.

S. G.

A CHART FOR FIRST AID TREATMENT OF ELECTRIC SHOCK. Obtainable from 'Vijalini Dunliy' Karyalaya, 5007, Modh Champaner Society, Wadaj Road, Ahmedabad. Price, 9 annas each, Rs. 6 per dozen. Postage extra

In view of the increasing employment of electricity in industry and the household, it is natural to expect the first-aid treatment of electrical shock to be a familiar subject.

The author, in this chart, has described in English and in Guzrati how to release the victim and to give artificial respiration, with illustrations. He has stated what to do when there are burns on the abdomen, when on the chest, and when there are none. A layman may be puzzled when he encounters burns on both.

More importance might have been laid on the necessity of calling a doctor as quickly as possible, as a patient may require lumbar puncture, intracardiac injection and/or respiratory stimulants.

The price of the chart is perhaps a little high.

R. C.

SULPHONAMIDES IN GENERAL PRACTICE.—By M. L. Gujral, M.B., M.R.C.P. (Lond.). 1941. Published by the author (1, Curzon Road, New Delhi). Pp. 106.

The introduction of the sulphonamide group of drugs for the treatment of bacterial diseases is a distinct landmark in the conquest of disease. This small book provides a fairly good account of the subject with reference to the mode of action, dosage, uses in various diseases and toxicity of the drug. The author has collected in it facts which should be known to practitioners in order that they may be able to exploit chemotherapy with efficiency and safety. The likelihood of serious harm resulting from their indiscriminate use has been stressed.

We have however one criticism to offer, namely that the use of sulphonamides in the local treatment of wounds seems to have been overlooked.

R. C.

ANTIQUITY OF HINDU AND GREEK MEDICINE.—By Dharendra Nath Banerjee, M.B. (Cal.), M.D. (Berlin). 1941. Published by Mr. A. Roy of the Medical Bureau, 50, Chawringhee Road, Calcutta. Pp. 18. Price, 8 annas

This is a reprint of a lecture, now published at a very modest price.

It provides a rapid review of the history of medicine from the earliest historical times, with particular emphasis on Indian medicine.

Abstracts from Reports

REPORT ON THE ADMINISTRATION OF THE EXCISE DEPARTMENT IN THE PRESIDENCY OF BENGAL FOR THE YEAR 1939-40

Ganja.—The total quantity of ganja consumed in the province amounted to 866 maunds 31 seers as against 848 maunds 37 seers, showing a net increase of 17 maunds 34 seers or 2.1 per cent of the people. Though there was a fall in the consumption of the drug in French Chandernagore in comparison with the issues of the last year, the issues to that settlement are still heavy. As against 1,665 seers in 1938-39, this settlement took 1,470 seers of ganja during the year under report which is just 23 seers less than the total amount of ganja consumed in the Hooghly district. There would appear to be some justification for believing that a large portion of the ganja finds its way back to British India.

Two maunds five seers of ganja were issued at the concession rate of duty of Rs. 15 per seer for the manufacture of medicinal preparations by chemists against 4 maunds 10 seers in the preceding year.

Bhang.—The demand for bhang was mostly confined to the West Bengal districts. In some of the districts in East and North Bengal, bhang grows wild. In one district headquarters town it was observed growing along most of the municipal roads, beside the jail walls and most luxuriantly of all in the collectorate. Where the plant grows in such profusion, its extensive use as an illicit substance for bhang and partly also for ganja is hardly to be wondered at. There has been a considerable decline in the use of bhang by village kabirajes, as it is reported that the patients prefer either the products of one or other of the advertised ayurvedic pharmacies, or the medicines of the charitable dispensaries. The total quantity of bhang consumed in the Presidency amounted to 222 maunds 38 seers against 230 maunds 16 seers in the previous year, showing a decrease of 7 maunds 18 seers.

No case of abuse of medicinal preparations manufactured from the drug was reported during the year, but as mentioned in last year's report there is need for strict control of the kabirajes.

Charas.—The total quantity of charas imported by the wholesale dealers at Birbhum and Calcutta into the Province was 21 maunds 1 seer 13 chittaks against 21 maunds 9 seers 6 chittaks in the previous year, showing a decrease of 7 seers 9 chittaks. Owing to the restrictions imposed by the Punjab Government on the supply of charas to this province, 1 maund 15 seers 8 chittaks and 13 seers 5 chittaks of confiscated charas out of the stocks of such charas in the Calcutta Excise Office and Central Detective Department, respectively, were issued to the wholesale dealer at Calcutta to meet the demand.

Two maunds fourteen seers eleven chittaks of charas were exported to the Consulting Chemist, Treasury Department, Washington (America). The total issues to retail shops were 23 maunds 18 seers against 19 maunds 30 seers in the preceding year, showing an increase of 3 maunds 28 seers or 19 per cent. The actual consumption in Calcutta amounted to 14 maunds 15 seers against 9 maunds 7 seers in the previous year, showing an increase of 5 maunds 8 seers due to the restrictions of the illicit sale of the drug in small quantities through *pan* shops and *biriwallas*. From 1937-38 the increase in consumption in Calcutta was 6 maunds 27 seers or 86 per cent. The consumption in the other districts was not appreciable, the heaviest consumption outside Calcutta being in Burdwan (2 maunds 22 seers). In Howrah with its two shops the total consumption was only 11 seers and in Rajshahi it was 3 seers.

Thirty seers of charas were exported to French Chandernagore during the year against 18 seers in the previous year.

Opium.—The consumption of excise opium during the year under report was 655 maunds 28 seers as compared with 662 maunds 33 seers of the previous year showing a decrease of 7 maunds 5 seers or 1 per cent. In some districts there is evidence that with the increase in the retail price many consumers have taken smaller supplies of the drug, and there is evidence extending over a series of years that the younger generation is not taking opium, and that, at any rate in *mofussil* places, as veteran opium eaters die of old age, the demand for the drug falls.

The use of morphia as a substitute for opium does not appear to have been prevalent in any district of the province. The doping of children with opium pills was not reported from any district. The habit of opium smoking is prevalent among a few Chinese and Tibetan residents in Darjeeling as well as amongst the Mughals in Barisal. The Opium Smoking Act and the rules made thereunder were administered as efficiently as possible. This Act is hedged about with restrictions which go far to render it useless as a practical measure for tackling the vice of opium smoking. Effective action can only be taken under the rules made under the Opium Act.

Cocaine.—There is no evidence of the use of cocaine as an intoxicant and the habit is unknown in almost all the districts of the province except that it is reported to exist in a very limited extent in the

districts of Calcutta and Dacca and in the mill areas of the 24-Parganas and Hooghly districts.

ANNUAL REPORT OF THE MYSORE STATE MEDICAL DEPARTMENT (WITH THE GOVERNMENT REVIEW THEREON) FOR 1939

At the close of the year 1939, the total number of medical institutions in the State was 330, compared with 311 at the close of the previous year. One privately aided institution at Mandagadde was closed and twenty new institutions were opened during the year. The latter include two tuberculosis institutions, six local fund dispensaries on a reduced scale, nine subsidized rural dispensaries and three malaria relief centres.

The number of beds available for in-patients was 3,210 as against 3,056 in the previous year. A total number of 65,285 in-patients was treated in the various hospitals and dispensaries as against 61,537 in the year 1938. The number of out-patients treated was 6,140,706, as against 5,612,993 in the previous year. The total number of parturition cases was 33,093, of which 13,808 were attended to inside the institutions.

The number of midwives working during the year was 339 as against 335 in the preceding year.

Under the scheme for the subsidizing of medical practitioners in rural areas, nine appointments were made during the year, making a total of sixteen such practitioners working in the State.

A sum of about Rs. 1,49,000 was received as donations during the year, either for the construction of buildings or for equipment.

Eight new buildings were completed and opened for work, among which mention may be made of—

- (i) The Cheluvamba Hospital, Mysore.
- (ii) The Lady Willingdon Tuberculosis Clinic and Dispensary at Bangalore.
- (iii) The Tuberculosis Dispensary at Davangere.
- (iv) The new pathological block of the Krishnarajendra Hospital at Mysore.

The Boards of Visitors of the several medical institutions continued to evince interest in their improvement and made valuable suggestions to increase their usefulness.

A special grant of Rs. 1 lac was made during the year for providing up-to-date surgical instruments and other equipment to the major hospitals in Bangalore and Mysore, the district hospitals and certain selected local fund dispensaries, so as to bring the most modern methods of diagnosis and treatment within the reach of the rural population.

A State Tuberculosis Association was formed for the organization of a State-wide campaign against tuberculosis and for operating the State's share of the funds of the King-Emperor's Anti-Tuberculosis Fund.

KASHMIR MEDICAL MISSION OF THE CHURCH MISSIONARY SOCIETY: REPORT FOR 1940

In spite of the war in Europe in which every part of the Empire is involved, we have been enabled to carry on without curtailing any part of our work, without having to turn away a single patient from our doors through lack of funds, or to refuse admission to any of the over two thousand needy in-patients who have occupied our wards, and without having to dismiss a single member of our staff. This is indeed something to be truly thankful for.

Owing to the war we have, as was only to be expected, received much less than usual in the way of bandages from England, and so we are especially grateful to the ladies in Srinagar who have come forward to our help, and either knitted, or made bandages for us, which have been extremely useful.

We quote with pleasure from His Excellency the Viceroy's speech on the occasion of the laying the foundation stone of the new State Hospital, last October.

SEPT., 1941]

'On an occasion such as this, I should like to pay a tribute to the excellent work in the medical field which has been done in the past and is still being done in Kashmir by the mission hospitals. They have indeed played an important and valuable part in the development of institutional treatment, and their share in the medical system which has been built up in the State is a worthy one.'

THE PREMANANDA FREE CHARITABLE OUT-DOOR LEPER DISPENSARIES, CALCUTTA: ANNUAL REPORT FOR 1940

LEPROSY IN CALCUTTA

It is becoming clear to those who have studied the leprosy problem in Calcutta that we must have, as soon as possible, a modern leper colony. Leprosy in a city like Calcutta must be tackled by four types of institution.

1. The outdoor clinic. Most patients, especially in the earlier stages, are not infectious, and do not need indoor treatment. Outdoor clinics such as ours are primarily useful for such people, and can also become centres of preventive work.

2. A hospital, to which those who need temporary hospital treatment can be sent.

3. A colony, for those who need more thorough treatment than an outdoor dispensary can give, and to which those who are in an infectious state can be sent. This should be well away from the town, in as healthy a district as possible.

4. A home, where those who are so advanced in the disease that they are not likely to be cured can be cared for. Most of the street beggars would come under this category. This home could be run in conjunction with the colony but would have to be distinguished from it.

At present Calcutta is fairly well provided with 1, though further branch dispensaries might well be opened. Gobra Leper Hospital provides an ideal 2, but at present is also being used as 3 and 4 for which it is quite unsuitable, and very few beds are left for real hospital cases.

On the other hand 3 and 4 are entirely lacking. The only colonies in Bengal are small ones serving *mofussil* areas, all overcrowded. The result is that the dispensaries in Calcutta are crowded with patients who are highly infectious, and whose only chance lies in treatment in a colony, and the lack of such a place, and the extreme difficulty of finding room for hospital patients in Gobra are the greatest handicaps on our work.

The chief event of the year has been the completion of the new building at Maniktola. The main structure consists of a large room downstairs for examination and treatment, and a smaller room for dressings, and corresponding rooms upstairs which serve as laboratory, office and store. Part of the old building has been reconstructed to form an adequate dispensary and a smaller building provides quarters for the caretakers, and latrines. There is also a verandah for waiting patients.

The new quarters provide first of all proper conditions under which the staff can work, and the work has hereby gained in efficiency. We are also able to do all our own laboratory work and to carry out tests which were not possible before. Also respectable premises increase the confidence of the public, and an increased attendance is already noticeable.

The total number of patients who attended for treatment during the year was Maniktola 1,438 ordinary patients and 250 beggars, who are classified separately; and at Kalighat 567 and 46 beggars. The total attendance was 33,147 at Maniktola and 13,466 at Kalighat. The average daily attendance was 131.5 for Maniktola with 252 working days, and 87.4 for Kalighat with 154 working days.

Of our patients 1,113 at Maniktola and 468 at Kalighat attended sufficiently regularly to justify re-examination at the end of the year. The following

results were obtained. Last year's figures are in brackets.

Disease arrested, Maniktola 75 (71), Kalighat 36 (39). Much improved, Maniktola 344 (301), Kalighat 162 (115).

Slightly improved, Maniktola 332 (179), Kalighat 146 (81).

No change, Maniktola 361 (60), Kalighat 124 (58). Worse, Maniktola 1 (4), Kalighat nil (1).

HOME VISITING

Our laboratory assistant spends part of his time visiting those patients who have discontinued treatment in order to persuade them to return, explaining to them the serious nature of the disease and of the danger to which their family is exposed. He paid 288 visits, but was only able to trace 55 patients, of whom 44 returned for treatment.

The next improvement, most urgently needed, is the provision of new premises at Kalighat. This will require a large sum of money. The committee has already been able to set aside Rs. 3,000 as the nucleus of a building fund but this must be augmented by a large grant from the Government or the Corporation; application is being made in the proper quarter.

This must be our first objective, but we have not lost sight of the need of branches in other parts of the city which are badly infected with leprosy.

ANNUAL REPORT OF THE CHEMICAL EXAMINER'S DEPARTMENT, GOVERNMENT OF MADRAS, FOR THE YEAR 1940

Human poisoning cases

The total number of human poisoning cases examined during the year was 427 cases with 2,438 articles as compared with 458 cases with 2,605 articles in 1939. Poison was detected in 235 cases or 55 per cent.

Among the organic poisons opium heads the list with 34 cases while datura and oleander come next with 25 cases and 24 cases respectively. Among the inorganic poisons copper sulphate claimed 25 cases while arsenic claimed 15, mercury 12 and arsenic and mercury together 6 cases.

INTERESTING CASES

Arsenic.—A quack prepared a 'specific' for leprosy for a neighbour suffering from this disease. The patient was suspicious and wanted to test the medicine before he consumed it. He gave small portions of the medicine to each of two children. They were both taken seriously ill and one of them died. We detected arsenic in minute quantities in the viscera. The police were unable to secure the remainder of the medicine for analysis but they seized from the house of the quack a mortar and pestle which had been used for grinding the medicine. The washings of the mortar and pestle revealed white arsenic weighing about one and nine-tenths grains.

Mercury.—On the day after the *Pongal* it is the custom in some villages in South India to catch a fox in the forest and to march it in a procession through the village. While such a procession was approaching the village with a fox, the accused greeted the crowd with sugar packets which he distributed amongst them by way of celebration of the birth of a son to him that morning. One member of the crowd ate the contents of one packet, which were sweet. A little later another packet was offered to him by the accused. The contents of the second packet were irritating to the taste and the victim vomited several times. Some of the vomits were eaten by two dogs which died. The victim was taken very ill and removed to a hospital where he recovered after his stomach was washed out. The stomach contents were sent to us and we detected about three grains of corrosive sublimate in them.

Copper.—Most of the cases of copper sulphate poisoning were attempted suicides. A young man waited 'to solve the problem of unemployment'. He was admitted to a hospital and recovered after a stomach wash. We detected in his stomach washings copper

equivalent to about six grains of crystalline copper sulphate. He was convicted for attempted suicide but released on probation of good conduct.

There were also some accidental cases of copper sulphate poisoning and these could be explained only by the omnivorous nature of some human beings. One young man found a blue lump on the floor of a latrine and ate it thinking it to be candy. Another found a packet containing cashew nut kernels mixed with blue stone pieces in front of a cinema and ate the lot in spite of the disagreeable taste. Still another found a packet of blue stone lying on the road and ate the contents. Vomiting ensued in each of these cases, and recovery followed after removal to hospital. We found small quantities of copper in the stomach washings of each of these victims.

Yellow phosphorus.—A man was invited to dinner. After eating a few morsels of food served to him, he was seized with an uneasy sensation in the stomach and vomited. He reported the matter to the police who seized the uneaten food and sent it to us along with a bottle containing a yellow lump immersed in water which was found in the house of the accused. We detected yellow phosphorus weighing about two-fifths of a grain in the food, and the lump in the bottle was yellow phosphorus.

Nitrite.—After dinner at about 6 p.m. a man told his wife that he was having abdominal colic. His wife gave him a powder believing it to be sodium bicarbonate. After swallowing the powder he went into the street but soon returned home stating that he was feeling giddy and that the pain in the stomach was intense. He vomited and purged once and lay breathing hard on a mat. He was found to be dead at about 8 p.m. The post-mortem examination revealed bleeding from the mouth and nose, features livid; the lungs dark red in colour and the liver, pancreas, spleen and kidneys congested. The stomach was distended with food and gas the outer surface being vascular and injected. The small intestines were slightly injected. We detected in the viscera nitrite equivalent to about three and one-fourth grains of sodium nitrite, in the vomit nitrite equivalent to about half a grain of sodium nitrite and in the motion nitrite equivalent to about one-fiftieth of a grain of sodium nitrite.

A rag bundle stated to contain the specimen of sodium bicarbonate administered to the victim was sent to us by the police. The bundle was actually found to contain sodium nitrite tied up in one corner of the rag and sodium bicarbonate contaminated with traces of sodium nitrite tied up in the opposite corner of the same rag.

Alcohol.—One morning a young man went to an arrack shop and went on drinking till he had consumed about five rupees worth of arrack. He was removed to a hospital in a comatose state in the afternoon, and died just before midnight without recovering consciousness. The post-mortem examination revealed features flushed, heart normal, lungs intensely congested, liver forty-two ounces in weight and congested, pancreas, spleen and kidneys congested, stomach with injected patches all over the inner surface and containing a dark greenish fluid smelling of arrack, intestines injected in places and the brain fifty ounces in weight and congested. We detected alcohol but not any other poison in his stomach washings and in his viscera. Considering the fact that about three pints of arrack can be bought for five rupees and that arrack as sold to the public is thirty-five degrees under-proof, it is probable that alcohol equivalent to about a pint of anhydrous alcohol had been drunk by the victim. About a quarter of a pint of anhydrous alcohol is regarded as a fatal dose.

Datura.—A man in the Andaman Islands was suspected of being in possession of some mysterious Burmese poison which would produce unconsciousness in small doses and would kill in large doses. The police raided his house at 3 a.m. and found a packet inside his pillow. They sent the packet on to us and we found the contents of the packet to be powdered datura seeds.

THE REPORT ON THE WORKING OF HOSPITALS AND DISPENSARIES IN THE PUNJAB FOR THE YEAR 1939

DURING the year under report the total number of medical institutions in the province was the same as in the preceding year, namely, 974. The civil hospitals at Dharamsala, Isakhel and Pakpattan, and the hospitals for women at Dharamsala and Hazro were provincialized. The number of rural dispensaries, for the maintenance of which district boards receive a grant-in-aid from Government, remained unchanged. The expenditure incurred by Government in the grant of a fixed travelling allowance of Rs. 10 per mensem each to the medical officers in charge of these dispensaries to enable them to visit neighbouring villages within a radius of five miles has justified itself, inasmuch as 243,000 patients were treated in their villages or in their homes. In order to bring medical relief within still easier reach of the rural population, Government have now adopted a scheme of subsidizing private practitioners to encourage them to settle in villages. Sixty-three subsidized dispensaries were established before the end of the financial year 1939-40, and more will be set up gradually as funds permit.

The total number of patients treated both indoor and outdoor was 176 lacs against 171 lacs in the preceding year. As there was no epidemic during the year under report, the increase in the number of patients treated in hospitals and dispensaries can only be interpreted as an indication of increased willingness on the part of people to resort to a hospital for treatment. Malaria was not unduly prevalent, but the number of cases treated for this disease rose from 14.9 lacs to 16.7 lacs. There is an increase of 77,250 in the number of patients who were treated for diseases of the eye.

The total income of all hospitals and dispensaries rose from Rs. 53.4 lacs to 54.7 lacs, the increase being almost entirely due to larger receipts under the heading 'Contributions from local and municipal bodies'. In recent years several charitably-disposed persons have donated large sums of money for the treatment of tuberculosis patients. The tuberculosis hospital at Amritsar, which was opened during the year under report by Her Excellency the Marchioness of Linlithgow, is the outcome of the munificence of Rai Bahadur Gujjar Mal after whom it is named. Another sanatorium, for the construction of which funds have been provided by Rai Bahadur Jodha Mal Kothiala, will shortly be ready in the vicinity of the city of Hoshiarpur. The sons of the late Rai Bahadur Bawa Dinga Singh have donated Rs. 1 lac for a tuberculosis hospital at Lahore to be named after their father.

There was noticeable expansion in the institutions which provide medical treatment for women exclusively. A maternity hospital under the charge of a woman assistant surgeon was opened at Montgomery. An indoor maternity home known as the Shrimati Janki Devi-Jamiat Singh Hospital containing 16 beds was built at Lahore, the money having been raised by contributions from private individuals and a grant-in-aid from Government. Separate female sections were provided in seven civil hospitals at *taluk* headquarters. The number of assistant surgeons in the women's branch of the Punjab Civil Medical Service has increased from 3 to 7; and the provincial cadre of women sub-assistant surgeons has been strengthened by the addition of 8 posts, raising the total to 55. Satisfactory progress has also been made in the training of *dais* by the grant of scholarships. The Lady Aitchison Hospital, Lahore, which is in charge of a member of the Women's Medical Service, retained its usual popularity and high standard of efficiency.

The Mayo Hospital, Lahore, maintained its high reputation. It can now boast of a most up-to-date x-ray plant which has been installed at a cost of Rs. 1 lac and a Radium Institution for which L. Tirath Ram gave a generous donation of Rs. 50,000. The bed accommodation at present is insufficient but will be increased as soon as funds become available for the

construction of new buildings on the site which Government have acquired close by at a cost of Rs. 6½ lacs from the authorities of the Forman Christian College. The civil hospital at Amritsar, which *inter alia* provides practical and clinical training for students of the medical school, has also another year's useful work to its credit. Its medical superintendent is now a lecturer of the school instead of the civil surgeon. It has a separate eye hospital with accommodation for 150 indoor patients which is fully utilized, although not yet properly equipped for reasons of financial stringency. There was an all-round increase in the work done at the Lady Willingdon Hospital, Lahore. The Tika Devi Health Centre works in close association with the hospital, and a scheme has been introduced which enables students to conduct midwifery cases under proper supervision at the patients' homes. The clinical material is, however, not yet sufficient for the training in practical midwifery of all students of the King Edward Medical College, and some have still to be sent to Madras.

A 'blindness week' was held in February 1939, and was inaugurated with an appeal from His Excellency the Governor for the help and co-operation of all who valued the gift of sight. The publicity and propaganda side of the week was entrusted to the Commissioner for Rural Reconstruction who printed literature in several languages for distribution, on a large scale. Arrangements were made with the co-operation of All-India Radio, Lahore, for broadcast talks on the prevention of blindness by eminent eye specialists in the province. Medical officers in districts played their part by touring and lecturing in villages, giving demonstrations on the care of eyes, examining cases of defective vision and treating cases of eye diseases. Reports which were received about the celebration of the week were encouraging and showed that it had been a great success.

Correspondence

INSULIN REQUIREMENTS IN INDIA

SIR.—Will you or any one of the readers of your journal be good enough to let me know either through the columns of your esteemed monthly or otherwise about the source of getting insulin in these war days? And if it cannot be procured easily in India, what is the best possible treatment for a diabetic?

BAL RAJ VIJ,
Palace Physician.

KHILCHIPUR STATE (C. I.),
KHILCHIPUR,
4th August, 1941.

INSULIN REQUIREMENTS IN INDIA

SIR.—With the war-cloud spreading rapidly in different zones, particularly in the East, there is an increasing difficulty in India in getting supplies of some of the essential life-saving drugs, for which India still depends on foreign countries. One, therefore, naturally fears what will happen to those unfortunate individuals the continuance of whose life depends on a regular and uninterrupted supply in their proper doses of those drugs which are not manufactured in India.

Insulin appears to me to be such an essential drug and it is very unfortunate that, though nearly 20 years have passed since the discovery of insulin, its manufacture has not been taken up in India. That insulin can be manufactured in India, there is no doubt. As a matter of fact, during the early days of insulin therapy, when the export of the drug to India was limited, the writer with the collaboration of Col. T. C. Boyd, the then chemical examiner to the Government of Bengal, prepared insulin in the laboratory which was found to be of quite good potency. The reason why the research was not continued was, firstly, because

the cost of preparing insulin on a small scale in the laboratory was prohibitive and, secondly, because we began to get adequate supplies from abroad.

There is no gainsaying the fact that the life of most diabetic patients depends on insulin and there is also no denying the fact that India, most particularly Bengal, is one of the leaders so far as the incidence of diabetes is concerned. The death rate is also high. Insulin thus is one of the most essential drugs, and, now that the supply is gradually getting scarce, it is high time that the medical profession in India should devise ways and means for its manufacture in India. The manufacturing firms, as far as I know by talking to a few of them, appear to be nervous as to what their fate would be when the war is over and the insulin market flooded with all sorts of foreign insulin. They apprehend that even if they produce the properly standardized insulin, they would not be in a position to compete with the foreign production unless they get Government support and backing in several ways. Personally, I think their fear is not well founded. If the Indian insulin satisfies the physiological tests and is carefully standardized as regards potency, etc., and certified by a Board as such, I do not know why it will not sell as well as the others and at a price which may be said to be competitive.

The reason of my approaching you through these columns is obvious for the following reasons:—

(1) Insulin is the life of the huge diabetic population in India, particularly of the aristocratic, the intelligent and middle classes, and if by chance the supply is interrupted, or stopped, the death rate which will follow will be appalling.

(2) The manufacture and the standardization of insulin can be taken up by any of the big manufacturing concerns in India.

(3) Insulin production in India would be an asset and will prove to be so in the long run.

May I have your sympathy and co-operation in the name of the very large number of the unfortunate diabetic patients in this country?

J. P. BOSE, M.B., F.C.S. (Lond.).

SCHOOL OF TROPICAL MEDICINE,
CALCUTTA,

15th August, 1941.

[Note.—It is true that at present many doctors and patients prefer drugs of British or American manufacture, not because they are British or American, but because they are made by firms with established reputations. The present situation seems to present the pharmaceutical trade in India with a splendid opportunity. If during the war firms can establish their reputations they will certainly be able to compete with foreign pharmaceutical products.

Apparently, according to Dr. Bose, certain manufacturers are holding back until they can get some guarantee of Government protection to be maintained after the war. Whilst a promise of protection for a limited period, so that they will have time to recoup their original outlay, would be fair, we do not think that it would be right for them to use this shortage of insulin to blackmail the Government into promising a degree of protection that would later react to the disadvantage of the diabetic patient.

We understand that an enterprising firm in Bombay are already exploring the possibilities of manufacturing insulin in India.—EDITOR, *I. M. G.*]

BACTERIOPHAGE AND WATER CONTAMINATION

SIR.—Whilst in no way attempting to belittle the interest and importance of Major Pasricha's and Dr. DeMonte's findings recorded in their paper 'Bacteriophage as an Index of Water Contamination' in your issue of August 1941, I feel that the unfortunate public health analyst would be hard put to it to pass any water sample as potable if the authors' suggestion to include examination for these bacteriophages in the routine examination of water were to be adopted.

One may accept, I think, that such bacteriophage contamination of water indicates that the water has at some time been contaminated by human excreta, but I venture to suggest that there are few, if any, water supplies which have not been so contaminated somewhere during the course of their passage from the rain after it has fallen on the ground to the actual source of supply to the consumer, be this water tap, spring, well or tank.

Surely the purity of water, in the sense of its freedom from pathogenic organisms, depends, whether naturally or artificially produced, not on its never having been contaminated but chiefly on its having undergone filtration through the ground or through filter beds and on the relatively poor hold on life exhibited by the pathogenic intestinal bacteria outside the human body.

But bacteriophage is a filter-passenger, and it is also a pretty hardy organism. It would not be removed, I suggest, either by natural or artificial filtration, or by reasonable storage and perhaps not even by ordinary chlorination, though I have no facts to support the latter suggestion.

I suggest that even London's tap water, which comes from a highly contaminated source originally and which yet, after treatment, maintains a very high standard of purity, would be found contaminated with bacteriophage active against pathogenic bacteria and would therefore presumably be condemned if absence of this contamination were regarded as a necessary criterion of potability.

L. A. P. ANDERSON,

LIEUTENANT-COLONEL, I.M.S. (Retd.).

PASTEUR INSTITUTE,

SHILLONG,

27th August, 1941.

Service Notes

APPOINTMENTS AND TRANSFERS

To be D. M. S. in India

MAJOR-GENERAL A. C. MUNRO, K.H.R. Dated 12th July, 1941.

Lieutenant-Colonel H. K. Rowntree, M.C., I.M.S. (Retd.), Director of Production, Instruments and Appliances, is appointed Additional Deputy Director-General, Indian Medical Service (Stores), for the duration of the war, with effect from the 3rd July, 1941.

On his reversion to military duty Lieutenant-Colonel Amri Chand, Professor of Medicine, K. E. Medical College, Lahore, made over charge of his duties to Major G. F. Taylor, Professor of Clinical Medicine, K. E. Medical College, Lahore, on the afternoon of the 14th July, 1941. Major Taylor will hold this charge in addition to his own duties till further orders.

The services of Lieutenant-Colonel W. H. Crichton, C.I.E., are replaced temporarily at the disposal of His Excellency the Commander-in-Chief, with effect from the 29th May, 1941.

On his reversion to military duty Lieutenant-Colonel K. R. Batra, Civil Surgeon, Jullundur, made over charge of his duties to a non-I.M.S. officer on the forenoon of 8th July, 1941.

On his reversion to military duty Lieutenant-Colonel H. Chand, M.C., Civil Surgeon, Sialkot, made over charge of his duties to a non-I.M.S. officer on the afternoon of the 10th July, 1941.

The services of Lieutenant-Colonel S. D. S. Greval are placed temporarily at the disposal of His Excellency the Commander-in-Chief, with effect from the afternoon of the 12th July, 1941.

On his reversion to military duty Lieutenant-Colonel H. S. Anand, Professor of Physiology, K. E. Medical College, Lahore, made over charge of his duties to a non-I.M.S. officer on the afternoon of the 14th July, 1941.

On his reversion to military duty Lieutenant-Colonel Jamal-ud-Din, Civil Surgeon, Rawalpindi, made over charge of his duties to a non-I.M.S. officer on the forenoon of the 14th July, 1941.

Lieutenant-Colonel M. Das, M.C., Superintendent of the Alipore Central Jail, made over executive and medical charges of the Alipore Central Jail to Mr. Chas. A. W. Luke and Lieutenant-Colonel K. S. Thakur, respectively, on the afternoon of the 15th July, 1941.

The services of Lieutenant-Colonel A. C. Chatterji, Director of Public Health, Bengal, are placed at the disposal of the Government of India in the Defence Department, with effect from the 15th August, 1941.

The services of Major C. K. Lakshmanan, Deputy Public Health Commissioner with the Government of India, are placed at the disposal of the Chief Commissioner, Delhi, for appointment as Chief Health Officer, Delhi, with effect from the afternoon of the 28th May, 1941, vice Lieutenant-Colonel W. H. Crichton, C.I.E.

The services of Major J. D. Grant, an Agency Surgeon, are temporarily replaced at the disposal of His Excellency the Commander-in-Chief, with effect from the 15th May, 1941.

On return from leave Major S. Smyth resumed charge of his duties as Civil Surgeon, Lahore, on the forenoon of the 23rd June, 1941, relieving Major G. F. Taylor, Professor of Clinical Medicine, K. E. Medical College, Lahore, of the additional charge.

The Secretary of State for India has appointed to the Indian Medical Service (Civil) the following officers of the Indian Medical Service, with effect from the dates stated against their names:—

Central Government

Captain C. J. H. Brink. Dated 3rd February, 1940 (forenoon).

Captain H. A. Ledgard. Dated 27th March, 1940 (forenoon).

Madras

Captain G. E. S. Stewart, M.B.E. Dated 16th January, 1940 (forenoon).

Captain W. H. G. Reed. Dated 31st January, 1940 (afternoon).

Bombay

Captain T. M. Williams. Dated 22nd February, 1940 (forenoon).

Captain W. W. Laughland. Dated 23rd February, 1940 (afternoon).

Captain T. C. M. M. Morrison. Dated 27th February, 1940 (forenoon).

Captain C. C. Harvey. Dated 26th May, 1940 (forenoon).

Assam

Captain J. H. Caverhill. Dated 12th April, 1940 (forenoon).

North-West Frontier Province

Captain M. Ata-Ullah. Dated 22nd February, 1940 (forenoon).

Sind

Major A. K. M. Khan. Dated 22nd February, 1940 (forenoon).

Captain G. S. Chopra, A.I.R.O. (Medical), is appointed to officiate as Deputy Assistant Director-General (Medical Stores), Karachi, from the forenoon of the 18th June, 1941, until further orders.

Captain R. de Soldenhoff, Resident Medical Officer, St. George's Hospital, Bombay, reverted to military duty. He was relieved of his civil duties on the forenoon of 10th July, 1941.

INDIAN LAND FORCES

(Emergency Commissions)

The undermentioned Captains (on probation) are confirmed in their rank, with effect from the dates specified:—

V. Sivasankaran. Dated 22nd June, 1940.

K. N. Rao. Dated 1st July, 1940.

R. Kasliwal. Dated 23rd September, 1940.

S. D. Dalal. Dated 23rd September, 1940.

A. S. Rao. Dated 10th October, 1940.

M. N. Rajan. Dated 15th October, 1940.
 S. N. Kaul. Dated 15th November, 1940.
 K. L. Jetley. Dated 2nd December, 1940.
 C. V. Krishnaswami. Dated 2nd December, 1940.
 I. H. B. Ghosh. Dated 5th December, 1940.
 C. L. Bhola. Dated 15th January, 1941.

The undermentioned Lieutenants (on probation) are confirmed in their rank, with effect from the dates specified:—

10th June, 1940

Emergency Commissions

The undermentioned appointments are made:—

To be Lieutenants

27th February, 1941

Colin Ibbotson. Ronald Michael Vanreene.

The following appointments are made:—

*INDIAN LAND FORCES**(Emergency Commissions)**To be Lieutenant (on probation)*

Balkrishna Kesheo Sheorey. Dated 23rd June, 1941.

*PROMOTIONS**Lieutenant-Colonels to be Colonels*

W. C. Spackman. Dated 11th June, 1941, with seniority from 26th January, 1936.

M. L. Treston. Dated 1st June, 1941, with seniority from 1st February, 1937.

Captain to be Major

D. K. L. Lindsay. Dated 1st August, 1941.

Captain to be Brevet-Major

V. A. Edge (retired officer re-employed). Dated 3rd September, 1939.

Note.—The promotion of Major B. S. Nat to his present rank is antedated to 20th November, 1934.

*INDIAN LAND FORCES**(Emergency Commissions)**Lieutenants to be Captains*

10th June, 1941

H. L. Bhatia.

13th June, 1941

M. S. Boparai. T. R. Bargotra.

V. Parkash.

14th June, 1941

S. M. Shafi. M. Ali.

1st July, 1941

S. S. Sekhon.

15th July, 1941

G. Singh. G. V. Munje.
 M. Singh. K. S. Seth.
 A. L. Som. H. D. Varma.
 A. R. Tampli. B. B. Choksi.
 R. Subramanian. S. C. P. Sinha.

18th July, 1941

E. R. F. Rebello. K. P. Joseph.
S. D. Basu. M. A. Paul.**REVERSION**

The undermentioned, at their own request, revert to the rank stated whilst employed during the present emergency:—

As Majors

Lieutenant-Colonel A. N. Dickson, M.C., I.M.S. (Retd.). Dated 25th February, 1941.

Lieutenant-Colonel M. R. C. McWatters, I.M.S. (Retd.). Dated 3rd March, 1941.

RETIREMENTS

Lieutenant-Colonel W. C. McKee, on account of ill-health. Dated 21st March, 1941.

Lieutenant-Colonel S. N. Makand. Dated 10th July, 1941.

Notes**CIPLA PRODUCTS**

THE enterprising Bombay firm of drug manufacturers, Chemical, Industrial and Pharmaceutical Laboratories Limited, have just issued their *Therapeutic Index*. To quote from their foreword:—

'In presenting the new 1941 edition of our *Therapeutic Index* we hope to serve the medical profession by giving very useful details of various clinical applications of our products.'

We are now entering the fifth year of manufacture of pharmaceutical products and the name CIPLA has been well established not only all over India but even

in many foreign countries, where our medicines are in constant demand.

All our products are manufactured under strict chemical, biological and clinical control and each batch is carefully tested before being put on the market.

The various preparations are arranged in alphabetical order and the composition, indication, dosage, technique of administration and packing are described under each head. The space in such a concise booklet does not permit to furnish detailed information regarding each product. Full literature on each product and any other information will be gladly supplied on request.'

The booklet contains a long list of pharmaceuticals which will almost completely supply the requirements of the average practitioner.

We notice in particular their Nicosil which is a sulphonamide preparation combined with nicotinic acid. This indicates how well abreast of recent advances the firm have kept themselves, for it is only within a short time that the observation regarding the detoxicating effect of nicotinic acid was made.

This booklet can be obtained from Messrs. Chemical, Industrial and Pharmaceutical Laboratories Limited, 289, Bellasis Road, Byculla, Bombay.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints gratis; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more, after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributors should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles

EXTRA-PLEURAL PNEUMOTHORAX—ITS SCOPE AND LIMITATIONS

By P. V. BENJAMIN, M.B., B.S. (Madras),
T.D.B. (Wales)

Medical Superintendent, Union Mission Tuberculosis Sanatorium, Arogyavaram, near Madanapalle

EXTRA-PLEURAL pneumothorax is one of the more recent methods of collapse therapy in pulmonary tuberculosis. Though this method has been suggested and tried after Tuffier introduced the 'extra-pleural pneumolysis' operation in 1913, it was abandoned after a short trial. In 1934 Baer and Graff returned to it as did others, but it is only since 1937 that it has come to be extensively used. However, since the experience of the operation covers only a short period of five years, any conclusions about it should still be considered tentative and possibly subject to revision in the light of further experience, but enough work has been done to give a preliminary opinion about its scope and limitations.

The extra-pleural pneumothorax operation is similar to extra-pleural pneumolysis except that the space formed between the parietal pleura and the thoracic wall is filled with air instead of fat, muscle or paraffin.

The technique of the operation

The operation is usually done under local anaesthesia; a general anaesthetic can be given but we have never found this necessary.

The patient is placed in the lateral position as for a thoracoplasty, and the arm on the side to be operated on is pulled forward so that the vertebral border of the scapula comes to lie on or parallel to the fourth rib. An oblique incision 5 to 6 inches long is made in the line of the fourth or fifth rib. After severing the fascia and muscle the rib is cleaned and 4 to 5 inches of it resected subperiosteally. By blunt dissection with a flat thin spatula a cleavage can be made between the intercostal muscles to the endothoracic space under the rib, above and below. If there are no adhesions it is fairly easy to get access to this space by gentle manipulation with the gloved finger and it can little by little be enlarged; as the stripping goes further in beyond the reach of the fingers, swabs can be used to separate the pleura from the chest wall and the apex also can be released from the dome of the chest.

But unfortunately there are often adhesions which may vary from thin adhesions covering small areas to very thick fibrous adhesions extending over a large area and penetrating deeper than the pleura into the chest wall. It is dangerous to attempt to break extensive adhesions as it may tear the lung, but more frequently it will lead to severe bleeding. Small areas of fresh adhesion can be separated by

gentle and careful manipulation. This procedure may be described as 'wiping the lung away from the chest wall'.

When a sufficient area of the lung has been stripped and the necessary space created, the space is wiped dry of blood. There is always some oozing of blood, but, if no adhesions have been broken, the bleeding is slight and easily controlled. If adhesions have been broken, the bleeding will be more profuse and has to be controlled by pressure. Sometimes electro-coagulation of the bleeding points may be necessary. But before closing the wound it must be made certain that all the bleeding has been controlled.

In the later operations of our series we have at this stage filled the space with warm normal saline before closing the wound. It probably helps to control the oozing of blood, a certain amount of which is bound to take place into the extra-pleural space for some time after the operation. But more important is the ease with which the effused blood can be aspirated in post-operative care.

The wound is closed in three layers, the deep layer by interrupted catgut sutures, including the periosteum of the two adjacent ribs and the intercostal muscles, the second layer by continuous catgut suture including muscles and fascia, and the third layer, the skin, by silkworm gut. No drainage tube should be introduced.

Air is then injected into the space, between 100 c.cm. and 400 c.cm., according to the space and the pressure; the closing pressure should be a low positive between +2 and +10.

Post-operative care

The success of extra-pleural pneumothorax depends mainly on careful post-operative care. The patient has to be examined frequently by the fluoroscope to note the amount of collapse and the presence of fluid. Our procedure is to take an x-ray film immediately after the operation to find out the extent of the space created and the nature of the collapse of the lung. Twenty-four hours later the patient is screened, and if there is found any effusion of blood it is aspirated and a refill of air is given at the same time. During the first week the patient is screened at least every other day and refills of air are given as required according to the condition of collapse noted on screening. Usually two or three aspirations are needed during the first week after the operation, then refills once a week during the first month. After that if everything goes well the intervals can be still further increased.

Aspiration of effusion in the first week is essential, otherwise the fluid is likely to leak through the deeper layers and escape into the tissues under the skin; also it may leak through the wound, soak the dressings, and lead to infection and later to sinus formation. Also, if aspiration is not done and refills are not given at the proper time, the extra-pleural space may get

obliterated; the effused blood gets organized and drags out the lung to the chest wall and so the effect of the operation is spoilt.

Complications

Shock produced by the operation is surprisingly little, much less than ordinarily seen in a thoracoplasty operation. We have operated on some very weak patients who would have been considered very poor risks for a major operation and they have all stood the operation without any severe shock.

Bleeding is the most common and serious complication. As mentioned above there is bound to be some oozing of blood, but, unless adhesions have been broken, it is mild and easily controlled. It is more serious if adhesions have been broken, depending on the extent of the adhesions. In one case in our series in which one thick adhesion was broken, bleeding at the time of the operation was controlled, but a secondary haemorrhage took place twenty-four hours later and in spite of blood transfusions the patient did not recover from the effects of it and died forty-eight hours after the operation. Learning by experience we do not now attempt an extra-pleural pneumothorax if the x-ray picture suggests there are likely to be extensive adhesions.

The tearing open of cavities is a danger, especially if manipulation is not gentle and there are thin-walled superficial cavities. So far we have not had this complication.

Subcutaneous emphysema sometimes occurs. If the suturing is done properly this is not usually extensive or serious. Sub-fascial emphysema and air embolism are mentioned as possible complications, but so far we have not experienced them.

Infection of the extra-pleural space occurs in some cases. In a few this is a tuberculous infection from the pleural surface and it has been possible to find tubercle bacilli in the extra-pleural fluid. When frequent aspirations of blood have to be done it may happen occasionally that even with the utmost care infection takes place. Infection from the skin through leakage of effusion has already been mentioned. Proper aseptic precautions during aspiration and dressing will prevent most infections. If infection does take place, it can usually be controlled by aspiration and washing out, but sometimes the space may have to be opened and drained. This may lead to a persistent sinus which may later require a thoracoplasty.

Indications for extra-pleural pneumothorax

Where collapse therapy is indicated in pulmonary tuberculosis it is generally recognized that intra-pleural artificial pneumothorax is the best procedure. Therefore extra-pleural pneumothorax is only indicated when intra-pleural pneumothorax has failed either completely or partially. Thus the indications for the extra-pleural operation are the same as for artificial

pneumothorax with the reservation that the latter can be tried in very weak patients in whom extra-pleural pneumothorax, being a major operation, is contra-indicated.

'Extra-pleural pneumolysis' and extra-pleural pneumothorax have usually been advocated for patients in whom artificial pneumothorax has failed but in whom thoracoplasty is contra-indicated because of contralateral disease or because of the general debility of the patient. But this general indication does not now hold good as the indications for thoracoplasty are not now so restricted as they were some years ago. Bilateral disease is no longer considered an absolute contra-indication for thoracoplasty when it is done in small stages and when the principle of selective collapse is carried out. We have had several cases in which resection of the seven upper ribs has been done with good results, while artificial pneumothorax has been carried on simultaneously for active disease in the contralateral lung. Hence unsuitability for thoracoplasty cannot now be taken as an indication for choosing extra-pleural pneumothorax. In practice, it is generally found that when a patient is not suitable for thoracoplasty according to the modern technique mentioned, he is not suitable for extra-pleural pneumothorax. Therefore when the patient is suitable for major surgery the question is whether thoracoplasty or extra-pleural pneumothorax is to be preferred in that particular case.

Thoracoplasty is an operation which collapses the lung permanently. If the lung in the area to be collapsed is extensively affected with chronic fibrosing disease with one or more cavities and there is little chance of this part of the lung functioning at any time, the best procedure will be to collapse the lung permanently by a thoracoplasty. But frequently there are cases with soft-walled cavities in the sub- or infra-clavicular region, surrounded by some infiltration and a good deal of healthy lung. To collapse such cavities by a thoracoplasty would usually mean a six or seven rib resection which would put out of action permanently a good portion of healthy lung also. Therefore in such cases, on the basis of our experience in artificial pneumothorax treatment, where, after one or two years when the cavities have healed, the lung can be allowed to expand and function normally, it is reasonable to prefer extra-pleural pneumothorax to thoracoplasty.

Extra-pleural pneumothorax is also preferable in cases where there are extensive scattered infiltrations in one lung with patches of healthy lung intervening; there may be a cavity in the sub-clavicular region. In such cases a partial thoracoplasty is not likely to be effective enough and a complete thoracoplasty is too drastic.

In cases where there is a thin-walled superficial cavity, a thoracoplasty is usually to be preferred, because there is the possibility of extensive adhesions and also the danger of tearing open the cavity during the operation.

An extra-pleural pneumothorax is generally to be preferred in young people during the growing stage as a thoracoplasty is likely to interfere with the growth and shape of the thorax and cause deformity.

Cases with rapidly spreading disease, especially bi-lateral, are not suitable for extra-pleural pneumothorax or any major surgery.

Combined intra- and extra-pleural pneumothorax

It has been suggested that an extra-pleural pneumothorax should be done to make the collapse effective in artificial pneumothorax cases where uncauterizable adhesions cause an ineffective pneumothorax. An extra-pleural pneumothorax can be done over the area where the lung is adherent, and the extra-pleural space can be connected with the intra-pleural cavity. We have tried this in three cases but in all there was a severe reaction with effusion in the pleural cavity which required frequent aspirations; two of them became infected and later required a thoracoplasty, while the third had a stormy post-operative course with high temperature but did eventually get better after frequent aspirations and washing out of the pleural cavity. Therefore on the basis of this experience we cannot advocate this procedure generally.

Oil-filling in extra-pleural pneumothorax

In some cases of extra-pleural pneumothorax there is a tendency for the space to become obliterated in spite of aspiration of fluid and correct filling with air. This can be prevented by filling the space with oil (gomenol 10 per cent in paraffin oil). This is also useful when it is necessary for patients to leave the sanatorium and collapse should still be maintained. Experience with artificial pneumothorax has shown that for complete healing cavities need to be collapsed usually for two to three years. At present it is difficult for many patients with extra-pleural pneumothorax to continue the air filling outside the institution and therefore before they are discharged the space can be filled with oil in order to maintain the collapse. Of five cases discharged with this we have been able to observe three later and all were doing well without trouble.

What happens to the space, after it has been filled with oil for some time, has been seen in two cases in which a thoracoplasty was done later. The space has shown a thick capsule and it would have been unlikely that the lung could have expanded again and therefore probably a permanent collapse had been produced. In extra-pleural pneumolysis when a paraffin wax filling was employed, it was frequently found that some of the wax worked its way out from the space. Whether this will ultimately happen with the oil-filling is not yet known, but so far we have not observed it.

Review of cases

Since 1938, thirty-nine patients have had an extra-pleural pneumothorax in this sanatorium. In 5 patients after the operation had been begun it was found impossible to complete it because of extensive adhesions; in 3 of these the operation was immediately converted into a thoracoplasty, another had a thoracoplasty subsequently and the fifth is waiting for a thoracoplasty. Five patients are still under treatment of whom 3 have already shown definite improvement. This leaves 29 patients who can be considered in detail.

Of these 29 patients, 6 had a thoracoplasty later, 3 of them because the extra-pleural space became obliterated and 3 to close an empyema space.

Of the remaining 23 patients who had only an extra-pleural pneumothorax, 12 were discharged as 'much improved' and 3 as 'improved'; 8 obtained no improvement; 13 of the 23 became 'sputum negative'.

Of the 29 patients, 21 could have been selected for thoracoplasty but extra-pleural pneumothorax was preferred for various reasons given earlier in this paper. Of the 21 patients 2 had extra-pleural pneumothorax followed by thoracoplasty. Of the remaining 19 patients 15 gained improvement and 12 became bacilli free. Of the remaining 8 patients who were considered at the time unsuitable for thoracoplasty, only 2 gained some but not marked improvement and only 1 became bacilli free.

As regards complications in this series of 29 patients, one patient died of secondary haemorrhage 48 hours after the operation; one patient died four days after the operation, post-mortem examination showing a marked pleural effusion in the lower part of the pleural space which had had an artificial pneumothorax and which was thought to have been obliterated. This patient had also fairly extensive affection in the contralateral lung which had not been controlled by artificial pneumothorax and for which a thoracoplasty was in view. Death was due to pressure of the effusion on the heart.

In 8 patients there was a subsequent infection of the extra-pleural space. In 5 of these it was controlled by aspiration and washing out and in 3 a thoracoplasty was done later.

Conclusion

In extra-pleural pneumothorax we have a useful addition to collapse therapy with results in properly selected cases comparable to those of thoracoplasty. It produces far less shock than thoracoplasty, is less deforming, and is a less permanent operation, that is, air filling can be stopped if necessary and advisable, and the lung can be allowed to expand.

There has to be a careful selection of patients for the operation and even then it may not be suitable as adhesions may be found which will make it impossible.

While the best results are seen in patients who could be chosen for either extra-pleural pneumothorax or thoracoplasty, there are certain indications why one should be preferred to the other in a particular individual, and extra-pleural pneumothorax cannot be regarded as a substitute for thoracoplasty.

Finally it must be emphasized that the success of the operation depends on post-operative care. For this a well-trained staff is needed and facilities for frequent x-ray control. Without the trained staff and without the x-ray facilities the operation should not be attempted.

Summary of case reports

Case 1.--Male, aged 25 years, admitted on 25th January, 1939.

Right side.--Artificial pneumothorax attempted on 31st January.

No air could be given.

Two courses of sanocrysin--ending on 12th July.

Extra-pleural pneumothorax on 22nd August. Five inches of the 5th rib resected; 5 refills were given.

As the lung showed a tendency to re-expand in spite of refills, oleothorax was started and the extra-pleural space was filled with oil in small doses; the total quantity of the oil introduced was 500 c.cm.

The patient had been TB-positive since admission and at the time of operation, but was TB-negative one month after operation and remained so till the time of discharge.

Culture of the sputum done twice on 8th May and 20th August, 1940, was negative.

Discharged on 20th October, 1940, as 'much improved'.

Came for re-examination in February 1941. Oil was still present in the extra-pleural space; TB-negative. Keeping good health.

Figure 1, plate XXXII.--Before operation. Note cavity right sub-clavicular region. Scattered infiltration right lung.

Figure 2.--Extra-pleural pneumothorax right side, with slight effusion.

Figure 3.--Right lung beginning to expand but controlled by oleothorax.

Case 2.--Female aged 23 years, admitted on 18th July, 1939.

Artificial pneumothorax attempted on right side on 22nd July. No air could be given.

One course of sanocrysin ending 18th October.

Extra-pleural pneumothorax on 26th October. (Five inches of the 4th rib resected.)

Eleven extra-pleural pneumothorax refills given.

As the lung showed a tendency to re-expand in spite of refills, oleothorax was started and the extra-pleural space was gradually filled with oil. Total oil introduced was 480 c.cm.

Sputum was TB-positive since admission and at the time of operation, but became negative after the commencement of extra-pleural pneumothorax and remained negative till the

time of discharge. Cultures of the sputum done twice on 5th July and 22nd August, 1941, were negative.

Discharged on 17th October, 1940, as 'much improved'.

Figure 4.--Extensive mottling right lung with a cavity at the level of the 2nd rib anteriorly, and 6th rib posteriorly. (Not easily seen in the print.)

Figure 5.--Soon after extra-pleural pneumothorax right side.

Figure 6.--Some time before discharge. Lung beginning to get expanded, but controlled by oleothorax.

Case 3.--Female, aged 16 years, admitted on 25th July, 1939.

Artificial pneumothorax left side attempted on 28th July. No air could be given.

One course of sanocrysin ending on 4th October.

Sputum positive for TB since admission and at the time of operation.

Extra-pleural pneumothorax done on 30th October. (Five inches of the 4th rib resected.)

Eighteen extra-pleural pneumothorax refills were given; oleothorax started on 16th April, 1940.

After oleothorax, effusion in the extra-pleural space appeared. Hence aspiration of fluid and replacement with air done. In the end, 310 c.cm. of oil introduced.

Discharged 8th March, 1941, as 'much improved'.

Sputum became negative 4 months after the operation and remained so till the time of discharge.

Cultures of sputum done twice on 13th September, 1940, and 21st January, 1941, were negative.

Figure 7, plate XXXIII.--Note extensive involvement of the left lung with signs of breaking down middle zone.

Figure 8.--Extra-pleural pneumothorax left side. Practically complete collapse of the lung.

Figure 9.--Extra-pleural space partially filled with fluid and oil.

Case 4.--Female, aged 35 years, admitted on 16th October, 1940.

Artificial pneumothorax left side attempted on 25th October. No air could be given.

Extra-pleural pneumothorax done on 5th November. (Four inches of the 5th rib resected.)

Twelve extra-pleural pneumothorax refills were given.

Preliminary to discharge oleothorax started in the extra-pleural space. 210 c.cm. of oil introduced.

Discharged on 28th May, 1941, as 'much improved'.

Sputum was TB-positive at the time of the operation, but was negative one month after operation and remained so till the time of discharge.

TRANSILLUMINATION AND SIMULTANEOUS CAUTERIZATION OF PLEURAL ADHESIONS

By K. EISENSTAEDT, M.D.
and

A. U. RINDANI, M.B., B.S.
State Hospitals, Jamnagar

In endopleural pneumolysis (operation of Jacobaeus), the preceding pleuroscopic examination is of utmost importance. After the general inspection of the pleural cavity and its topographical conditions, the attention of the operator is drawn to the pleural adhesions proper. In order to determine the feasibility of cauterization, three factors should be examined very carefully, *viz.*, the position of the adhesions, their shape and as far as possible their anatomical structure.

Generally the operator succeeds rather easily to get the exact view of the position and the shape of the adhesions (dimension, direction and correlation with surrounding organs). There remains, however, the third factor to be investigated, *viz.*, the anatomical condition of the adhesions. This is as important as their position and shape, because of the danger of falling upon the vascular tissue or the penetrating parenchymatous tissue of the lung. There may be some adhesions, the internal structure of which may be guessed from their shape. Most of them, however, do not reveal their anatomical secret to our inspection, however careful it is.

During the last few years, progressive pleuroscopic technique has brought forward a valuable improvement, *i.e.*, the transillumination of adhesions. Various models of diaphanes have been recommended for this purpose by Bethune (1933), Graf, Heine (1930), and Maurer (1928, 1930). The general procedure is as follows: under the guidance of the pleuroscope, the diaphane is introduced through the second opening (destined for the cautery) and directed behind the adhesion which is to be dealt with. If the pleuroscope and the diaphane are brought into an optimal position on the opposite sides of the adhesion, we observe a more or less distinct transparency of the strand according to its thickness and extent. This transparency is also more or less modified by the presence of vessels or pulmonary tissue, the latter showing always some cicatricial densification at the proximity

(Continued from previous page)

Cultures of sputum taken on 22nd January and 6th May, 1941, were negative.

Figure 10.—Infiltration left upper and middle zone with a small cavity in the left clavicular region. (Not quite obvious in the print but clear in the film and confirmed by fluoroscopic examinations.)

Figure 11.—Extra-pleural pneumothorax on the left side with selective collapse.

of adhesions. In spite of the incontestable utility of such diaphanes they have, however, some inconveniences in their use.

(1) It is impossible to use a common plug for the electric lamp of the pleuroscope and for the diaphane because of the risk of electric shocks.

(2) It is impossible to introduce the pleuroscope, the cautery and the diaphane at the same time, even by making a third aperture, because the operator would be unable to handle simultaneously three instruments. Hence, the operator has to retain in his memory the fleeting impression of the transilluminated spot as soon as he replaces the diaphane by the cautery. If he wants to check the condition after cauterizing for some time, he is compelled to remove the cautery for reintroduction of the light, which means always a loss of valuable time particularly in cases with complicated orientation.

The first inconvenience mentioned might be easily overcome by using separate plugs for the cautery and the light.

The second inconvenience, however, should be obviated by finding a particular device attached either to the pleuroscope itself or to the cautery, as the use of a third instrument is impracticable. Rappe suggested a cautery with the connection of a lamp. This model is, however, hardly practicable for the following reasons. Firstly, it would be difficult to obtain the optimal illumination by the lamp and the optimal position of the cautery at the same time because of the fixed coupling. Any movement intended either for the lamp or for the cautery involves some displacement of the connected part. Moreover, it would be impossible to follow one of the most important rules in adhesion cutting, *i.e.*, never to lose sight of the point of the cautery during the very act of burning. The operator would be always troubled by the light which cannot be directed behind the adhesion unless the point of the cautery would disappear as well.

On the other hand, the following lines will show that the pleuroscope itself and its lamp are able under certain conditions to produce the diaphanous effect.

Before entering into any discussion about various pleuroscopic models we should like to stress some facts of optical conditions. If we want to obtain an optimal effect of transillumination, the light should fall upon the reverse side of the adhesion which lies in front of our view. It goes without saying that no pleuroscope can be contrived for this ideal purpose. The transillumination of the object may still be obtained, if the source of light is deviated from the opposite point of the visual axis, as far as the rays fall upon the visual field in a more or less obtuse angle. The limit of transillumination is reached, if the light and the view meet the object at the right angle. Naturally the force of transillumination decreases gradually the more the rays deviate from the

opposite point of view towards the right angle. Beyond the right-angular crossing of the rays and the visual field, no transillumination can be obtained because of the increasing direct illumination of the object. Consequently, in order to contrive a pleuroscope which can give the required transillumination, the adjustment of the visual field and the lamp should fulfil two conditions.

(1) The rays of the light should cross the visual field at an obtuse angle.

(2) The distance between the focus of the light and that of the optical lens should be sufficiently large to allow a suitable approach to the adhesion between them.

The question arises therefore whether any pleuroscopic model exists which could fulfil these conditions. We mention below some of the most common instruments having various angles of view with respect to the main axis.

- (a) View of 90° model of Jacobaeus-Unverricht.
- (b) " " 120° " " Maendl and Kornitzer (1927).
- (c) " " 135° " " Kalk (1929), Graf.
- (d) " " 150° " " Chandler (1930).
- (e) " " 155° " " Davidson (1929).
- (f) " " 180° " " Kremer.

The following illustrations demonstrate the above-described optical conditions, especially the rays of the lamp crossing the visual field of the optical system.

Figure 1 shows the adjustment of the model (a), i.e., Jacobaeus-Unverricht (view 90° , visual

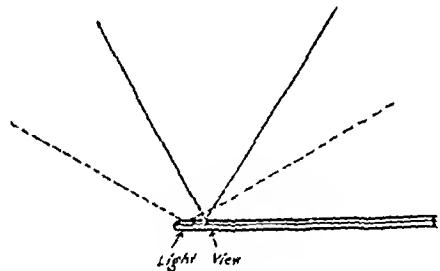

Fig. 1.

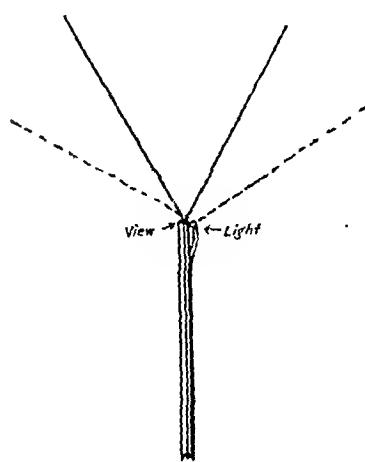

Fig. 2.

field 60° , luminous field about 120°). Out of all the rays which are crossing the visual field

only an extremely small portion forms an obtuse angle and hence the device is impracticable.

Figure 2 demonstrates the condition of the model (f) of Kremer (view 180° = axial view). The axis of the optical system goes parallel with the central ray of the light, and so no diaphanous effect can be obtained.

Figure 3 shows the condition of the model (c) of Kalk, the visual axis of which lies in the middle between the two extremes of (a) and

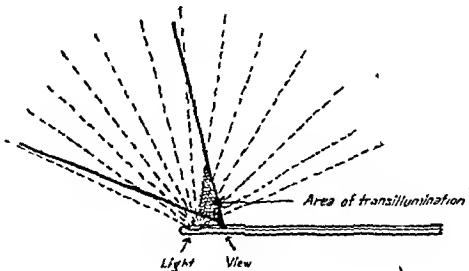

Fig. 3.

(f), i.e., an oblique view of 135° (visual field 58° , luminous field about 132°). Almost all rays are traversing the visual field, a certain part of them crossing in an obtuse angle, forming quite a large area in which transillumination of the diaphanous object results.

None of the other above-mentioned models with oblique view gives sufficiently similar adjustment of view and light compared with Kalk's pleuroscope.

Any operator who is experienced in pleuroscopy will realize at once the advantage of simultaneous diaphanoscopy of adhesions when using the model of Kalk (1935). By approaching the adhesion with the pleuroscope, as if going to touch it, a sudden transillumination results. The more the instrument is directed in a perpendicular sense towards the longitudinal axis of the adhesion the better will be the diaphanous effect. In such a way we are able to localize easily the thinnest part of the adhesion which becomes most transparent and hence suitable for cauterizing. In adhesions which appear like threads, bands, veils or membranes the diaphaneity appears mostly uniform along one to three centimetres. If, however, the adhesion presents a shape like a cone, hour-glass or falk, the translucent zone may become very narrow, up to a few millimetres, situated close to the thoracic wall. This narrow fibroid zone fit for cauterization is only detectable by transillumination. Hence, in cases which do not reveal any such transparency no cauterization in the ordinary way should be risked. In such conditions the intraparietal enucleation of the whole costal pedicle of the adhesion should be tried according to the particular technique recommended by Maurer (1928, 1939).

It is, however, surprising how many large, irregular and complicated adhesions can be dealt with in the ordinary way of cauterization by the help of transillumination. Although they may show a very narrow transparent

ledge, the severing may advance quite smoothly by cleaving small notches into this diaphanous part. Owing to the gradual relaxation of the strand new translucent ledges appear suitable for further cauterization.

In similar cases we observe sometimes an apparently paradoxical phenomenon, *viz.*, an increasing transparency of the tissue in spite of the increasing broadening of the adhesion while advancing with the cautery. We find at once the explanation, when we break finally through the most transparent spot and detect a cavitary pocket of the pleura caused by a circular parietal insertion of the adhesion. It would have been impossible by means of ordinary direct illumination to surmise that such an apparently thick and solid adhesion included only a thin-walled hole and was so easy to be cauterized. It goes without saying that the mistake of opening a pulmonary cavity should hardly happen at the hands of an experienced operator in cases similar to the aforesaid conditions.

Generally we choose the third, fourth or fifth intercostal space in the posterior axillary line for the introduction of the pleuroscope, at the second or third intercostal space in the mid-clavicular line, for the cautery. Both openings can be interchanged for either pleuroscope or cautery. In this way we gain not only the best view from either side, but also the greatest chance of meeting the adhesion with both instruments at the right angle for yielding the best conditions for diaphanoscopy and simultaneous cauterization.

The instrumental set (figure 4) comprises three principal parts, the trocar (1), the lamp-carrier (2), and the optical system (3).

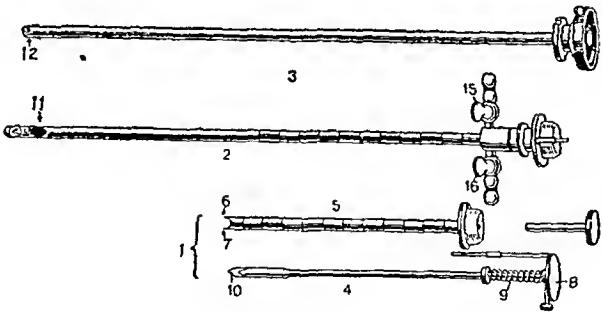

Fig. 4.

The perforator (4) of the trocar has a flat, two-edged lancet-shaped point (10) instead of the usual conical or triangular one. The perforator is held back inside the tube (5) by a spring (9). The point would only protrude by pressing upon the flat top of the perforator, a small disc (8) replacing the ordinary handle. By loosening the pressure the point would retreat automatically into the end (6 and 7) of the tube. This trocar has the great advantage of allowing quite a smooth perforation of the thoracic wall without using much effort. The recoiling point of the perforator lessens the risk of injuring the lung.

The lamp-carrier (2) has the shape of a tube intended for the introduction of the optical system (3), the lens (12) of which gives free visual field through the opening of the tube (11). The tube of the lamp-carrier serves moreover as an air-conductor (15 and 16) between the pleural cavity and the manometer of the pneumothorax apparatus. The intrathoracic pressure, therefore, is continuously checked and regulated during the operation without interruption as it happens most frequently in devices with combined cautery and air-conductor.

The advantages of the optical system with the oblique view of 135° consist mainly in its optimal adaptation to the topographic conditions of the pleural cavity. The optical picture corresponds to the axial view whatever movement is done (inclination or turning) and there is no phenomenon of reversing as we see in the optical system with a view at right angles. Most of the adhesions can be inspected at least from three sides and small adhesions would reveal their surface from all sides. Briefly we may say that this instrument (with the oblique view of 135°) gives in an ideal way the two-fold advantage of the axial view of Krcmer's instrument and the right-angular view of the instrument of Jacobaeus-Unverricht.

A further progress has been achieved by Graf in contriving the pleuroscope of Kalk into an instrument for combined use of optical system and cautery (figure 5). The threefold combination of Graf's model as endoscope, cautery

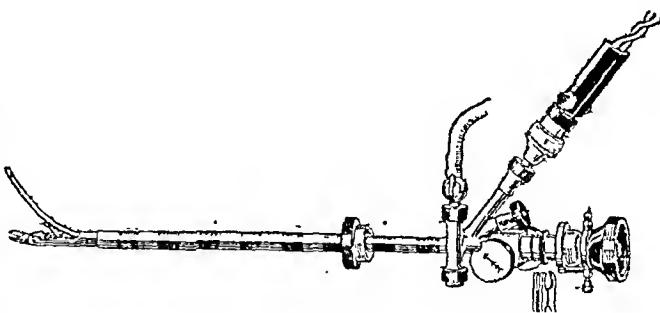

Fig. 5.

and diaphane can be considered as an ideal technical perfection in order to perform endopleural pneumolysis by way of only one incision.

Conclusion

Experience in more than 200 operations performed with the pleuroscopic models of Kalk and Graf proved the superiority of these instruments to any other model contrived for endopleural pneumolysis. Their main advantage is to allow transillumination of adhesions and simultaneous cauterization. The use of these instruments gives the operator a feeling of safe manipulation by simplifying complicated and doubtful conditions.

THORACOSCOPY AND PNEUMOLYSIS IN TUBERCULOSIS

By R. VISWANATHAN, B.A., M.D.,
M.R.C.P. (Lond.), T.D.B.

*Lecturer in Tuberculosis and Infectious Diseases,
Andhra Medical College, Vizagapatam*

ARTIFICIAL pneumothorax is, perhaps, the easiest and the most efficient method of collapse therapy in pulmonary tuberculosis. The efficacy of pneumothorax is in direct proportion to the degree to which the diseased portions of the lung can be collapsed. Adhesive pleurisy, depending on its extent, might either completely prevent induction of pneumothorax, or allow only a partial collapse of the lung. According to Alexander (1937), in about 20 per cent of all cases in which it was undertaken, induction of pneumothorax failed, while in 42 per cent the presence of adhesions produced only partial pneumothorax. Any supportive surgical procedure which can transform a partial pneumothorax into a complete one with minimum risk and complications and maximum efficiency must therefore take the highest place of importance in the surgical collapse-therapy programme. Intrapleural pneumolysis under thoracoscopic control is the method of choice.

Jacobaeus of Stockholm in 1913 originated the method of cauterizing adhesions in the pleural cavity through the help of a thoracoscope. By him, and by many others after him, has intrapleural pneumolysis been brought to a high level of effectiveness. The several reports published so far in medical literature testify to its importance and efficacy. Moore in 1934 reviewed the literature and summarized the published reports of 2,043 cases of intrapleural pneumolysis. Matson (1934) reports that among his 249 patients the operation was technically and clinically successful in 152 (61 per cent) patients and that all of these have negative sputum and 83 per cent are working. In 19 patients the operation was technically unsuccessful but clinically successful, all have negative sputum and 68 per cent are working. In 76 patients the operation was both clinically and technically unsuccessful. Jacobaeus (1915) had technical success in 80 per cent of 150

patients and clinical success in 60 per cent. Gravesen (1930) reports that technical success was obtained in 60 of 85 patients (clinically), 25 of the 60 patients were much improved, 29 were merely improved, two became worse and four died. Newton (1940) claims 87 per cent clinical success in 146 patients on whom pneumolysis was performed. In Benjamin's (1939) report on 186 patients, 121 cases are reviewed in detail. Only in 38 could all the adhesions be cauterized. Amongst them he obtained 76.2 per cent positive results. In the 83 patients in whom not all the adhesions were cauterized he reports 73.4 per cent positive results. In my series of 56 cases all adhesions were severed in 34 cases. Technical and clinical successes were obtained in 24 cases giving thereby 70 per cent positive results. Amongst 16 cases in whom not all adhesions were cut 62.4 per cent positive results were obtained. Six cases proved unsuitable for pneumolysis after thoracoscopic examination.

Indications for thoracoscopy.—Artificial pneumothorax is a necessary preliminary to thoracoscopy. Apart from its usefulness in cauterizing adhesions in the interpleural space, examination by thoracoscope will enable the diagnosis of other diseases and tumours affecting the pleura and the mediastinum.

Indications for pneumolysis.—Closed intrapleural pneumolysis is the operative procedure for making an incomplete pneumothorax complete by the severance of adhesions. The presence of adhesions is not always an indication for cutting them, for bands of adhesions may exist without preventing the necessary relaxation of the lung. Moreover, many adhesions get either naturally severed or get sufficiently stretched as to be innocuous in course of time. Hence ordinarily pneumolysis should not be attempted before three months after induction of pneumothorax. Even such an experienced thoracic surgeon as Alexander considers pneumolysis a difficult and potentially dangerous operation. It should not therefore be employed unless there is definite indication.

A cavity that has not been closed by a partial pneumothorax of sufficient duration constitutes the chief indication for the operation of pneumolysis. Peripheral cavities that hang as it were by adhesions should be freed by cauterization. The operation is indicated also in those non-cavernous lesions which are kept under tension by adhesion particularly in exudative types.

Excessive coughing, pain and haemoptysis when provoked by pneumothorax refills are occasional indications for pneumolysis.

Acute exudative serous pleurisy and empyema are contra-indications for pneumolysis in the acute stages. But in the later stages of effusion pneumolysis can be attempted after respiration. It should also not be performed in the presence of progressive obliterative pleuritis. No attempt

at internal pneumolysis should be made when the parietal and the visceral layers of the pleura are intimately adherent and without band formation or when a cone-shaped projection of lung tissue is found extending to the periphery inside the band of adhesion.

Except under exceptionally favourable circumstances cauterization should not be attempted on an adhesion which is less than two centimetres in length.

Preliminary study of adhesions.—Radiographic, fluoroscopic and tomographic examination of the adhesions ought to be done in order to understand their location, size, number, direction and extent. Very often many adhesions are missed in radiographs as they are not radio-opaque. The thickness and extent of the adhesions and the presence of lung tissue in them

of the pleura or in the posterior axillary line or near the angle of the rib. Out of the total number of 243 adhesions seen in all the 56 cases, 142 were in the upper posterior, 41 apical, 41 upper middle and 19 in the lower part of the pleural cavity.

Pre-operative preparation.—A refill is to be given the day previous to the operation and the patient is radiographed to localize the adhesion. The chest is prepared as if it is for major surgical procedure to ensure complete asepsis. A quarter grain of morphia and one hundredth grain of atropine is given an hour before the operation. As local anaesthesia is usually chosen, there is no need to starve the patient.

Technique

Choice of instruments.—There are two types of thoracoscopes: one giving direct vision and the other right-angle vision. Whereas the field of vision is limited with the first, practically the whole pleural cavity can be surveyed by the use of the latter by merely rotating the instrument. There are also the single-puncture as well as the double-puncture thoracoscope sets. In the former the thoracoscope and the cautery are introduced by the same cannula, while in the latter they are introduced through separate cannulae. Some prefer galvano-cautery, while others favour electro-coagulation and cutting by diathermy electrodes. Jacobaeus and Alexander prefer galvano-cautery while Matson and Newton extol the advantages of electro-surgery. I have had experience only of galvano-cautery. I consider that galvano-cautery at dull-red heat will produce sufficient coagulation of the adhesion before cutting through it, so much so that there is very little risk of haemorrhage, as suggested by the exponents of electro-surgery.

The thoracoscope is introduced through the selected intercostal space, preferably in the anterior axillary line. After a good survey of the pleural cavity and localization of the adhesions the cautery is introduced through the most convenient spot on the chest depending on the situation and direction of the adhesions. Long thin bands can easily be cut a little away from their attachment to the chest wall. The short thick ones have actually to be released from the chest wall by careful enucleation. This procedure will obviate possible injury to lung tissue which might have been pulled into the adhesion. Sometimes it may not be possible to cut through a broad thick adhesion which might contain lung tissue inside. In such a case a superficial cut may be made all round the adhesion and the remaining uncut portion may be allowed to stretch. It can be tackled at a future date.

Post-operative care.—Strict bed rest is ordered and the pulse and respiration noted every hour. Pain and cough ought to be controlled by aspirin and codeine. I usually give

Empyema	nil

cannot often be accurately judged by radiography. Under these circumstances they can be studied only by direct visualization by thoracoscopy.

Nature of adhesions.—More than one adhesion are always found. In my experience 54 is the largest number found in a single patient. Many adhesions are in the form of string-like bands. Sometimes they are like flat tapes. Some are very thick and fleshy. Occasionally fan-shaped adhesions are met with. In one case I had to cut such an adhesion extending from the anterior axillary line to the angle of the ribs behind. The vast majority of the adhesions are found over the upper lobe. Peripherally they are attached mostly to the cupola

2 c.cm. hæmoplastin as a routine before and after operation. Sulphonamide pills, two *t.d.s.*, also form part of the routine post-operative management. A refill is done the day after the operation.

Complications

Hæmorrhage is perhaps the most dangerous but fortunately is rendered rare by efficient operative technique. I had two cases which developed hæmorrhage, both to an alarming degree. In severe cases, thoracoscopy should be attempted again and the bleeding point cauterized. Open operation is rarely necessary.

Subcutaneous emphysema is a very common complication. In most cases it does no harm except some crackling discomfort to the patient. In three cases I found emphysema extending to the face, neck, chest, upper limb and abdomen. In one case owing to delay in refill the lung almost completely expanded and as the patient developed obliterative pleuritis pneumothorax had to be abandoned. In another case, the patient coughed out all the air from the pleural cavity into the cellular tissue causing extensive subcutaneous emphysema; and the result was that an *x-ray* after a subsequent refill showed more adhesions than he ever had before.

Spontaneous pneumothorax as a result of inadvertent cutting of lung tissue may occur as a complication.

Tuberculous empyema might develop in some cases after pneumolysis. Sepsis and consequent non-specific empyema are avoidable through correct aseptic precautions.

Some of the cases develop serous effusion soon after pneumolysis.

GAS REPLACEMENT IN PLEURAL EFFUSIONS

By R. VISWANATHAN, B.A., M.D.,

M.R.C.P. (Lond.), T.D.B.

Andhra Medical College, Vizagapatam

ASPIRATION of pleural effusions under certain conditions has been a long-recognized procedure in treatment, but it was left to Holmgreen to recommend simultaneous substitution of air with aspiration of effusions, particularly in tuberculous pleurisy.

INDICATIONS

(1) *Tuberculous pleurisy*.—The connection between the morbid conditions of the lung and pleura is so close that the interests of both are intimately connected. Collapse therapy has revolutionized our knowledge concerning diseases of the pleura and their treatment. The chief result of this new knowledge is the ability to make the effect of a pleurisy beneficial to the prognosis of the cases, by adopting a plan of treatment so as to support the healing factors connected with the pleurisy itself, and at the same time check the threatening factors involved in it.

Theoretically a primary idiopathic pleurisy is quite possible, but practically in all cases of pleurisy some signs of lung affection can be traced. Tuberculous pleurisy is in all probability due to a latent or unrecognized pulmonary lesion. Clinically it would be an extremely wise procedure from the patient's point of view to classify every pleurisy of doubtful aetiology as a case of pulmonary tuberculosis. The reason why this idea is not given wide credence by general practitioners may be that pleurisy from its very onset exerts a healing influence upon the original causal pulmonary lesion, bringing it to a temporary or permanent quiescence (Gravesen, 1925).

The pleural effusion keeps the lung in a state of collapse and hence has the beneficial effect of helping the lesion in the lung to heal. On the other hand, there are certain adverse effects due to effusion. The existence of pleurisy itself is an expression of allergy and activity of the disease. Moreover, the production of fluid may cause strain upon different organs, interfering with the metabolic and circulatory functions (Gravesen, *loc. cit.*). It might also cause respiratory and cardiac embarrassment. It is just to effect a *via media* so as to have the beneficial effects of collapse without the detrimental influences of effusion that gas replacement is advocated. This procedure has several advantages. Gas replacement enables all the fluid to be removed without any immediate change in size and position of the collapsed lung. Pleural effusion necessarily causes mediastinal displacement. In long-standing pleurisy, the body has become accustomed to a displaced mediastinum. Hence aspiration of fluid alone will naturally result in sudden expansion of the lung and replacement of the mediastinum back to its normal place

Fig. 1a.

Fig. 2a.

Fig. 2b.

Photographs through
the thoracoscope.

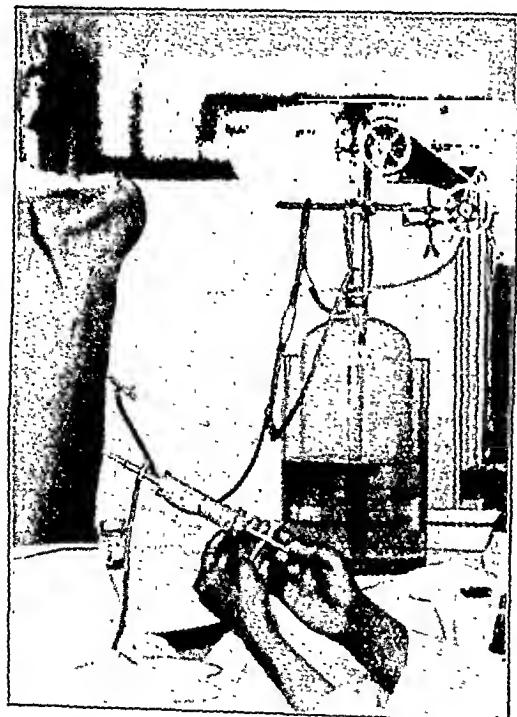

Fig. 3.

Fig. 4.

(which is for the moment abnormal under the altered circumstances). It may be accompanied by disastrous results. Gas replacement on the other hand is a much safer method and it can be done without any feeling of oppression on the part of the patient. Besides, as the lung remains collapsed there is no risk of its being injured by the needle while the effusion is being removed. Probably the greatest advantage of this method of aspiration is that it allows of examination of the underlying lung chiefly by radiography.

Gas replacement is the treatment of choice when pleural effusion occurs in the course of a manifest lung lesion, but is it indicated in serous pleurisy occurring as an initial manifestation of phthisis? Conservative treatment in such cases no doubt might bring about the desired result as a rule. Considering the practical impossibility of inducing pneumothorax at a

A new type of simple pneumothorax apparatus, with a bell jar suspended in water by counter-weights, allowing air to be sucked inside the pleural cavity while the fluid is being aspirated through one of the lower intercostal spaces.

later stage by necessity if the pleurisy is allowed to heal by conservative methods, I would suggest gas replacement in all cases of idiopathic pleural effusions suspected to be tuberculous. Moreover this is the only way by which one can make certain of the condition of the underlying lung. If the lung is found to be free from disease, it can be allowed to expand gradually. If on the other hand the lung is diseased, it can be kept collapsed by refills for the requisite period of time. Even in primary pleurisy no harm is done by replacing the effusion by air.

PNEUMO-PERITONEUM IN THE TREATMENT OF ADVANCED PULMONARY TUBERCULOSIS

By L. R. DONGREY, M.B., B.S., T.D.B. (Wales)

Medical Officer, King Edward Sanatorium, Dharampore, Simla Hills

In spite of many recent advances in the treatment of tuberculosis in the form of various surgical procedures advanced, bilateral pulmonary tuberculosis still remains a distressing therapeutic problem. Its treatment at present

(Continued from previous column)

(2) Even in pleurisy with effusion due to causes other than tuberculosis, gas replacement is to be done if aspiration is indicated, as this will enable removal of all the toxic material from the pleural cavity.

(3) Gas replacement can be done as a diagnostic measure in pleural effusion so as to enable thoracoscopic examination in cases of suspected tumours.

Technique.—Gas replacement is best undertaken by the use of two separate needles, one belonging to an aspirating set like the Potain's or Morton's aspirator and the other belonging to pneumothorax apparatus. They are introduced under local anaesthesia in different places in the chest-wall according to the circumstances of the case. I usually introduce the aspirating needle in one of the lower intercostal spaces in the posterior axillary line and the pneumothorax needle in the middle axillary line in one of the upper intercostal spaces above the upper level of the effusion. While the fluid is withdrawn a similar amount of air is simultaneously admitted. When the fluid has run down to the level of the cannula air will appear in the aspirating tube. At this stage the patient is tilted to the operated side and the cannula is so inclined that the remaining fluid can be aspirated from the lowest part of the pleural cavity. The cannula is then removed and the perforation sealed. The pneumothorax needle is removed after introducing sufficient air to produce the optimum intrapleural pressure.

I have used in some cases the same needle and cannula for alternate aspiration and gas insufflation.

Gas replacement has been done in 33 cases of pleural effusion in the tuberculosis department of the King George's Hospital, Vizagapatam. Six were primary tuberculous pleurisy, 14 were pleurisy with manifest lung lesions, nine in effusions developed during the course of artificial pneumothorax therapy, and four for diagnostic purposes.

is only conservative with generally disappointing results. The brilliant achievements of collapse therapy in a few suitable cases naturally makes one feel that if the procedure could be extended with any benefit to these far-advanced cases, perhaps the prognosis might improve.

It is well known that many tuberculous women during the latter period of pregnancy show marked clinical improvement; sometimes the disease appears almost quiescent, only to flare up after delivery. The hormonal changes during pregnancy may be partly responsible for this, but the mechanical effect of the rise of the diaphragm due to the enlargement of the uterus during pregnancy, resulting in the relaxation and partial rest of both the lungs, is now recognized as an equally, if not a more, important factor in bringing about this clinical improvement. Similarly, during recent years, while treating intestinal tuberculosis with pneumo-peritoneum, simultaneous improvement in the co-existing pulmonary lesions was often noticed, and this is also equally explained as mainly due to the same mechanical effect, although the improvement in nutrition and general health brought about by pneumo-peritoneum in these cases is not a negligible contributory factor.

Until lately no advantage was taken of these observations. The idea of using pneumo-peritoneum in the treatment of pulmonary tuberculosis first occurred to Banyai (1934) who employed the procedure in a few cases and reported favourable results. Since then other workers have also corroborated his observations.

The treatment has a scientific basis. Pneumo-peritoneum by raising the diaphragm diminishes the apico-basal diameter of the lung and thus reduces its volume, except in a few cases where extensive costo-phrenic adhesions prevent the rise of the diaphragm. This effect compares very favourably with that obtained after a successful phrenic nerve paralysis. In some of our cases under pneumo-peritoneum the diaphragm was seen to rise as high as the third rib anteriorly. Secondly, it has also been shown that a sustained rise of the diaphragm limits the amplitude of its respiratory excursions, and the higher it rises the lesser are its movements. We have been able to corroborate the observation that at times in quiet breathing the diaphragm is seen to be almost stationary. The raised position of the diaphragm in comparative immobility obviously diminishes and at times almost abolishes the vertical movements of the lungs and thus gives them partial rest. The two main objects of collapse therapy—diminution in volume and limitation of movements—are thus met with by pneumo-peritoneum, and this mechanical effect secondarily results in passive hyperæmia and lymph stasis which are considered important contributory factors in the healing of tuberculous lesions.

During the past 2 years we have employed this method of treatment in 49 cases of pul-

monary tuberculosis. Only those were selected in whom, for some reason or the other, collapse therapy was either not feasible or was ineffective, and who were considered unlikely to improve on conservative treatment alone. Thus our indications for the treatment were : (1) bilateral extensive pulmonary tuberculosis unsuitable for collapse therapy; (2) bilateral pulmonary tuberculosis cases in which the patients were too ill for any form of collapse measure; (3) pulmonary tuberculosis with marked intestinal disturbance where collapse therapy was considered inadvisable, for the time being; (4) pulmonary haemorrhage which could not be controlled with artificial pneumothorax; and (5) insufficient result of collapse therapy.

Of the 49 cases given this treatment, eleven received it for a too brief period (less than one month) to derive any appreciable benefit from it. From the clinical study of the remaining 38 cases we have gathered an impression that pneumo-peritoneum is a valuable method of treatment in certain types of pulmonary tuberculosis. It brings about marked clinical improvement in a few cases while giving symptomatic relief to many. Its first and early beneficial effect is the relief from troublesome cough and expectoration, and this was experienced by many of our patients under this treatment. During the earlier phases of the treatment the sputum is increased, as one would expect, but the patient is able to raise it easily, and this is a great relief to him. This facilitates effective drainage of pulmonary cavities and bronchial tubes, and as a necessary consequence of this the period during which cough and expectoration manifest themselves becomes short, allowing longer intervals of freedom from this troublesome symptom and consequently giving more rest to the lungs. In course of time, the amount of sputum is gradually diminished and so is the cough. The effect on temperature, however, is not so immediate. Although we were gratified to see early abatement of fever in a few cases, almost simultaneously with the decrease of cough and expectoration, it generally took some weeks before the fever showed any tendency to subside.

Digestive disturbances, particularly abdominal pain, are relieved by pneumo-peritoneum, resulting in better assimilation of food with improvement in nutrition and general health. In two of our cases only one refill completely removed the abdominal pain. In two others improvement in appetite and digestion with steady gain in weight occurred only after pneumo-peritoneum was induced. This obviously has a beneficial influence on pulmonary lesions as well.

In two cases haemoptysis was controlled with pneumo-peritoneum. In one, artificial pneumothorax could not be induced on account of extensive adhesions, and as the patient continued to bleed profusely pneumo-peritoneum was given on two consecutive days with the arrest of

bleeding. After a week, a phrenic crush was performed and pneumo-peritoneum is being continued. In another case artificial pneumothorax was unsuccessful in controlling the bleeding because of inadequate collapse due to multiple adhesions, and although the haemoptysis did not stop completely it was brought fairly under control after artificial pneumothorax was supplemented with pneumo-peritoneum. There was no profuse haemoptysis after that, although clots and tinged sputum continued for a week or ten days. We fully realize that pulmonary haemorrhage is a queer phenomenon. Frequently it stops automatically without anything being done for it, and often it persists no matter what we do to stop it, short of complete collapse with artificial pneumothorax. However, we have reason to suppose that in these two cases pneumo-peritoneum was directly responsible for the control of haemoptysis which, we think, would have otherwise continued.

In addition to this symptomatic relief we found improvement in some cases radiologically as well: general clearing of the pathological shadows, diminution in the size of cavities, in some cases, and in a few their complete obliteration. We have seen that exudative lesions are benefited earlier than those with established fibrosis. The allergic manifestations in the lung clear up earlier under pneumo-peritoneum than they do under bed-rest regimen alone. In bilateral cases with gross extensive anatomical changes in one lung requiring early induction of artificial pneumothorax, which, however, is contra-indicated on account of contra-lateral disease, we found that in some cases the latter cleared up under pneumo-peritoneum within a period of 3 to 6 months, depending upon the extent of the disease, thus permitting the application of appropriate collapse measures on the more diseased side. We found this in 5 cases.

Theoretically, many indications suggest themselves for pneumo-peritoneum, but we have had no occasion to try it in any of them. So far we have used this procedure only in advanced bilateral cases either too ill or too extensive for any collapse measure. However, in addition to the case mentioned above in whom artificial pneumothorax was combined with pneumo-peritoneum to control the haemoptysis, we have used this procedure in another case in combination with phrenic nerve paralysis to enhance the mechanical effect with satisfactory result. In another two cases a similar procedure is under contemplation. There are cases in which the rise of the diaphragm is insufficient after phrenic nerve interruption, and we have particularly noticed this after a temporary paralysis. The diaphragm can be raised higher by the addition of subphrenic pressure with pneumo-peritoneum. It is claimed that the amount of elevation of the diaphragm obtained by the combined effect of pneumo-peritoneum and phrenic paralysis is almost double that obtained by phrenic paralysis alone (Trimble and Wardrip, 1937).

The test of the efficacy of any method of treatment in pulmonary tuberculosis is said to be, and rightly so, its ability to change a positive sputum into a negative one. When judged from this standard our results are not encouraging, because so far only 3 cases out of 38 lost bacilli in their sputum, 2 in the sanatorium and the third was reported negative soon after his discharge. But in view of the far-advanced cases that were given this treatment, many of whom were too far gone for any line of action, this failure is not surprising. Moreover, important though this test is in judging the ultimate value of any method of treatment, it would be wrong to evaluate every method by this standard alone. A treatment which gives symptomatic relief to many, improves the general condition of the patient, and although it may not finally arrest the disease, it at least prepares the patient for a more effective line of attack, which was not feasible before, is not a mean factor in the therapeutics, even if it fails to satisfy the acid test. Pneumo-peritoneum has been seen to meet these requirements in a certain proportion of cases and, therefore, we feel that it has a therapeutic value in the treatment of some cases of pulmonary tuberculosis.

The technique of pneumo-peritoneum is similar to that of artificial pneumothorax. The site of puncture is about 2 inches below and lateral to the umbilicus on either side or an inch below the costal arch near the lateral border of the rectus muscle, preferably on the right side. For the initial induction and a few subsequent refills, the head-end of the bed is slightly raised. This helps the air to collect under the diaphragm and be recognized by the obliteration of liver dullness, which is an important indication of a successful pneumo-peritoneum.

After the preliminary anaesthesia the artificial pneumothorax needle, connected with the apparatus, is inserted, and while it is still in the abdominal wall the pressure bottle is raised and by momentarily connecting the air chamber with the manometer a positive pressure of about 20 mm. is registered on it. The intra-abdominal pressure in the lower abdomen is either neutral or slightly positive and, therefore, as soon as the needle enters the peritoneal cavity there is a sudden fall in pressure, as shown by the manometer, either to zero or to about plus 2 to plus 4 or slightly higher, depending upon the intra-abdominal condition. This is an important indication of the needle entering the peritoneal cavity (Dr. F. S. Master) and must always be looked for to avoid the complication of extensive surgical emphysema. It is important to remember that the fall must be rapid. Sometimes it is gradual which indicates that either the connections are not airtight or the needle is blocked and requires stiletting.

The initial 'fill' should not be more than 200 c.cm. which we consider the safe limit.

Some of our patients had most distressing pain over the shoulders and round the lower part of the chest even with 200 c.cm. at induction. This amount is gradually worked up by giving refills twice a week in the beginning and then weekly refills of 600 to 800 c.cm. depending upon the individual case. The *sine qua non* of successful pneumo-peritoneum treatment is to raise the diaphragm to its optimum level with the minimum respiratory movements, and then to maintain it at that throughout the course of the treatment by properly regulating the refills. This is a point the importance of which cannot be over-stressed. The amount of refill and the interval which will attain this object vary in individual cases, as these depend upon factors such as laxity of the abdominal wall, size of the abdominal cavity, presence or absence of costo-phrenic adhesions, sensitiveness of the patient, etc. It must, therefore, be determined by frequent fluoroscopic examinations. As a general rule an interval of more than a week is not advisable.

Beyond indicating the presence of the needle in the peritoneal cavity the manometer is not a helpful guide in this treatment. Frequent fluoroscopic checks, clinical observation, and the patient's sensations are more reliable indications than the manometer readings. When, however, the manometer shows a rise in pressure as the air enters, it is advisable not to exceed it beyond plus 12 or plus 15, preferably stopping at plus 10, as higher pressures are not well tolerated by many; they lose appetite and the digestion is impaired. A few cases show these symptoms of intolerance when the refill is larger than a certain amount even if the pressures are not increased.

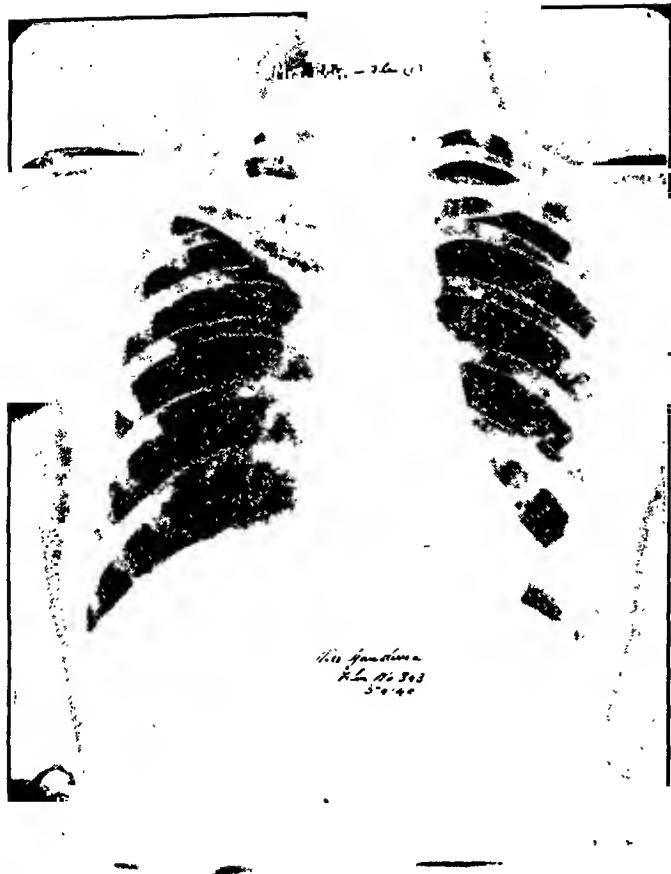

The action of pneumo-peritoneum is primarily mechanical and depends upon the rise of the diaphragm; the higher the rise the greater is the effect. In cases with costo-phrenic adhesions the respiratory excursions of the diaphragm are restricted, and consequently its rise after pneumo-peritoneum is also less with a proportionately limited therapeutic effect. With strong and extensive adhesions, the diaphragm is almost stationary and there is no rise. In such cases pneumo-peritoneum is not likely to be of any benefit. A preliminary fluoroscopic examination is, therefore, very necessary to determine previously the range of movements of the diaphragm and the suitability or otherwise of the case for pneumo-peritoneum. Moreover, the rise of the diaphragm must be even to have the full mechanical effect. In not a few cases we have seen that the anterior part of the dome rises fairly high while the posterior portion is almost fixed below. This is evidenced by the fact that the lung markings are clearly seen in the air space created by pneumo-peritoneum below the diaphragm. This uneven rise of the diaphragm can also be visualized by lateral screening. In such cases the rise is only partial and consequently the pulmonary relaxation is

not uniform. The therapeutic effect, therefore, is also proportionately less. Those of our patients who had a high rise of the diaphragm with the clear air space below it benefited the most, both clinically and radiologically. Others derived benefit proportionately less, while those in whom there was no rise of the diaphragm did not have any benefit at all.

Here it must be emphasized that a mere pad of air below the diaphragm does not always mean that it has risen. In cases with a rigid diaphragm the air space is created entirely by the downward displacement of the liver and the stomach. Similarly, in cases with movable diaphragm, the distance to which it has risen is not given by the height of the air space below it, because here too the space is partly made up by simultaneous downward displacement of the subjacent viscera. The rise of the diaphragm is measured either by its relation to the ribs before and after the refill or by the difference between the perpendicular distances measured from the clavicle to the highest point on the curvature of the diaphragm before and after the treatment.

In the treatment of pulmonary tuberculosis with pneumo-peritoneum, refills have to be large in amount and more frequent to ensure a sustained rise of the diaphragm at its optimum level. As a consequence of this there is sometimes a marked displacement of intra-abdominal organs and the digestive functions are interfered with. In such cases the feeds should be smaller and more frequent to ensure proper assimilation and nutrition.

Pneumo-peritoneum is said to be a safe procedure, and we also found it so. However, we met with three cases of what we consider to be peritoneal shock. In two it was of a milder type and occurred at a refill, while in one it was of a more serious nature. There was no trouble during the preliminary anaesthesia, even when the needle pierced the peritoneum, but, in two cases, when the other needle was inserted and hardly 50 c.em. of air had flowed in, the patient suddenly fainted with perspiration on the forehead, hands and feet and some gurgling in the abdomen, while the third patient suddenly became unconscious and pale, eye-balls rolled, the breathing slowed down and so also the pulse rate. The needle was at once removed, injection of strychnine and digitalin was given and the patients came round in a couple of minutes. Perforation of the gut is the most dreaded accident with pneumo-peritoneum, but this is considered unlikely. 'If the needle is slowly forced inwards (slightly oblique), the omentum and the intestines being soft, pliable, and movable, are pushed in front of the needle but are not punctured' (Banyai, 1937), unless a portion of the gut is adherent to the abdominal wall at the site of puncture. Still markedly tympanitic areas should be avoided. Except subcutaneous emphysema in a few cases—in one case from

Mrs. P. P. G. Fig. 1.—Bilateral disease with a cavity at the right apex and active infiltration at the left base. Sputum over two ounces in 24 hours, positive to tubercle bacilli.

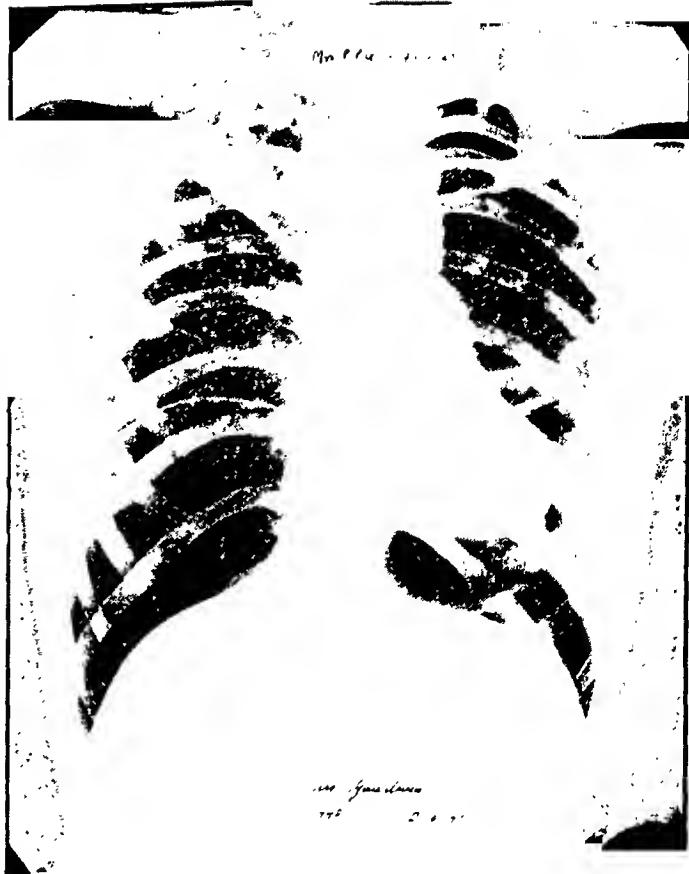

Fig. 1a.—After one month's treatment with pneumoperitoneum diaphragm raised to the 3rd interspace on the right side and 4th interspace on the left. The right interlobar septum is proportionately pushed up and the size of the cavity diminished.

Fig. 1b.—Taken two months later. The right dome is raised to the level of the 3rd rib and the left to the 4th rib anteriorly. The right interlobar septum is further pushed up above the clavicle and the cavity practically closed up; proportionate improvement on the left side. Sputum less than a drachm in 24 hours, only occasionally positive to tubercle bacilli, very few bacilli being detected.

Mr. M. K. Fig. 2.—Extensive bilateral disease with multiple cavitations. Sputum over two ounces in 24 hours, strongly positive to tubercle bacilli. Marked intestinal disturbances.

Fig. 2a.—After 12 months' treatment with pneumoperitoneum diaphragm pushed up along with the liver by a little less than one interspace; considerable clearing of diseased areas on both sides with diminution in size and number of cavities; very little sputum, positive to tubercle bacilli. Marked improvement in intestinal condition.

Mr. T. D. R. Fig. 3.—Bilateral disease with cavitation persisting after 17 months of conservative treatment. Sputum over two ounces in 24 hours, strongly positive to tubercle bacilli. Marked intestinal trouble with no tendency to increase in weight.

Fig. 3a.—After 20 months' treatment with pneumoperitoneum, marked clearing on both sides with closure of cavities; both the domes of the diaphragm raised by one interspace; sputum about one drachm in 24 hours, positive to tubercle bacilli. Marked amelioration in intestinal condition with steady increase in weight.

the neck to the scrotum—and a large haematoma in three cases we met with no serious complication.

Criticism.—The action of pneumo-peritoneum being similar to that of phrenic nerve paralysis, it may be argued that the procedure is useful only in middle or lower lobe affections and that it has no effect on the upper lobe lesions; and as pulmonary tuberculosis is generally a disease of the upper lobe, it is of no value in a large majority of cases. But this argument is not sound. Generalizations are never good in tuberculosis. Although, other things being equal, middle and lower lobe affections are more benefited by pneumo-peritoneum, as well as by phrenic interruption, than the upper lobe lesions, the location of the disease is not the only determining factor. The character of the lesion is an equally, if not more, important consideration than merely its situation in the lung field. Dense fibrotic areas, thick-walled cavities, also adherent cavities are not influenced by pneumo-peritoneum, or by phrenic interruption—as a matter of fact such lesions are definitely unsuitable for these measures—even when situated in the lower lobe and a satisfactory rise of the diaphragm has been obtained. On the other hand, early and thin-walled cavities surrounded by healthy tissue and cavities surrounded by an exudative area (not fibrotic) are materially benefited by these procedures, even if situated high up in the upper lobe. Davies (1933) has clearly observed while discussing the value of phrenic paralysis that unless the adhesions prevent it, the mechanical effect of the rise of the diaphragm is evenly distributed throughout the whole lung and the pulmonary relaxation is most marked where the diseased area is already showing strong tendencies to contract, thus giving selective relaxation with selective therapeutic effect. These observations are amply supported by the obliterations of apical cavities in suitable cases by phrenectomy. In two cases of the present series apical cavities closed under pneumo-peritoneum. In one of them there were bilateral apical cavities which resisted conservative treatment for over one and a half years.

The argument that pneumo-peritoneum does not give complete rest to the lungs does not lessen its value when we remember that in a low-tension artificial pneumothorax, which is much in favour to-day, the movements of the lungs are not completely abolished, neither in many cases of bilateral pneumothorax where of necessity the collapse has to be of low tension.

It might be argued that the results of pneumo-peritoneum, at least what we got in our present series, might have as well been obtained only on bed-rest regimen. Possibly so, but looking to the clinical condition of many of our cases in this series our impression is that this was unlikely. Moreover, many of our cases were given a reasonable trial on bed rest before putting them under pneumo-peritoneum. One case of bilateral apical cavities resisting conservative

treatment for 18 months, but closing under pneumo-peritoneum, has already been mentioned above, and a few other cases can also be cited whose improvement can be definitely attributed to pneumo-peritoneum. Besides this it cannot be gainsaid that pneumo-peritoneum gives additional rest to the lungs and thus enhances the effectiveness of conservative treatment, and is therefore bound to be of some help. It may materially shorten the period of bed-rest regimen, besides making it comfortable owing to symptomatic relief. Above all, the procedure has a beneficial psychological effect in that the patient who is too far gone for any treatment beyond bed rest feels that he is being actively treated, his troublesome symptoms are ameliorated, his nutrition and general health improved, and thus he is brought back from a state of despondency and despair into a more hopeful mental attitude which is a great asset in the recovery from tuberculosis. The treatment, therefore, has a great palliative and curative value.

Plates XXXV and XXXVI illustrate the progress in three cases.

Conclusions

(1) Pneumo-peritoneum is a valuable measure of treatment in some cases of advanced bilateral pulmonary tuberculosis either too ill or too extensive for any measure of collapse therapy.

(2) It is also useful as a temporary measure to prepare the patient for a more effective line of treatment as much as artificial pneumothorax is sometimes used to improve the contra-lateral disease with a view to doing thoracoplasty subsequently on the more diseased side.

(3) It is a valuable adjunct to phrenic nerve interruption where the rise of the diaphragm is insufficient, also in certain cases of artificial pneumothorax.

(4) Its early beneficial effect is to give relief to the troublesome cough and make expectoration almost effortless, thus establishing an effective drainage of pulmonary cavities and bronchial tubes.

(5) By giving rest to the lungs it reduces toxæmia.

(6) In two cases it was able to control haemoptysis.

(7) Exudate lesions are benefited earlier and better than those with established fibrosis.

(8) Fibrotic lesions, thick-walled cavities, and adherent cavities are not influenced by pneumo-peritoneum and such cases are unsuitable for this treatment.

(9) The *sine qua non* of successful pneumo-peritoneum treatment is to raise the diaphragm to its optimum level and to maintain it at that throughout the treatment.

(10) The improvement is proportional to the rise of the diaphragm. Hence cases with strong costo-phrenic adhesions rendering the diaphragm rigid and fixed are not suitable for this treatment.

THE FORMATION, EVOLUTION, AND HEALING OF TUBERCULOUS CAVITIES IN THE LUNGS

By T. J. JOSEPH, B.A., M.B., B.S. (Mad.), F.M.R. (Rome)
Medical Superintendent, The Lady Linlithgow
Sanatorium, Kasauli

CAVITIES in the lungs were known to the Hippocratic school of medicine. However it was not until the 17th and 18th centuries that these cavities became associated with tuberculosis. It has been possible to detect large-sized cavities in the lungs by means of physical examination for a long time, but it was not until after the advent of x-rays that the nature of pulmonary cavities was studied at first hand. It is radiology coupled with systematic post-mortem examinations, and lately cavernoscopy that revealed the mode and site of formation, evolution, behaviour and mode of healing of cavities.

In this article an attempt is made to review present-day knowledge regarding pulmonary cavities.

I. Formation

When tubercle bacilli enter into a suitable host, they produce exudative and proliferative changes, the extent and intensity of which depend upon the resistance of the host and the structure of the tissues, and upon the number and virulence of the bacilli. These changes culminate in the absorption of the products of exudation and proliferation or in their necrosis and caseation.

When the resistance against infection is high, the caseated tissue may become inspissated, encapsulated, fibrosed, calcified and ossified, in that order. But where the resistance is low, softening and liquefaction of the cheesy material takes place. The softening is due to an absorption of water causing a swelling of the necrotic cellular debris (Goldberg, 1941). Liquefaction is the result of an immigration of polymorphonuclear leucocytes. These leucocytes break down and liberate proteolytic enzymes which digest the caseous material. Early suppurative liquefaction stops at the border of the caseation, and a wall of non-specific granulation tissue is built around before the liquefaction reaches the border.

Walls of cavities

The walls of the cavities are formed in layers often visible to the naked eye. The inner lining usually consists of necrotic tissue, degenerating leucocytes and fibrin. In this layer, tubercle

bacilli proliferate luxuriously and often form dense clumps. The lentil-shaped bodies in the sputum of patients with cavities, which are eagerly sought for by pathologists, because they are so rich in bacilli, are pieces of this necrotic membrane. The inner lining rests on a deeper layer usually consisting of a firmer purple-grey tissue which in turn rests on the outer coat of granulation tissue with numerous small round cells. Where the cavity-wall merges with surrounding lung tissue discrete tubercles containing giant cells are found.

The walls of newly-formed cavities are irregular and jagged, and appear to vary in their thickness when seen in serial x-ray examination, within short periods of time. The walls of old-standing cavities are firmer and more uniform and do not vary so frequently. It is a common observation under the x-rays that a jagged, irregular, and indistinct wall of a cavity, when partially collapsed by pneumothorax appear thicker, smoother, and more regular.

A characteristic of older tuberculous cavities seen on the post-mortem table is the presence of ridges protruding from the inside of the walls and trabeculae crossing the lumen of the cavities and fusing with the opposite walls. These ridges and bridges consist of firm fleshy tissue and are derived from the larger blood vessels which resist liquefaction. While the veins are occluded by thrombi, the arteries are obliterated by proliferative endarteritis. In spite of this productive obliterating process, sometimes an aneurism develops from an artery in a tuberculous cavity, which may rupture and cause a severe haemoptysis.

The content of cavities

The content of cavities is pus formed as a result of the liquefaction of caseous material. Pieces of caseous material may be found floating in the pus. It is this pus which when spat into water floats and takes a circular shape and is described as 'nummular sputum'. The pus may be thick and creamy, or thin and watery. It may be yellow, greenish or blood-tinted owing to small haemorrhages from the limiting membranes. Erosion of an artery or small aneurism causes the cavity to become filled with blood clots which may arrange themselves in concentric layers.

Much controversy has raged with regard to the frequency of mixed infections in tuberculous cavities. Pus taken from tuberculous cavities usually contains no organisms but tubercle bacilli. Even the ordinary pus-forming organisms are not as frequently found as might be expected. Anaerobes are found in only about 12 per cent of large cavities in the living. However, it is a remarkable fact that anaerobes such as the bacillus of Welch are said to be found in almost 100 per cent of giant cavities in the cadaver.

When most of the liquid content of a cavity has been coughed out, the cavity appears as a

hole in the lung filled with air. Under the x-ray screen a small quantity of residual pus is often seen shaking at the bottom of cavities and is of diagnostic value.

The air in the cavity is ordinarily at atmospheric pressure. Sometimes it may show higher pressure and sometimes lower. Pressures as low as -56 mm. of mercury are reported to have been found in large cavities.

Ordinarily the composition of the air in cavities is practically the same as that of outside air, but sometimes it is found richer in CO₂ and poorer in O₂ than outside air.

The draining bronchi

In the process of caseation and liquefaction the very small bronchi are destroyed while the larger ones become the outlet for accumulating pus.

Draining bronchi may be single or multiple, large or small. It has been found that 98 per cent of large cavities have only one bronchus that functions effectively as drainage.

When the draining bronchus is single and large enough to be seen in the x-rays and the attachment is straight the cavity has been described as a tennis-racket-cavity or a stem-cavity. When the attachment is at a tangent, the opening tends to be valvular and has been called saxophone opening. During inspiration air enters freely through such openings into the cavities, but during expiration or coughing pus and air do not escape freely.

Post-mortem examinations and cavernoscopy have shown that the opening of a cavity may be situated at the top or bottom or side of a cavity and that it may be placed at the bottom of a funnel soaked in pus or at the apex of a fleshy cone which projects into the cavity.

The bronchial opening may be widely open or small and narrow. It may be temporarily or permanently blocked. It may be intermittent, i.e., opening and closing at intervals, or it may be valvular, i.e., admitting passage in one direction only. Ninety per cent of cavities have however open drainage. It is estimated that 73 per cent of temporary blocks are due to mucus plugs (Coryllos and Ornstein, 1938), the remaining being due to congestion and oedema of the bronchial lining wall. Permanent blocks are usually due to fibrosis or kinking of the bronchi.

II. Evolution and behaviour

Formerly it was thought that phthisis was essentially a chronic disease requiring long periods of time to develop. The fact that cavities can form in the lungs in periods as short as one or two weeks (Zorini, 1934) was practically unknown in the pre-x-ray days.

Productive as well as exudative lesions in the lungs may lead to cavity formation. However, the exudative lesions are of greater significance and most of the larger and more rapidly-forming cavities can be traced to them.

As a rule cavities grow in a caudal direction, probably because in the erect position the pus

is in contact with the bottom of the cavity. Extension of a cavity from one lobe into an adjacent one is rare, and takes place only at a late stage of the disease when the originally-affected lobe is almost completely involved.

The shape and size of the cavities vary very much depending on the mode of formation and the subsequent changes in the surrounding tissues. Cavities may be only just large enough to be visible in the x-rays or they may involve one whole lobe or even more. The shape may be spherical, ovoid, lobulated or very irregular with pouches and fistulous tracts running in different directions.

For some reason or another the most favoured sites for the formation of cavities are the peripheral, lateral and dorsal regions of the lungs. The apex of the lower lobe is more prone to be affected than the base of the upper lobe.

Modern observations with the help of physical examinations, fluoroscopy, serial radiography, tomography, thoracoscopy, cavernoscopy, pressure recording manometers and post-mortem examinations, show that pulmonary cavities behave in a manner which is difficult to explain. For example the following phenomena may be mentioned:—

Silent cavities.—A lung over which hardly any of the classical physical signs of excavation, such as râles, cavernous or amphoric breathing, etc., are present may reveal a large cavity when radiographed. All the signs of cavity may be evident over the same lung at another time.

Vanishing cavities.—A cavity which is clearly revealed in the x-rays may have vanished without leaving almost any trace two weeks later. This may happen to cavities larger than the size of a rupee and with a level of sputum standing and shaking in them.

Accordion cavities.—This name is given (Coryllos, 1933) to cavities which under serial x-ray examinations appear to enlarge and contract periodically. Usually when the cavities appear large, they are empty, but their walls look thick; while in the contracting stage they may contain a layer of pus and their walls appear thinner.

Balloon or tension cavities.—Occasionally a cavity is found to enlarge rapidly without any radiographic signs suggesting extension of the lesions or sloughing of the lung parenchyma around. In such cases the manometer usually records an air pressure higher than atmospheric pressure in the cavity.

Migrating cavities.—Cavities situated in one particular interspace may be found to have become smaller and moved to a higher space after a phrenic interruption operation on that side. Also, a cavity which is situated in the outer half of a lung may sometimes be found to move behind the mediastinum without collapsing completely under artificial pneumothorax (A-P). Apart from these movements which are

easy to understand, there are cavities which appear to move without any evident reason. For example a cavity situated just below the clavicle in a radiogram may appear to have moved above the clavicle in a subsequent radiogram taken under the same conditions and technique as the first one.

Hanging cavities.—It is often observed in A-P cases that even when one whole side of a cavity is adherent to the chest wall the cavity gets collapsed and heals, and tubercle bacilli disappear from the sputum rapidly, whereas other cavities which are held up by only a thin string adhesion refuse to collapse or heal, although they may be surrounded by air under pressure. It is also observed by surgeons who do closed internal pneumolysis that the results of these operations with regard to cavity closure vary considerably according to the nature and site of the adhesions (see plate XXXVII, figures 3, 4 and 5). In some cases the cavities close easily after the severing of the adhesions, while in others they do not, even when all adhesions are cut.

Possible explanations of some of these phenomena will be mentioned in the discussion that follows.

Healing of cavities

Since the advent of collapse therapy, it is admitted on all hands that even large cavities can and do heal provided that a complete collapse is obtained and maintained for a sufficiently long time. It is also generally admitted that cavities of 2 to 3 cubic centimetres or less may heal spontaneously and leave hardly any trace. However, there has been much controversy between clinicians and morbid anatomists as to whether cavities of larger diameters fill up or get obliterated and heal (de Marchi, 1938). Clinicians claim (see figures 1 and 2) that in the large number of instances where cavities heal, the morbid anatomists do not get a chance to look at the lungs on the post-mortem table; while the morbid anatomists claim that in the so-called healed cases, residual cavities remain but are not detected by physical examination or radiology, and that these cavities tend to enlarge again after the period of treatment by bed rest, etc.

In 1928 the fate of 1,454 patients in whom tuberculous cavities had been diagnosed were followed (Barnes and Barnes, 1928). Eighty per cent of these patients died within one year and 95 per cent within 15 years. The great progress in roentgenological diagnosis of incipient cavities and in the surgical treatment of pulmonary cavities will however make the future statistics much more favourable.

Textbooks describe a condition called 'open healing'. It is said that the cavity heals in spite of its remaining open. 'The pyogenic membrane gradually disappears and the internal lining of the cavity becomes smooth and shiny. In places transitional or squamous epithelium derived from the bronchi may cover the free

surface. The sputum is free of tubercle bacilli and there is no immediate danger of progression or aspiration'. Now it is admitted that a patient can have an open cavity and yet be free from practically all symptoms of disease. The author of this article must, however, confess that during a decade of close and continuous study of tuberculous cases, he has not met with even one case which originally had tubercle bacilli in the sputum becoming bacillus-free for any length of time while the cavity remained open as seen in the x-rays.

Discussion and Conclusion

During recent times the study of the draining bronchi of cavities and their openings into cavities have assumed great importance. These studies have not only produced clues to the explanation of the behaviour of cavities but also placed the therapeutic value of bed rest and 'open air' in cavity cases on a more rational basis, and have shed fresh light on the mechanism of action of collapse therapy.

The production of cavernous breath sounds depends on the passage of air over the opening of the cavity. When it is remembered that a draining bronchus may be temporarily blocked by congestion or a mucus plug or advancing fibrosis, preventing air entry, the phenomenon of silent cavities is easily understood. When the bronchial opening of a cavity is blocked, there is accumulation of pus, while the air in the cavity gets absorbed, in the same way as air in a pneumothorax gets absorbed. The thinner the walls and healthier the surrounding tissues, the quicker the absorption. As the air gets absorbed the negative pressure produced draws the walls of the cavities in, causing the surrounding retracted lung tissues to re-expand and fill up the cavity space. This explains the phenomenon of vanishing cavities. If the space to be filled is small, the re-expansion of the surrounding retracted alveoli would be enough to fill the space, but when the cavity space is large, the negative pressure in the cavity may be so great as to produce emphysema in the surrounding tissues. If the cavity is very large and the surrounding tissues unhealthy, no amount of negative pressure would be adequate to fill up the cavity.

Intermittent opening and closing of a bronchial aperture would produce an expanding and contracting cavity. If the opening is valvular and air enters with deep inspiration, but does not escape on expiration or coughing, then a balloon cavity is produced.

If the bronchus of an area of lung adjacent to a cavity becomes involved in the disease and blocked, the atelectasis produced (Coryllos, 1933) draws the cavity towards the shrinking lung and a migrating cavity is produced.

If the collapse produced by artificial pneumothorax, intra-pleural pneumolysis, or thoracoplasty is such that it kinks or in other ways tends to close the bronchus of the cavity, then cavity-closure and sputum-conversion are

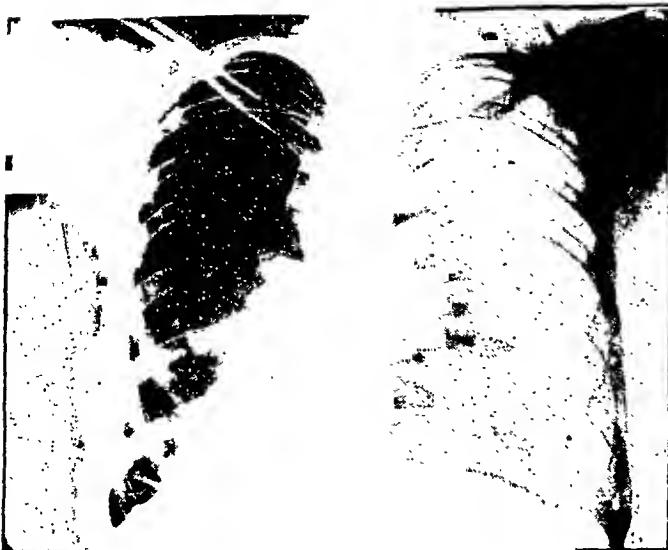

Fig. 1 (T. P., Hindu, male, age 25 years).—Shows two symmetrical cavities of more than a rupee size—one in each lung. Tubercle bacilli in sputum.

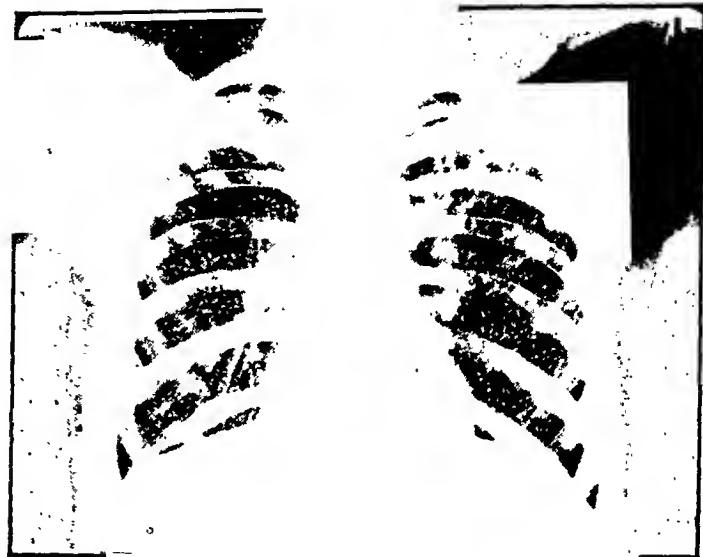

Fig. 2.—Same patient as figure 1—taken 5 months after the first picture. Both cavities disappeared. The patient had no treatment other than bed rest and sanatorium routine treatment. On discharge, the sputum was persistently negative to tubercle bacilli and the patient had gained 45 pounds in weight. Nine months after discharge, no cavities seen, patient keeping well, no tubercle bacilli in sputum.

Fig. 3 (D. R., Hindu, male, age about 30 years).—Left lung under partial collapse. Several cavities held open by apical pleural adhesions. Right lung extensively diseased, but no definite outlines of cavities visible.

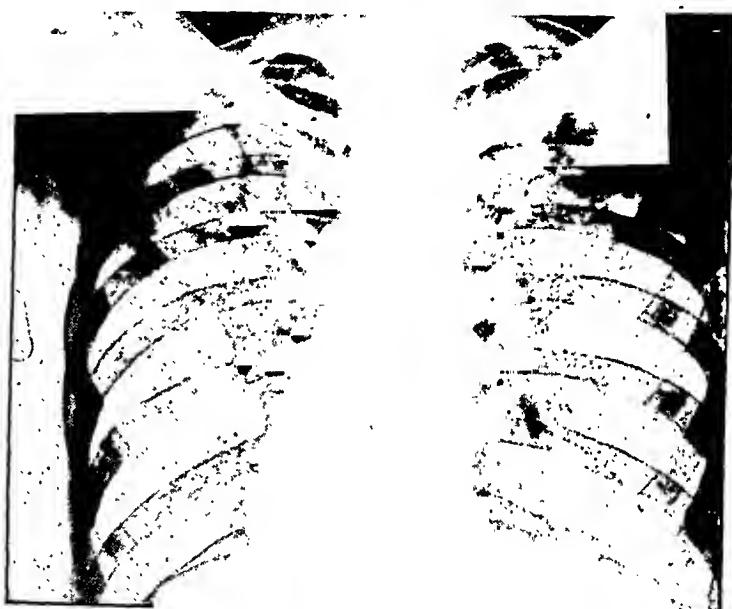

Fig. 4.—Same patient as figure 3. The adhesions on the left have been severed by internal pneumolysis. The apex dropped immediately and all cavities closed soon. Artificial pneumothorax on right side. Large cavity mid-zone held open by a thick adhesion directed towards the axilla.

Fig. 5.—Same patient as figures 3 and 4. Adhesion on right side also severed (stump clearly seen). But the cavity had not closed when the patient left the author's observation.

effected much more quickly than otherwise. For example, a downward drop of the apex of a lung produced by artificial pneumothorax or by section of the first and second ribs, or by the severing of an apical pleural adhesion, tends to cause a kink in the upper bronchi, an apical cavity closes soon, and the sputum becomes free of tubercle bacilli rapidly; whereas a cavity near the hilus with a wide and short bronchial outlet may resist all forms of collapse therapy.

The tubercle bacillus is an aerobe. A pulmonary cavity filled with air is an ideal place for its growth. But when the bronchus is blocked and the air in the cavity is absorbed the condition in the cavity becomes less favourable for the multiplication of tubercle bacilli. If the cavity and the lung are collapsed together and the whole organ converted into an air-free mass, tubercle bacilli will find it still more difficult to grow in it.

Tubercle bacilli as well as the cells of the human body are aerobes, and fresh air benefits both. The problem is to give sufficient fresh air to the cells of the body while withholding it as far as possible from the tubercle bacilli.

Haldane (Goldberg, 1941) observed that in shallow breathing only about one-seventh of the air contents of the lungs are renewed and when the patient is at rest in bed the breathing is at its shallowest and the natural air entry into the lungs is at its minimum. Moreover, during rest, the diseased bronchi have a greater tendency to close up, whether it be due to plugs which remain undisturbed or due to healing by fibrosis and contraction. Thus, bed rest helps in achieving the result of withholding fresh air from the bacilli-containing cavities, thereby creating physical conditions resembling those in a closed cavity which tends to heal rapidly. Collapse therapy, however, achieves this result in a more specific manner.

It would be an exaggeration to claim that the benefit obtained by tuberculous cavity cases from general bed rest or from local rest as in collapse therapy is all due to the diminution of air supply to the cavities. It is nevertheless a possibility that the diminished air entry into cavities plays an important part in the mechanism of healing produced by rest in bed and collapse therapy.

BONE AND JOINT TUBERCULOSIS : A REVIEW OF 175 CASES

By RICHARD E. STRAIN, M.C.P.&S., M.D., M.C.

Professor of Experimental Surgery, Miraj Medical Centre, Miraj, S. M. C.

TUBERCULOSIS of bone is a relatively common, disabling disease of childhood and young adult life which begins in cancellous bone. The joint or bone lesion is thought to be always secondary to pulmonary, gastro-intestinal, or glandular foci. The occurrence of a lesion in bone indicates that the resistance of the soft tissue is high (Christopher, 1939). The infecting organism may be human, bovine, or avian in type, but the marked reduction in bone tuberculosis in countries which have adopted pasteurization of milk on a wide scale and tuberculin testing of cattle leads one to believe that most commonly the organism is bovine in type and origin. Amberson takes exception to this and states that only 0.4 per cent of tuberculosis of the spine is from infected cattle (Gill, 1940).

Pathology

The route of infection is haematogenous; minute emboli of organisms lodge in the capillaries adjacent to the epiphyseal cartilage. The implantation of emboli is due to the peculiar anatomical loop arrangement of the smaller blood vessels prior to epiphyseal closure. Small infarcts are followed by typical tubercles which produce bony destruction without stimulating reparative reaction. Tuberculous processes are destructive and very little formative in contrast to pyogenic infections of bone which are at once destructive and formative, while syphilitic processes are almost always formative. Extension to the joint in tuberculosis results from destruction of the epiphysis and articular cartilage (Boyd, 1938).

Diagnosis

- (A) Primary focus (pulmonary, gastro-intestinal) or glands;
 1. Sputum—acid-fast staining and guinea-pig inoculation.
 2. X-ray of the chest.
 3. Excision of gland with histological study and guinea-pig inoculation.
 4. Stool examination.
- (B) Secondary focus (local bone lesions).
 1. Tuberculin test.
 2. Aspiration of joint fluid and guinea-pig inoculation.
 3. Excision of gland draining involved joint with histological study and guinea-pig inoculation.
 4. Acid-fast staining of pus.
 5. X-ray of involved joint.
 6. Biopsy of involved joint.

The diagnosis of tuberculosis of bone is not easy. In reviewing 175 cases it is apparent that the full value of various diagnostic procedures

is not widely appreciated. Early diagnosis as regards the final result may not be of great value if the patient is in the hands of an expert who does not use specific treatment until sure of a diagnosis, as the end-result of nearly all bone tuberculosis is ankylosis no matter how well the patient is treated; but in the hands of the innocent, the adoption of specific measures before specific aetiology has been decided may be very tragic. This is best illustrated by (a) needless amputation; (b) the incision and drainage of a tuberculous joint. This is tragedy to the patient as it usually condemns him to a life of draining sinuses due to secondary infection. Secondary infection invariably follows drainage of tuberculous joints and should never be practised. Aspiration of pus is the method of choice to remove any pus present. Joints already infected secondarily do not fall in this category. Chronic mono-articular arthritis in a child should always be regarded as tuberculous until proved otherwise. The same is true of a painful back in a child. Multiple articular processes, other than those in the wrist, hands, ankles, and feet diagnosed as tuberculous should be regarded with great scepticism.

The tuberculin test should always be done in a suspected case of bone tuberculosis. A negative test is strong evidence that the patient does not have tuberculosis but a positive test is only suggestive in that it shows the patient has, at some time, harboured the bacillus and become sensitive to it (Cecil, 1933). This test was performed in 24 of my cases.

Aspiration of joint fluid and guinea-pig inoculation is a positive test of great value. If the guinea-pig develops tuberculosis, the diagnosis is made; if it does not, the patient probably does not have tuberculosis. In this series this test was not used. Pickof (1939) reports the diagnosis of tuberculosis in 10 to 12 days by taking one gramme of fine amorphous non-purified silica powder (SiO_2), and placing it in a sterile flask with 20 c.cm. of boiling saline; it is shaken and allowed to cool, and 1 to 1.5 c.cm. is injected subcutaneously into the flank of a plucked guinea-pig. The suspected material is concentrated and injected through the same skin puncture to the same depth and in the same direction. The skin puncture is closed with collodion. The site is examined every few days and if by 10 to 12 days a firm induration develops some of the exudate is obtained by aspiration for examination on a slide. If negative, the process is repeated in 3 to 4 days. The animal is kept for 1 month as a check. It is thought that silica by enhancing the factor of tubercle strain virulence probably spares the bacilli much of the initial struggle against the guinea-pig defences, permitting them to proliferate earlier.

Excision of a gland draining the joint with guinea-pig inoculation and histological study has been found to yield positive results in about 80 per cent of cases of the knee joint (Seddon, 1939). The epitrochlear gland has been found

to be positive in wrist and elbow cases, while the inguinal gland is positive in ankle and knee cases and the external iliac gland positive in hip cases. This test was not used in this series.

Acid-fast staining of pus should always be applied. Guinea-pig inoculation is a more delicate test, but the smear is quicker and gives evidence of value relative to bacteria present. This was applied in 2 of our cases.

X-ray examination of the joint is absolutely essential. This usually discloses the typical reaction of bony destruction without new bone formation. This is a late sign of bone tuberculosis. Just as in early osteomyelitis due to pyogenic bacteria, so in early tuberculosis of bone, no changes are seen in the bone. The writer has seen a number of cases of his own, as well as other men's cases, in which the x-ray examination of the painful joint did not show any changes for a period of 2 to 5 months after the onset, but later developed the typical changes. Usually, antero-posterior and lateral views of the joint are taken. Skiagrams were taken in 73 of the present series.

Biopsy of the joint is mentioned with a word of warning. It is rarely used and only after all other diagnostic measures have been exhausted as danger of secondary infection and persistent draining sinuses is great. This is not true if sinuses already exist. As tuberculosis of bone is considered as always secondary to pulmonary, gastro-intestinal or gland infection, other tests of value should always be applied to find the primary focus.

Sputum examination with guinea-pig inoculation should be performed on all cases of bone tuberculosis. This was done 15 times in these cases.

X-ray examination of the chest, either fluoroscopic or by plate, should be done in every case as a majority of bone cases have pulmonary infection. Cave reported that 60 per cent of 122 children with tuberculosis of the spine had pulmonary infection. This test was performed 16 times in this series and 4 cases of pulmonary infection discovered.

Excision of a gland with histological study and guinea-pig inoculation where primary glandular infection is suspected is the only certain method of diagnosis.

Stool examination may be of value, but in a minority of cases, as contamination with the smegma bacillus is common in the stool, and the usual clinical history of diarrhoea and tenesmus gives a definite lead. Stool examination was performed in 50 cases.

Clinical history

Pain is the outstanding symptom in tuberculosis of bone. Early in the course of the disease, pain is insidious and irregular and may only be noted as slight limitation of movement but it is progressive until it becomes constant.

Trauma may be associated with the onset of the pain, in the mind of the patient. In 44 cases or 25.1 per cent in this series a definite history of injury was obtained.

One joint is practically always involved in the process. One should seriously question a diagnosis of tuberculosis of multiple joints, unless the condition is limited to the bones of the wrist, hands, ankles or feet. In the present series 4 cases of spinal tuberculosis had infection in other bones (2 elbow; 1 hip; 1 foot); 2 cases of hip tuberculosis had infection in other bones (1 knee; 1 elbow); one case had tuberculosis in the wrist and ankle; therefore a total of 7 cases or 4 per cent had more than one joint involved.

Muscle spasm is almost always present when the pain becomes constant. It is only an effort on the part of the body to splint and protect the joint from motion.

Cool swelling may form and is frequently associated with a 'cold' abscess. This is a late sign of tuberculosis wherever it occurs. Very occasionally a tuberculous joint may be quite warm and associated with fever and marked leucocytosis. In these cases the tuberculin test, aspiration of joint contents, and other studies give the correct diagnosis. Five patients or 2.8 per cent of all spinal cases came with abscess unruptured. Others had draining sinuses from ruptured abscesses.

Age of the patient is a factor of importance. Tuberculosis is a disease of cancellous bone which is the characteristic bone of youth. In the present series, 42 were in children, 15 years or under, 88 aged 15 to 30, 40 aged 30 to 50, and 5 patients were over 50. Thus 130 cases or 74.2 per cent occurred under the age of 30.

Sex is not a factor of importance; 95 occurred in males and 80 in females.

Location of the lesion. In this study 68 involved the spine of which 6 were cervical, 42 thoracic, and 20 in the lumbar area. The hip was involved in 35 cases of which 17 were in the left and 18 in the right hip. The ankles were involved in 23 cases, knees in 19, elbows in 9, sternum in 5, wrists in 4, ribs in 4, foot in 3, and sacro-iliac joint in 1 case. This is an unusually high number of infections of the sternum, and these cases are being reported in detail elsewhere.

Duration of the disease was fairly long with an average for the group of 14 months. More important than the duration is the stage which the disease has reached in the individual case. This is best illustrated by the complications present.

Complications. Fifty patients or 28.8 per cent came with draining sinuses some of which developed spontaneously; many followed operations by doctors who in their ignorance had incised and drained a tuberculous joint because pus was present. A tuberculous joint which is drained will certainly become infected and continue to drain for months. Thirteen patients

came with contractures and 18 came with ankylosis, usually in a poor position. Of the spinal cases, 11 came with abscesses 6 of which had ruptured; 7 had paralysis of the legs; 4 had incontinence of urine or faeces or both; 17 had kyphosis; and 3 had scoliosis. Thus, it is seen 123 or 70.3 per cent of the 175 cases came to us with rather far advanced stages of bone tuberculosis and presenting complications, most of which are preventable if the disease is diagnosed early and proper treatment given.

Treatment

The best treatment of tuberculosis is, of course, prevention. Isolation of contacts and education of the public is greatly needed.

The treatment of tuberculosis is rest—complete and prolonged rest—plus a building up of the body's natural defences by diet of high-vitamin high-calorie variety combined with heliotherapy in chosen cases. If the disease is in the spine or lower extremity, the patient must be recumbent as weight-bearing will not permit rest, no matter what type of brace or cast is used. Rest must be mixed with intelligence, as the end-result of all bone tuberculosis is usually ankylosis. Deformities must be prevented and the joints placed in the position of election for the type of work the patient concerned is doing.

Deformities already present are overcome by traction and extension. Abscesses are aspirated through normal tissue to prevent secondary infection taking place. Tuberculous abscesses should never be drained unless secondary infection and sinus formation have already taken place. Abscesses should never be permitted to rupture as secondary infection invariably takes place. If aspiration will not control the abscess, it may be opened, its contents evacuated, and sutured again but never drained.

Surgery is useful to a limited extent in tuberculosis of bone and is based upon two quite different principles. Surgical procedures are best confined to adults and the disease must be in a quiescent stage for the operation to be of benefit except in cases of amputation.

The first principle upon which surgery is based is that of splinting the diseased area and so providing rest to the part. This is the basic principle of the Hibbs and Albee spinal fusion operations and of fusion of any other joints. This is by far the most useful type of surgery in tuberculosis of bone and joints. In children, the same results can usually be obtained by prolonged immobilization without injury to the bone during the growth period and without danger of wide dissemination of the disease by the operation itself.

The second principle upon which surgery in bone tuberculosis is based is excision of the diseased part. Again its use should be confined to adults alone. This may take the form of amputation of an extremity or excision of a

joint or excision of the diseased bone. The excision of joints before the epiphyseal centres have become thoroughly ossified is to be severely condemned on the grounds :—

- (a) of interference with growth which produces a needless life-long deformity;
- (b) that immobilization for a prolonged period of time will produce as good or better results;
- (c) the economic factor does not loom as large in the life of a child as in an adult.

In the present series 17 operations (10 resections; 5 amputations; 2 spinal fusions), 32 incision and drainage of already infected joints, and 8 aspirations of abscesses were done. Seven deaths occurred in these 57 procedures, a mortality of 12.2 per cent. In many cases surgery may be delayed too long. If after 3 months of intelligent and careful treatment in adult cases of bone tuberculosis, improvement judged by lower pulse, temperature, and less pain is not noted, surgical interference should be considered where amputation can be done. Spinal fusions will accomplish in 6 to 10 months what it takes nature to achieve in 5 to 6 years and will usually prevent deformity, but it must not be used until the lesion has started to heal. Spinal fusion operations are rarely done on children at the present time.

In 109 cases no treatment other than application of plaster casts, sunlight, and high-vitamin high-calorie diet was given. Four deaths occurred in this group, a mortality of 3.6 per cent. Nine patients refused the treatment advised.

Summary

1. Tuberculosis of bone is a disease of young life, 74.2 per cent occurring under 30 years of age.

2. Out of 175 cases, 123 or 70.3 per cent came with far-advanced bone tuberculosis and presenting complications most of which are preventable if the disease is diagnosed early and proper treatment given.

3. Diagnostic methods have been pointed out.

4. Indications for surgical interference are reviewed.

THE IMPORTANCE OF A STANDARD IN EXAMINATION FOR TUBERCLE BACILLI

By R. M. BARTON, M.A. (Oxon.)

Pathologist, Union Mission Tuberculosis Sanatorium, Arogyavaram, near Madanapalle

In the *Report on the Classification of Pulmonary Tuberculosis* published by the Tuberculosis Association of India (1940), a plea is made for the recognition of a definite standard in the examination of sputum for tubercle bacilli, both on the admission and discharge of patients.

The minimum standard suggested for declaring a patient negative is that on discharge no tubercle bacilli should be found in smears on 4 successive days in 3 successive months, but it is recommended that whenever possible concentration tests and cultures should be made of the sputum and also of the stomach-wash water.

Technique

The following is a review of the work done on a series of patients in the Union Mission Tuberculosis Sanatorium, Arogyavaram. The routine examination on admission has been :— sputum examination by smear method on four successive days if negative and using pieric acid counter stain, followed by concentration and culture on Jensen-Lowenstein's medium using 6 per cent sulphuric acid for homogenizing and destroying secondary organisms; stomach washes were also done on a number of patients negative by other methods. Cultures were examined for a minimum period of 6 weeks, the majority being examined up to a period of 8 weeks.

On discharge, the routine has been to examine patients who have been negative by direct smear for 3 months by concentration method and sputum culture and in a few cases by stomach-wash culture also.

Material examined

The review covers all the patients who were admitted to the sanatorium from 1st April, 1940 to 31st March, 1941, numbering 442 together with 214 patients admitted before 1st April, 1940, but discharged from the sanatorium during the year ending 31st March, 1941, making a total of 656 patients examined on admission.

Examinations for tubercle bacilli on discharge from the sanatorium are reviewed for all patients discharged during the year ending 31st March, 1941, and those admitted during that year and discharged before the date of writing (20th June, 1941).

The classification of the patients according to diagnosis and the stage of the disease is shown in table I.

For the purpose of analysis there are omitted the patients who stayed too short a time,

TABLE I

Diagnosis		Number of patients
Pulmonary tuberculosis	Stage I ..	44
	Stage II ..	57
	Stage III ..	462
Non-pulmonary tuberculosis	Abdominal and intestinal.	6
	Glandular ..	5
	Bone ..	2
No active tuberculosis and non-tuberculous diseases.		75
Patients who stayed too short a time for full examination and diagnosis.		5
	TOTAL ..	656

and those who were diagnosed as not suffering from active tuberculosis or as suffering from non-tuberculous diseases such as bronchiectasis, lung abscess and asthma, although a good many examinations by smear and cultures were involved for the 75 patients included in this group.

It will be seen that 563 patients were diagnosed as suffering from pulmonary tuberculosis and 13 from non-pulmonary tuberculosis.

Examination for tubercle bacilli on admission

Taking first the 563 patients who were diagnosed as suffering from pulmonary tuberculosis, we find the result of sputum and stomach-wash examinations as follows (table II):—

TABLE II

Examination for tubercle bacilli on admission

	Stage I	Stage II	Stage III	Total
Number of patients	44	57	462	563
Tubercle bacilli found—				
None by any method.	33	20	25	78
1st smear	2	12	368	382
2nd smear	..	6	33	39
3rd smear	..	4	6	10
4th smear	..	4	7	11
5th to 13th smears	..	1	5	6
Concentration ..	1	..	3	4
Sputum culture ..	5	9	14	28
Stomach-wash culture.	3	1	2	6
By any method ..	11	37	438	486

In addition to the results given in table II, stomach-wash cultures were positive in 3 stage I, 3 stage II and 2 stage III patients in whom sputum culture was also positive.

In the group of patients found positive in smears subsequent to the 4th smear, one patient on admission showed numerous acid-fast bacilli in the stools, one patient acid-fast bacilli in a stomach-wash smear, two patients acid-fast bacilli in the pleural fluid; in one patient a sputum culture and in one patient both a sputum culture and a stomach-wash culture taken soon after admission showed no growth, but positive direct smears were obtained in the second or third months.

It will be noted that after the examination of direct smear on four consecutive days only 4 of the total of 486 positives were found by the concentration method used.

From table II it will be seen that 8 out of 11 positives in stage I patients were obtained by culture methods, 10 out of 37 in stage II patients, and 16 out of 438 in stage III patients.

In stage I, of 41 patients found negative by direct smear and concentration methods, 8 or 19.5 per cent were found positive by culture; of 30 patients in stage II 10 or 33.3 per cent, and of 41 in stage III 16 or 39 per cent.

Consideration of negatives on admission

The question now arises why, especially in stage III, are there any negatives at all. Are there explanations for the negative findings and have proper examinations, i.e., the full routine, been carried out, because while there may be an ideal routine, it may not always be possible to carry it out in every patient for various reasons? In table III are shown the examinations carried out on admission for the patients in whom no tubercle bacilli were found:—

From table III it will be seen that only 5 of the patients in whom no tubercle bacilli were found had neither a culture of the sputum nor stomach-wash culture or smear.

Of the patients in stage I with smears only, one stayed too short a time for complete examination, and two had a positive stomach-wash examination in this sanatorium some time previous to admission; in one stage III patient the sputum culture on admission was contaminated, but a later culture was positive.

In stage II patients grouped under 'others' two had mainly a glandular condition in one of whom tubercle bacilli were found in pus from a gland, and one had mainly an intestinal tuberculosis.

In stage III patients grouped under 'others' one had a tuberculous abscess (in the pus of which tubercle bacilli was found) and one was pregnant which affected the staging of the patient (i.e., the patients were not stage III by lung condition), one had a contaminated culture on admission but a later culture was positive;

TABLE III
Examinations made of patients in whom no tubercle bacilli were found on admission

		Stage I	Stage II	Stage III	Total
None found by any methods	33	..	20	25	78
Patients with pleurisy as the main or a prominent symptom.	3	7	9	24	
Sputum and stomach-wash culture ..	2	5	3	10	
Sputum culture and stomach-wash smear (stomach-wash culture contaminated).	4	1	..	5	
Sputum culture	3	3	
Stomach-wash culture	2	1	2	5	
Smears only	1	1	
Patients arriving with A-P	2	8	10	
Sputum and stomach-wash cultures	2	3	5	
Sputum culture	4	4	
Stomach-wash culture	1	1	
Others	25	11	8	44	
Sputum and stomach-wash cultures ..	16	7	6	29	
Sputum culture and stomach-wash smear	3	1	..	4	
Sputum culture	3	3	1	7	
Smears	3	..	1	4	

two patients who had sputum and stomach-wash cultures negative on admission had positive direct smears in the fourth month.

It will also be seen that of the patients in whom no tubercle bacilli were found on admission, 24 came with pleurisy which was either the main symptom or which in most of the stage III patients had caused a collapse of the diseased lung, and 10 patients came with A-P. In stage III patients, there were only three in whom there was no explanation of any kind why no tubercle bacilli could be found on admission in spite of sputum and stomach-wash cultures.

No tubercle bacilli were found in the sputum or stomach wash of the 13 cases of non-pulmonary tuberculosis, although sputum and stomach-wash cultures were done in 4, sputum cultures in 3, stomach-wash cultures in 4, and smears only in 2. Tubercle bacilli were found in pus from two of the patients with glandular tuberculosis.

Examinations for tubercle bacilli on discharge

Turning now to the examination for tubercle bacilli on discharge of patients diagnosed as suffering from pulmonary tuberculosis, we find the results as given in table IV.

TABLE IV
Examination for tubercle bacilli on discharge

	Stage I	Stage II	Stage III	Total
Number of patients	40	48	329	417
Tubercle bacilli found—				
None by any method.	34	36	123	193
1st smear ..	2	6	174	182
2nd smear	17	17
3rd smear	3	3
4th smear	1	4	5
Concentration

Stomach-wash culture.	1	..	1	2
By any method ..	6	12	206	224

N.B.—If a patient stayed less than 1 month in the sanatorium, the examination on admission is taken as the examination on discharge.

Oct., 1941]

EXAMINATION FOR TUBERCLE BACILLI: BARTON

From table IV it will be seen that 4 out of 6 positives in stage I patients were obtained by culture methods, 5 out of 12 in stage II and 8 out of 206 in stage III.

Of the 38 patients in stage I classed as TB-negative by direct smear and concentration test 4 or 10.5 per cent were found positive by culture; of 41 patients in stage II 5 or 12.2 per cent and of 131 patients in stage III 8 or 6.1 per cent.

Consideration of negatives on discharge

The question arises again, as with patients on admission, what was the standard of examination for patients discharged as TB-negative? The examinations carried out are shown in table V.

frequently longer periods went before a control culture.

It is found in the series of patients discharged that the following showed positive cultures:—

Period of negative direct smears	Number of patients' sputum cultured	Number of patients with positive culture
3 months ..	68	21
4 months ..	29	7
5 to 6 months ..	27	10
7 to 8 months ..	11	2
9 to 10 months ..	7	3
Over 12 months ..	2	2

N.B.—Many of the patients had subsequent negative cultures after the first culture but these are not included here.

TABLE V

Examinations made for patients discharged as TB-negative

Examination	Stage I	Stage II	Stage III	Total
Number of patients	34	36	123	193
Sputum and stomach-wash cultures	2	3	4	9
Sputum culture	7	16	101	124
Stomach-wash culture	3	..	1	4
Stomach-wash smear (culture contaminated)	1	..	1
Concentration (culture contaminated)	3	3
Smears only	22	16	14	52

Of the 52 patients who were discharged as sputum TB-negative on the result of smear examinations only, all except 3 stage II and 7 stage III patients were sputum TB-negative on admission. Many of these patients stayed only a short time and sputum and stomach-wash cultures made on admission were not repeated on discharge. Other patients left at short notice before sputum for cultures were obtained.

Of the patients discharged with sputum culture negative 42 had two negative cultures, 10 three negative cultures and 1 five negative cultures.

Of the 12 patients discharged who were suffering from non-pulmonary tuberculosis, the sputum was cultured in 1 only and was negative; in the others, smears were negative.

Cultures during treatment

It has now become the routine in this sanatorium to culture the sputum when a patient has had four negative direct smears in each of three consecutive months. This is the minimum period advocated by the Report on Classification, for a patient to be discharged as 'sputum negative'. In the earlier patients under review

A single culture may not be enough; for example one patient had 3 negative cultures followed by a positive culture and 63 negative direct smears; another had 2 negative cultures followed by a positive after 48 negative smears.

A negative culture is also not a guarantee that tubercle bacilli may not be found afterwards by direct smears. We have seen a patient with a negative culture after 5 months of negative smears who had a positive smear two weeks after the culture was made and several others have shown a positive smear one to three months after a negative sputum culture. In some cases exacerbation of a tuberculous focus has been the reason for the re-appearance of the tubercle bacilli in direct smear; in others there was no apparent explanation.

In three cases we have had a positive smear from centrifuged sediments, part of which has been cultured and the cultures have shown no growth.

Examination of stools for tubercle bacilli

Examination of the stools by direct smear for tubercle bacilli has been carried out in 280 of

the patients diagnosed as suffering from pulmonary tuberculosis. Owing to the present difficulty of procuring stain this examination has been stopped. The following results were found :—

Sputum direct smear	Stools direct smear	Number of patients
+	+	157
-	-	80
+	-	34
-	+	9

Of the nine patients showing acid-fast bacilli in the stools and not in the sputum smears, 8 showed tubercle bacilli on culture of the sputum or stomach wash.

In two cases one diagnosed as 'no active tuberculosis' and one 'probable cancer', a few acid-fast bacilli were found in the stool smears. Whether they were tubercle bacilli is impossible to say, but it must be remembered that acid-fast saprophytes may be found in the stools.

Discussion

A review has been made of the results of examinations for tubercle bacilli for a series of 563 patients admitted to the sanatorium and found to be suffering from pulmonary tuberculosis and of 417 patients discharged from the sanatorium, keeping in mind the standard of examination advocated by the *Report on Classification of Pulmonary Tuberculosis* published by the Tuberculosis Association of India.

From table III it will be seen that the standard of examination by culture methods where bacilli could not be found by direct smear and concentration methods on admission was attained. From table II it will be seen that the great majority of positive findings in stage III patients was, as was to be expected, in the first direct smear, 368 out of 438 positive. Subsequent smears added 51, concentration smears added 3, and cultures added 16. In an examination of the 25 stage III patients in whom no tubercle bacilli could be found either by smear or by culture, an explanation of the reason for this was found in all except 3 patients, pleurisy and artificial pneumothorax before admission being the principal reasons. That is, culture methods have brought up the positive findings in stage III patients to over 99 per cent on admission (unless there is some special explanation for a negative finding).

In stages I and II the increase of positive findings by using culture methods is very marked, 8 of 11 in stage I patients and 10 of 37 in stage II patients being found by these methods. Especially in stage I patients the finding of tubercle bacilli is of particular importance from the point of view of diagnosis.

(Concluded at foot of next column)

A MUNICIPAL SCHEME FOR TUBERCULOSIS CONTROL

By N. RAJAGOPALAN, M.B., B.S., B.Sc.
(Health Officer, Madura City)

and

K. S. SANJIVI, M.D.
(Department of Tuberculosis, Erskine Hospital, Madura)

MADURA CITY is one of the largest cities in south India with a population of 182,018 in 1931 and an estimated population of 235,000 in 1941. It is an important place of pilgrimage and a big commercial centre with large spinning mills.

On a strict calculation, with the health officer personally verifying the deaths in every instance, 327 persons died of pulmonary tuberculosis during 1939. The average number of annual

(Continued from previous column)

The examination of direct smears on the third and fourth days while not adding very many to the total number of positives, is yet justified from the point of view of saving of labour, expense and time, involved in culture methods.

It has been noted that very few positives were found by the concentration method.

One of the points to be remembered in considering the number found positive by concentration and culture methods is that the more efficient is the examination of direct smears, the less will be the positives found by these other methods.

On discharge of patients it is not quite so easy to attain the ideal standard as on admission. In table V it is seen that 52 patients discharged as TB-negative had direct smears only; of these 42 were TB-negative on admission when they had a full examination, but 10 who had been TB-positive were not controlled by culture before discharge. From table IV it will be seen that 17 of 224 positives, i.e., 7.6 per cent, were only found by culture. Again it is especially noticeable in the stage I and stage II patients how important is the culture method where 4 out of 6, and 5 out of 12 of the positives were found by this method.

One of the consequences of the introduction of culture methods has been that a number of patients are left under treatment longer, until the sputum is bacilli-free by culture.

The inadequacy of four negative smears in three successive months is shown by the number of positive cultures obtained in such patients.

An examination of the positive findings in stool examinations by the smear method suggests that where culture methods are not possible, it is worth while to examine stool smears in patients with a sputum negative by smear method.

deaths during the previous 10 years was 446 which gives a mortality rate of 245 per 100,000 of the 1931 census population. The reduced death rate in 1939 can be ascribed partly to the rigid verification and partly to the welcome change in the attitude of the public towards tuberculosis, as shown by their increasing eagerness to submit to early diagnosis and proper treatment.

The city health department has launched a frontal attack on this disease since 1938 and this paper describes the foundation, the working and the difficulties of the scheme.

A. Foundation

The foundation of the municipal scheme for combating tuberculosis in the city of Madura lies in the following fundamental facts :—

Tuberculosis is an infectious disease caused by the bacillus tuberculosis and must yield to prophylactic measures common to all infectious diseases. The ultimate responsibility for the control of tuberculosis must therefore rest with the very authorities responsible for other infectious diseases, *viz.*, the local bodies and their health staff.

With nearly 5,000 cases of active tuberculosis in the town the problem calls for immediate action. The need for formulating a scheme that is eminently feasible and practical and which will secure our objects within a reasonable time will be apparent.

Poverty with its attendant evils, poor nutrition, bad housing, overwork and worry lowers the individual's resistance to tuberculosis as to all other infectious diseases. Bad housing is of special importance in the spread of tuberculosis in so far as it promotes close and massive infection from an open case in the household. We believe that if the bacillus of tuberculosis can be excluded, no degree of poverty can by itself cause the disease. Further, the eradication or even the mitigation of these social evils falls outside the sphere of work of the medical officer of health.

Climate can no longer be believed either to cure or even markedly to benefit the case of tuberculosis, though it may somewhat add to his comfort. The fact that the rich patient indulges in the luxury of a special climate cannot mean that such indulgence is essential to cure his less fortunate brother. Considering the large incidence of the disease, something urgent, something cheap and effective is needed to stop this waste of human life and so far as municipal schemes are concerned we are convinced of the truth in Batty Shaw's conclusion that 'the enormous expenditure of money on sanatoria should be stopped and instead money should be spent in providing every tuberculosis officer with the facilities of a local pulmonary hospital or institute equipped with the means for carrying out full clinical bacteriological and skiagraphic examination of the lungs and provided with

adequate number of beds for the carrying out (a) of the more rapid, more effective and less costly collapse method of treatment of pulmonary tuberculosis in its truly early stage and (b) for accommodating advanced invalids suffering from this disease near the homes which they should no longer occupy'.

Sanatoria are good institutions, necessary in one phase of this control programme but they have their limitations. They are costly and can deal with only a small number of cases and play only a small part in the active prevention programme. Their chief value is that they serve as good educative centres for patient and doctor alike.

An anti-tuberculosis scheme to be successful should harness the services of every institution and every individual who can help in the scheme. The co-operation of the private practitioner who sees many cases when they are still early is of paramount importance. Unless the best relationship exists between the practitioner on the one hand and the municipal health officer and the tuberculosis officer on the other, and unless the former is confident that he can obtain the free help of the latter officers and can continue to retain the case, the scheme cannot be worked smoothly.

The object of the scheme is to have complete information regarding every 'open' case, so that he may be rendered bacilli-free by treatment when that is possible, or isolated; as also to detect the 'contacts' with early signs so that they may be arrested from becoming open cases. Such knowledge of every open case and its contacts and their cure or isolation, so essential to the effective check on the disease, can only be obtained by combining field work with the really important elements of sanatorium-regime which can be successfully practised without planting the institutions far away from the homes of the patient.

B. The scheme

Based on the above desiderata, our work has chiefly been concentrated on the 'open' case and his contacts.

Registration of cases.—Section 56 of the Madras Public Health Act of 1939 reads as follows :—

'Every medical practitioner who in the course of his practice becomes cognisant of the existence of any case of tuberculosis in any private or public building other than a public hospital shall, if the case has not been already reported, give information of the same with the least practicable delay:

(a) in municipal areas, to the executive authority, the health officer or a sanitary inspector; and

(b) in non-municipal areas to the health officer, a health or sanitary inspector or the village headman.

Explanation.—In this connection medical practitioners include hakims or vaidyas, whether registered or not.'

Cards have been supplied to all practitioners in the city to facilitate notification. The city health laboratory offers the following diagnostic service entirely free of any charge.

1. Blood—(a) Microscopic examination for malarial parasites.
- (b) Cultural examination for typhoid group of organisms.
- (c) Serological tests—Widal's and Kahn's tests.
2. Stool—(a) Microscopic examination for intestinal parasites, such as *E. histolytica*, and the eggs of parasite worms.
- (b) Cultural examination for pathogenic intestinal bacteria.
3. Sputum—Microscopic examination for tubercle bacilli.
4. Throat swabs—Microscopic and cultural examination for *C. diphtheria*.
5. Cervical or urethral smears—Microscopic examination for gonococcus.

These aids should deter any practitioner from diagnosing a case of tuberculosis as one of malaria or enteric. The results of the laboratory examination of the sputum are turned to immediate use by way of instituting means for the prevention of the spread of tuberculosis. No fresh report of the case as required under the Public Health Act is demanded from the practitioner. Simultaneously, as the result is communicated to him, special intimation is forwarded to the division sanitary inspector. Apart from these living cases all deaths which are not certified by registered medical practitioners are carefully enquired into by the medical officers of the municipal dispensaries, and finally by the health officer.

Detection of other cases.—The contacts of each of these open cases or deaths from tuberculosis are examined regularly at the municipal tuberculosis clinic or in a few instances by the medical practitioners in attendance. The municipal tuberculosis clinic, started in December 1938, is at present located in the office of the city health department. The work of examining the contacts is greatly facilitated by the municipal ambulance going round to fetch the contacts. All the contacts are Mantoux-tested as also examined clinically. The contacts who are suspected of having any active disease are x-rayed. Since the outbreak of the war, however, to economize in films such cases are being screened in the first instance and only those suspected as having lesions requiring treatment are later x-rayed.

Many modern authorities would insist that every positive tuberculin reactor should be x-rayed, as the x-ray furnishes the most definite picture of the early lesion. The expenditure involved is however beyond our means. Hence a judicious selection of cases needing skiagraphic examination is made by the clinical examination including careful records of personal and family history. To date 1,602 persons being contacts of 284 'open' cases, have been examined.

Provision of beds.—With reference to the provision of institutional treatment of cases

suitable for collapse therapy, the city council with its characteristic acumen readily realized the need for a hospital and at its special meeting on 25th February, 1939, passed a resolution signifying its desire to construct and maintain a tuberculosis hospital at a capital cost of Rs. 50,000 and recurrent expenditure of Rs. 10,000 per annum. In view of the inevitable delay in building the hospital and the urgent need for the provision of more tuberculosis beds than are now available in the city, the municipality has, on 29th March, 1940, further resolved to pay for the maintenance of 8 tuberculosis patients at the local American Mission Hospital.

There are thus about 40 free tuberculosis beds between the government hospital and the mission hospital besides the paying accommodation that may be available in certain private nursing homes. To those who doubt the importance of this and further provision of beds we can do no better than draw their attention to the following words of Dr. C. Frimodt-Möller :—

'In the West the tuberculosis clinic is one of the most important links in the whole campaign but in India the money spent on tuberculosis clinics is often out of all proportion to the value derived from them. The reason for this is that they are sometimes established in towns without any facilities for treatment in hospital or sanatorium of patients for whom ambulant treatment is unsuitable. With the severe type of tuberculosis found in India, ambulant treatment is not only impossible for the majority of patients but is actually a danger to them and through them to their surroundings.'

A site has been chosen for the Municipal Tuberculosis Hospital on the outskirts of the city with easy access to the heart of the city. The municipal water supply and electric supply can be made available to the hospital without much expenditure. The site will, in short, fulfil all the desiderata necessary for a tuberculosis hospital near a city (*vide Cummins, 1939*).

Organized home treatment.—Such of the cases as are not suitable for any form of collapse therapy or have been discharged from institutions after a period of treatment are included in the scheme for organized home treatment which has been fully explained in the following circular letter to all the practitioners sent out on 12th December, 1939 :—

'You may be aware of the city health department's anti-tuberculosis campaign. The surveys carried out during the last 12 months have shown that in Madura city there are about 5,000 active cases, many of whom are disseminating tubercle bacilli, needing treatment and control. We desire to reach as many of them as possible and take adequate steps for their personal treatment and against their being dangerous to the community. We realize that the success of any such scheme depends entirely on your kind co-operation. You can help in the following ways :—

1. Send the sputum of all suspected cases to the city health laboratory, for a free report.
2. Any help you desire to have in the diagnosis or the treatment (as induction of pneumothorax, etc.) of your indigent patients can be had at the tuberculosis clinic temporarily located in my offices on any Tuesday between 3 and 4 p.m. You can have the free advice

of the clinic and continue to retain the case under your treatment.

3. There are a large number of poor patients who have perforce to be under organized home treatment. They will be given detailed advice regarding their treatment, mode of living, etc., after personal inspection of their homes by the clinic doctors. They would however require frequent supervision to give them symptomatic treatment, to keep a strict control over their isolation and sputum disposal, etc. It is proposed to request each practitioner to look after a few cases near his residence or consulting room. This supervision will have to be done in an entirely honorary capacity at present but it is hoped that with the formation of a care and after-care committee and the collection of funds it will be possible in time to offer a small fee for these visits.

If you are willing to co-operate please sign the enclosed note and return it very early to facilitate the proper organization of home treatment of these poor unfortunate fellow citizens in their and our interests alike.'

Thirty-seven doctors have given their consent for co-operation in the scheme. At a meeting of the district medical association the exact rôle of the private practitioner in the organized home treatment of the domiciliary case has been further explained and discussed.

Survey and propaganda.—Apart from tracing out and examining the contacts of cases, the municipal tuberculosis clinic has also carried out an intensive house-to-house survey in the 28th ward. In connection with the survey a public meeting was arranged to explain the scope of the survey and the means for the control of the spread of tuberculosis. Several councillors including the chairman and vice-chairman and the district medical officer and other prominent medical officers were present. Notice of the meeting was furnished to every householder in the area it is proposed to survey through individual contact by the sanitary inspectors and the conservancy peons in the city. The result was highly gratifying in that the meeting was attended by more than 3,000, out of the total population of 10,000 in the area and among these there were not less than 400 women.

The effects made on this behalf were repaid by the most ready and hearty co-operation of the residents in the area included in the survey, proving the well-known principle that the most effective health education is that which is linked up with a practical programme for the control of any disease and an exposition of the rôle that each member of the community, the public health official, the council and the state have respectively to play in the furtherance of that programme. Nine hundred and eighty-six persons were included in the survey and the disease incidence rate in this area was found to be 2.23 per cent.

Socio-economic studies.—Apart from the medical examination careful enquiry has also been conducted into the housing conditions and the economic status of each family. Four hundred and fifty-five families in the house-to-house survey and 410 families in the contact survey have thus been completely investigated from

both aspects of tuberculosis—the contagious and the socio-economic.

We have thus records of great interest to the public health worker, the tuberculosis physician and the economist alike. We propose to submit them to a rigid statistical enquiry and to publish the results in due course.

The information obtained from the survey of the housing conditions has been put to immediate use by the issue of notices for effecting improvements and removal of defects. Such improvements do not usually cost much but are of great value in the home treatment scheme.

C. Difficulties

Having given a brief idea of our scheme and the beliefs underlying it, let us now recount some of our difficulties in working out the scheme.

Notification of cases.—Although section 56 of the Public Health Act applies equally to hakims or vaidyas, whether registered or not, those other than 'allopathic' practitioners and licentiatess in Indian medicine seldom notify cases of tuberculosis. We obtain knowledge of these cases only after they die. Thus, valuable time for prevention—and the collapse-therapist will claim also for cure—is lost.

In dealing with an essentially prolonged illness like tuberculosis, one often notices how the interest of the individual clashes with that of the community. Take for instance teachers, domestic servants and workers in the food industry, who are most liable to hand on the infection to susceptible children, or consider tailors and mill workers whose working conditions are often prejudicial to their own ultimate recovery and to the safety of their colleagues. When we discover an open case in any one of the above groups how long can we keep him out of his job and how far are we justified in taking away his bread? When such a patient has improved with proper treatment what are the criteria on which he is to be sent back to work, bearing in mind his own chances of relapsing and the chances of his associates getting infected? The answer to these questions will vary with each occupation and with each patient; but so long as we have not the means of providing any financial assistance through well established 'care and after-care' committees, we cannot be unduly harsh on the individual patient in our effort to save the community. Indeed the community has no right to expect to be saved so long as it has not awakened to its responsibility in the matter. 'There can be no happiness for any one of us unless it has been won for all'.—Mahatma Gandhi.

A large number of open cases, most of them in a pitiable state of extensive bilateral affection, arrive in the city every day seeking admission in the local hospitals. They doubtless stay in different parts of the city for varying periods during which they must be disseminating, 'gratis and

CERTAIN EPIDEMIOLOGICAL ASPECTS
OF PULMONARY TUBERCULOSIS IN
NORTHERN INDIA

By K. L. WIG, M.B., B.S. (Pb.), M.R.C.P. (Lond.),

Ex-House Physician, Rai Bahadur Amar Nath Tubercu-
losis Institute, Mayo Hospital, Lahore

OBSERVATIONS on some epidemiological aspects of pulmonary tuberculosis, based upon an analysis of a thousand consecutive cases and a thousand radiographs studied at the Government Tuberculosis Institute, Madras, were made by Sanjivi (1939). India is a very big country—very often termed a sub-continent—and the various parts of the country show a vast variety of climates, diets, economic conditions of the people, industrial conditions and state of communications, etc.—factors which may influence the incidence and type of tuberculosis.

We have, therefore, attempted in this paper to put forward an analysis, based upon a study of the histories of 1,298 patients who out of 3,153 new patients attending the out-patients' department of the Rai Bahadur Amar Nath Tuberculosis Institute, Mayo Hospital, Lahore, in 1939, were diagnosed as cases of pulmonary tuberculosis on the basis of some definite evidence. The analysis has been done on lines similar to those followed by Sanjivi (*loc. cit.*). Though most of the figures given below relate to the patients who attended the Tuberculosis Institute in 1939, under one item (age incidence) corresponding figures about patients who attended the Institute in 1937 are also given because they were also available. A study of this factor was made by one of us (K.L.W.) in 1937, but the results were not published.

(Continued from previous page)

post-free', billions of tubercle bacilli. We have an idea therefore of impounding such patients outside the city limits and debiting their maintenance cost to the respective local authorities, following the practice that at present prevails in the case of antirabie treatment.

Finally, we propose to intensify our efforts to gain information about every active case in the city by further studies. Surveys of selected groups, such as contacts, mill workers, etc., are more likely to yield results than a random house-to-house survey. We hope that by a fruitful co-operation of the householder, the family physician and the different institutions in the city, who have all already shown their keenness to help, the mortality and the morbidity rates of tuberculosis will be definitely brought down in the next two years.

TABLE I
Showing sex incidence, 1939: 1,298 cases

		Number	Percentage
Males	..	867	66.7
Females	..	431	33.3

TABLE II
Showing age incidence, males and females together, 1937: 1,233 cases

Age group		Number	Percentage
Less than 15	..	99	8.0
15 to 24	..	584	47.3
25 to 34	..	360	29.9
35 to 44	..	124	10.0
45 to 54	..	50	4.0
55 to 64	..	13	1.0
Over 64	..	3	2.0

TABLE III
Showing males and females separately, 1939:
1,298 cases

Age group	Males	Percentage	Females	Percentage
Less than 15	38	3.0	41	9.7
15 to 24	333	38.8	206	47.8
25 to 34	286	32.9	113	26.2
35 to 44	139	17.1	54	12.5
45 to 54	52	6.0	11	2.5
55 to 64	17	1.9	5	1.1
Over 64	2	0.2	1	..

It will be noticed from the 1939 table that the maximum incidence for both males and females is between the ages of 15 to 24, but that the peak rises much higher amongst the females of that age period and then falls quickly. It does not rise so high in males in the age period between 15 to 24, but falls slowly during the later age periods. These figures, we may say, differ somewhat from those of Sanjivi in his analysis of Madras cases. The incidence amongst his cases was highest, 37 per cent among males between the ages of 25 to 34, but continuously high amongst females in the age periods between 15 to 24, and 25 to 34, being 37.06 per cent and 37.74 per cent respectively.

There is however one similarity in the results of the two analyses. The incidence amongst females is very high in the age periods between 15 to 24, though preponderatingly high in our figures. As most girls in Punjab are married at about the age of 15, this is the age period during which they undergo their first two or three pregnancies.

In the 1937 analysis, figures were not collected separately for males and females. This table however again shows that the maximum incidence of the disease is below the age of 25. Both the tables moreover show that the disease causes its maximum morbidity between the ages of 15 to 45, which means that the disease takes its heaviest toll from the wage earners. This fact stresses the importance of the disease as a cause of great economic loss to the country.

The 1937 table shows 5.2 per cent of the cases occurring after the age of 45, and in 1939, 8 per cent of the males and nearly 4 per cent of the female cases were met with after the age of 45. This means that the common belief in the minds of many general practitioners that the disease is extremely rare amongst older persons is unwarranted. The disease is comparatively less common at this age period, but, in view of the fact that there are millions in this country suffering from this disease, thousands of old people are amongst its victims. Moreover, if we keep in mind the fact that the total number of people alive in this country above the age of 50 is much smaller than the number below that age, a fair proportion of those alive after the age of 50 seems to be affected and the incidence amongst them is not really as low as a figure of 4 to 8 per cent suggests. The belief that the disease is rare amongst old people is prevalent because of the infrequent use of x-ray in the diagnosis of pulmonary tuberculosis, as the symptoms at this age period very often simulate bronchitis and asthma, and the physical signs are often absent as the result of coincident emphysema.

Occupational incidence.—Figures given below relate only to males, as almost all women do only domestic work and are not employed in any definite trade, industry, or occupation.

It will be noticed that the percentage of agriculturists is low, when compared with their great preponderance amongst the general population. They form nearly 70 per cent of the population of the province. No undue conclusion should however be drawn from this, as the hospital, being in a town, it is likely that it would be frequented relatively more by the town dwellers than by the agriculturists from the villages.

One point, however, is noteworthy. The incidence amongst certain occupations notably clerks, students and tailors is very high and especially in the case of clerks and tailors much higher than would be warranted by the proportion of the number of those following

TABLE IV
Showing occupational incidence, 1939 : 867 cases

Occupation	males	below	
1. Unemployed (including 41 males below the age of 15)	110
2. Agriculturists	140
3. Merchants (shopkeepers and small business men)	98
4. Clerks	87
5. Students	40
6. Tailors	37
7. Coolies and labourers	26
8. Peons and chowkidars	26
9. Domestic servants	25
10. Carpenters	23
11. Mechanics and blacksmiths	22
12. Drivers	19
13. Teachers	12
14. Cooks	12
15. Painters and artists	12
16. Masons	12
17. Sweepers	11
18. Shoemakers	11
19. Goldsmiths	10
20. Policemen and soldiers	10
21. Dispensers	7
22. Bookbinders	7
23. Weavers	6
24. Barbers	5
25. Miscellaneous	33

N.B.—'Miscellaneous' is a collection of a number of occupations or trades. Those following any one of these occupations or trades did not number more than four in the series.

these occupations amongst the general population. Moreover the morbidity amongst people following these occupations is much higher than that amongst other occupations contributing to the general population numbers equal to any of these two occupations. One point is common to the above-mentioned three occupations. These people sit for the major portion of the day crowded together in one room. Both clerks and tailors moreover have to lead a sedentary life, sitting in a stooping attitude for the major portion of the day. Surveys carried amongst those following these occupations, i.e., amongst Lahore College and School students which number several thousand, amongst thousands of clerks in Lahore's numerous offices and in the tailoring shops of Lahore, might provide useful data. We may mention here that an analysis as regards this point of our records of the two previous years also has shown the preponderance of the disease amongst the people following these occupations, and a high rate amongst these people is not peculiar to the year under review but has been consistent, so far as the attendance at this institute goes.

The high incidence amongst domestic servants, cooks, peons and chowkidars, drivers and teachers is of special importance. These can very easily act as sources of infection, and may partially be responsible for the outbreak of cases in families which never had a case amongst them before.

The very low incidence amongst professional people such as doctors, lawyers, engineers and others following relatively lucrative trades

(they are included in the miscellaneous group in this series) may be due to the fact that the hospital is visited mostly by poor people, and that those who are well-to-do prefer to consult a private practitioner. So no conclusion about the incidence of the disease amongst such occupations can be formed upon an analysis based upon those attending a hospital.

Urban and rural distribution.—Table V shows the origin of 1,252 cases: 46 persons gave no definite address.

TABLE V
Showing incidence as regards urban or rural areas: 1939

	Number	Percentage
Cases coming from rural areas	390	31.1
Cases coming from semi-rural areas.	56	4.5
Cases coming from urban areas	806	64.4

Eighty-six per cent of the population of Punjab is rural but only 31.3 per cent of the cases come from rural areas. However this comparatively low incidence amongst the rural population, as deduced from the statistics of a hospital in Lahore, is likely to be fallacious. The remarks made by us in the above paragraph in connection with the apparent low incidence of the disease amongst agriculturists, apply even more strongly to this apparent low incidence in rural and semi-rural areas. The hospital being in the town of Lahore, more people from this town, as well as other neighbouring towns with easy means of communication with Lahore, are likely to visit it. In semi-rural areas were included cases coming from small towns with a population of 4,000 to 5,000. They are mostly small market towns and the life in them is mostly on the model of villages. The low incidence of the disease in such areas is only apparent and not real as the population living in such small towns forms only a small proportion of the total population.

Mode of onset.—The figures as regards the incidence of the first symptoms noticed by the patient are as follows:—

TABLE VI
Showing first symptoms

Symptom	Number	Percentage
1. Fever	478	37.3
2. Cough	335	25.7
3. Cough and fever	222	17.1
4. Haemoptysis	123	9.4
5. Pain in chest	61	4.7
6. Pain in abdomen, or diarrhoea, or other abdominal symptoms.	41	3.1
7. Cold and influenza	25	2.0
8. Loss of weight and weakness	9	..
9. Hoarseness	4	..

It may be mentioned that out of these 1,298 cases, 544 suffered from haemoptysis at some time or another—either at onset or later on during the course of the disease.

TABLE VII
Showing duration of the symptoms at the time of visiting the hospital

Period	Number	Percentage
1. Less than 1 month	28	2.2
2. 1 to 2 months	257	19.8
3. 2 to 3 months	178	13.7
4. 3 to 6 months	342	26.3
5. 6 to 12 months	257	19.8
6. Over 1 year	236	18.1

It may be mentioned that many of the patients, when they describe the duration of the illness, mention the period for which they have been ill during their present illness. They have often forgotten their previous attacks, especially if those have been merely of a catarrhal nature—so-called influenza—for they never considered them to be tuberculous in nature. Considered from this point of view, many cases giving a short history may really be suffering from the disease for a long time.

However, if we rely upon the onset as described by the patient it will be noticed that only 36 per cent visited the hospital during the first three months of their illness, and 18 per cent did not visit the hospital till their disease was of at least one year's duration. It may also be mentioned that more than 80 per cent were in an advanced stage (3rd stage—Turban Gerhardt) of the disease before they visited the hospital.

Many of these patients however had consulted private practitioners before coming to the hospital.

Quite a large number, especially out of those coming from the villages, had been under the treatment of vaidis or hakims before visiting the hospital.

The facts that only 2 per cent visited the hospital in the first month of the illness, and only 36 per cent during the first three months, and that 80 per cent cases were in the advanced stage before they visited the hospital, point to the urgent need of propaganda about the early symptoms of disease amongst the public and the necessity of educating the public about consulting a doctor early. Unless the latter point is stressed, simple propaganda about the early symptoms only might create a sort of neurasthenia when any one of the symptoms appeared, and not result in any benefit to the people, which can only accrue if the patients consult a doctor to find out whether the particular symptom is due to pulmonary tuberculosis or some other disease. Such propaganda is moreover necessary, because many patients, before the disease becomes advanced and the symptoms rather troublesome, rely mainly upon vaidis and

hakims. If they knew the importance of early diagnosis, when such symptoms appear they might come straight to the doctor. Of course we should also see that the standard of the training of doctors is such that they are able to diagnose the disease in the early stages, and that, when they are in doubt, diagnostic centres in the form of clinics are available for their aid. Wider facilities as regards x-ray examinations will of course be of great help in this connection and are in reality a necessity if cases are to be diagnosed early by the doctors.

History of contact.—History of close contact with a tuberculosis patient in the family or outside the family was available in 350, or 27.9 per cent of cases. That means that a large number, i.e., 72 per cent, give no history of contact. As about 28 per cent however do give a history of contact, the disease is obviously more common amongst families in which a case of tuberculosis has already occurred. [The reasoning is not clear and the conclusion is unsound.—EDITOR, I.M.G.]

Type of the disease.—There is a considerable difference of opinion as regards the predominant type of pulmonary tuberculosis prevalent in India. While some workers are of the opinion that exudative lesions preponderate, or at any rate are more frequently met with amongst patients in India, than the productive ones, others think that the disease as seen in India is practically of the same type as seen in Europe, i.e., that the productive type of lesions is common and accounts for the majority of cases. It may be that the disease differs somewhat in its characteristics in different parts of India. We are at present preparing detailed statistics on this point based upon an analysis of the histories and skiagrams of patients admitted into the Rai Bahadur Amar Nath Tuberculosis Institute, Mayo Hospital, during 1939, and propose to publish these in a subsequent paper.

In this paper, we propose to give an analysis based only upon an examination of x-ray skiagrams taken in the out-patients' department of the Rai Bahadur Amar Nath Tuberculosis Institute. Seven hundred and forty-six skiagrams were taken for the purpose of diagnosis and finding out the type and extent of the disease. Those who were suspected to be possible cases of pulmonary tuberculosis or some other lung disease, such as bronchiectasis, or those who on physical examination seemed to have tuberculous lesions amenable to collapse therapy, were x-rayed, but on account of the necessity of observing economy in expenditure those who had obvious extensive bilateral tuberculous disease were not skigraphed. Out of these 746 cases 361 turned out to be non-tuberculous (cases of bronchiectasis, bronchitis, lung abscess, etc.), 39 had lesions suspicious of tuberculosis, but not definitely so and are not included in the analysis given below. The rest, i.e., 346 skiagrams, showed definitely tuberculous lesions and are chosen for the analysis.

TABLE VIII
Showing nature of tuberculous lesions in 346
skiagrams

	Number	Percentage
I. Exudative ..	19	5.5
II. Mixed—		
(1) Predominantly exudative.	121	34.9
(2) Predominantly productive.	124	35.8
III. Productive ..	47	13.5
IV. Chronic fibroid ..	20	5.8
V. Pleural ..	15	4.6

Thus 40.4 per cent of the skiagrams showed exudative or predominantly exudative lesions, 35.8 per cent showed a mixture of the productive and exudative type with the former predominating and 19.3 per cent showed either a productive or a chronic fibroid type of lesion.

Sixty-eight cases, or 19.6 per cent had thick-walled cavities. Fresh soft cavities which were very frequent amongst the exudative and predominantly exudative cases have not been included in the list. It may be noted that the corresponding figure for thick-walled cavities in Dr. Sanjivi's analysis is practically the same, i.e., 20 per cent and 12.9 per cent of his cases belonged to the chronic fibro-caseous and chronic fibroid types.

Other studies have however revealed markedly different figures. Dr. Benjamin's (1938) detailed analysis based upon a study of the skiagrams of 2,021 Indian patients admitted into the Union Mission Tuberculosis Sanatorium, Arogyavaram, after 1930, revealed the exudative type to be responsible for 93 per cent of cases and he found thick-walled cavities in only 5.9 per cent.

We must point out certain sources of error in our analysis. As we have already mentioned patients with very advanced extensive lesions were not x-rayed, because of reasons of economy. The majority of such cases were obviously chronic in type and had suffered from the disease for a long time before attending the hospital. A large percentage of them will show thick-walled cavities, and so, in our opinion, thick-walled cavities and other evidences indicating a chronic type of lesion would have been found in a much higher percentage if all cases could be skigraphed.

We may point out that an analysis upon this question based upon cases in any sanatorium is likely to have many fallacies. Some sanatoria are expensive, and the majority of their beds are filled up by rich patients who may show a different percentage of certain types of lesions as compared with the general mass of the population. Other sanatoria and hospitals exert a marked selection when admitting cases, and are not likely to admit the very advanced chronic cases full of cavities, nor the very acute

(Concluded on next page)

LESSER KNOWLEDGE OF HUMAN
TUBERCLE BACILLUS: SEROLOGICAL
AFFINITY WITH ALLERGIC STATES,
VARIATION IN CONTENT, ETC.

By S. D. S. GREVAL, B.Sc., M.B., Ch.B., D.P.H.
LIEUTENANT-COLONEL, I.M.S.

*Imperial Serologist
(From the Imperial Serologist's Laboratory, School of Tropical Medicine, Calcutta)*

THE intention is to draw attention to (i) a complement-fixation reaction of a very high order given by the sera of cases of leprosy and kala-azar with an extract of human tubercle bacillus, (ii) the greater extractable content of the local bacillus, and to make (iii) observations on the similarity and possible associations between tuberculosis, leprosy, kala-azar and syphilis, from an immunological point of view.

Complement fixation in leprosy and kala-azar with an extract of human tubercle bacillus

Many workers going by the group relationship between *Mycobacterium lepræ* and *Mycobacterium tuberculosis* have fixed complement with sera from lepers and an antigen prepared from human tubercle bacillus, during the last 35 years (Eitner, 1906; Cooke, 1919; Lewis and Aronson, 1923; Taylor and Malone, 1924; Raëvsky and Braoul, 1926; Witebsky, Klingenstein and Kuhn, 1931; Brants, 1932; Kornel, 1933; Bier and Arnold, 1935; Rabello and Machado, 1936; Cerqueira and Pereira, 1936; Row, 1938). The writer using the antigen of Witebsky, Klingenstein and Kuhn (WKK antigen) has also evolved a satisfactory technique (Greval, Lowe and Bose, 1939; Greval, Chandra and Das, 1941). The antigen has now been prepared locally (Greval, Das and Sen Gupta, 1941).

(Continued from previous page)

cases. On the other hand, it must be admitted that many cases of the chronic type especially from poor and even middle classes not being able to afford any respite from their work excepting when it is absolutely enforced upon them, often prefer to get occasional treatment when necessary from the private practitioners, or as out-patients of the hospital rather than get admitted into any hospital or sanatorium. An out-patients' department of a hospital or a clinic is likely to supply more reliable data on this point than an analysis based on cases admitted in a hospital or sanatorium, though the latter have obviously got the advantage of supplying more comprehensive information, as detailed histories are available and prolonged observation is possible in such institutions. In my opinion, really reliable and decisive results on this question can only be obtained if a careful analysis is done of cases detected in some widely undertaken survey.

REFERENCES

- BENJAMIN, P. V. (1938). *Indian Med. Gaz.*, 73, 540.
SANJIVI, K. S. (1939). *Ibid.*, 74, 527.

In controlling the reaction with cases of other diseases a surprising fact has come to light, that the reaction with sera from cases of kala-azar is more constant and uniformly of a higher order than that with sera from lepers.

The degree of fixation of complement is comparable to that obtained in the Wassermann reaction of secondary syphilis. It is not likely to be missed or masked by any slight error or irregularity that is likely to creep into a serological procedure.

The antigen is essentially a solution in benzol of the alcohol-insoluble, pyridine-soluble and acetone-insoluble fraction of the human tubercle bacillus. Lecithin is added as a fortifying reagent. The benzol is evaporated and replaced by a much larger volume of saline.

The greater extractable content of the local tubercle bacillus

The only difficulty encountered in preparing the antigen according to the original description given by its discoverers (Witebsky, Klingenstein and Kuhn, loc. cit.) was that the final acetone-insoluble residue did not dissolve in the quantity of benzol recommended. The quantity had to be increased 2 to 3 times. The potency and specificity of the preparation were the same as those of the imported preparation. The conclusion, therefore, emerges that the desired content of the bacillus must be 2 to 3 times the content found in Europe.

The cultures of the bacillus were grown in the laboratory of Dr. A. C. Ukil in the Institute of Hygiene and Public Health, Calcutta.

Similarity and possible associations amongst leprosy, kala-azar, tuberculosis and syphilis, from an immunological point of view

Leprosy and tuberculosis.—The causative organisms of both the diseases belong to the same group. Does one of them sensitize a patient for the other? Is leprosy more likely to develop after the 'first infection' of tuberculosis? Is the reaction of the lepers' sera with WKK antigen a reaction of group specificity? Does a similar reaction occur in some cases of tuberculosis after the 'first infection'? Or is the reaction indicative of an allergic state in which the reacting substance, an 'auto-antibody' (like the substance reacting in the Wassermann reaction of syphilis), has been formed in the patient's system against his own tissue attacked, damaged and denatured by the organism (demoralized, after the technique of fifth columnists) but not destroyed (killed outright, after the technique of old fashioned invaders)? These questions are suggested by the reaction of the serum.

Leprosy and kala-azar.—The serum reactions with WKK antigen of both the diseases are identical. Is kala-azar too superimposed on the allergic state of tuberculosis? Or, again, is the reaction in kala-azar merely indicative of an allergic state producing an auto-antibody?

Why should the auto-antibodies produced in leprosy and kala-azar be identical and different from that of syphilis?

Leprosy, kala-azar, tuberculosis and syphilis.—Both kala-azar and leprosy produce occasionally an auto-antibody like that produced in syphilis and are thus responsible for positive Wassermann reactions which are false (Greval, 1928; Greval, Sen Gupta and Napier, 1939). Eosinophilia with or without association with tuberculosis also occasionally produces an auto-antibody like that of syphilis (Greval, 1940). The association between eosinophilia and pulmonary tuberculosis, however, may be remote, if not fictitious (Frimodt-Möller and Barton, 1940).

A speculation concerning mycotic infections.—Do these infections, causative organisms of which are genetically allied to the mycobacteria, sensitize a patient for tuberculosis, leprosy or kala-azar? They and leprosy are favoured by similar meteorological conditions.

Summary

1. Sera from cases of leprosy and kala-azar fix complement with an extract from human tubercle bacillus.

2. The alcohol-insoluble, pyridine-soluble and acetone-insoluble fraction of the local human tubercle bacillus, responsible for complement fixation appears to be greater than that of the imported European bacillus.

3. The auto-antibodies formed in tuberculosis, leprosy, kala-azar and syphilis show associations, close and remote.

[Note.—Attention is drawn to a letter on page 637 of this issue on the subject of the specificity of the WKK reaction in leprosy.—Editor, I. M. G.]

A Mirror of Hospital Practice

A CASE OF ETHER CONVULSIONS

By W. McN. NIBLOCK, F.R.C.S.
 CAPTAIN, I.M.S.

Second Resident Medical Officer
 and

D. B. SET, M.B.

Resident Anæsthetist, Presidency General Hospital, Calcutta

This case is of interest because ether convulsions appear to be a rare occurrence in this country, and we are not aware of a case having been recorded previously in any Indian medical journal.

At 1.45 p.m. on 22nd May, 1941, No. 3573 Pte. E. A., aged 19 years, was admitted to the Presidency General Hospital with the typical history and signs of acute mastoiditis of about a week's duration; there was a profuse pulsating discharge from an anterior perforation in the right drum, œdema of the roof of the external auditory meatus, and œdema of the mastoid process had pushed the pinna downwards and forwards. The temperature was 101.6°F., pulse 72 and respirations 24.

At 2.5 p.m. he was given an injection of atropine gr. 1/100 combined with inj. hyoscine. co. A (B. W. & Co.), and prepared for operation. At 2.45 p.m. anaesthesia was induced by chloroform and ether mixture, going on to ether by the open method. After about six ounces had been given in this way, a Boyle's apparatus was brought into use, and ether-oxygen mixture was given during the actual operation. A further two ounces of ether was expended in this way, making a total of about eight ounces for the whole anæsthetic.

The operation was begun at 3.0 p.m.; there was considerable oozing of blood from the operation area throughout the operation, pus escaped freely as the mastoid cells were opened, and exposure of the lateral sinus revealed granulations upon its wall. Work on the mastoid had just about finished when the patient went into a typical ether convulsion. The muscles of the face, arms and legs began twitching, the movements soon changing to clonic convulsions. Respiratory movements stopped, the pulse became soft, and it was noticed that the free oozing in the wound stopped and the tissues became cyanotic.

The flow of ether was stopped and a full dose of evipan successfully given in spite of the strong movements of the patient's arm. After five minutes morphia gr. 1/6 was given hypodermically. The convulsions

subsided after about another two minutes, and the patient's general condition became normal. The wound was dressed and the patient sent back to the ward at 3-45 p.m. After operation the temperature was 104.2°F., pulse 140, and respiration 30. At 10-0 p.m. the temperature was 101.6°F., pulse, 108, and respiration 24. Intensive sulphapyridine therapy was started on the same evening, and the patient's temperature and pulse rate became normal within 30 hours. Thereafter his progress was rapid and uneventful.

The operating theatre was equipped with a Frigidaire dehumidifier, and at the end of the operation the thermo-hygrometer readings were: temperature 84°F. and humidity 74 per cent. The readings at Alipore at 5-0 p.m. on that day were: maximum temperature 90°F. and humidity 76 per cent.

The control of ether convulsions

One of us (W.McN.N.) had previously seen three cases of ether convulsions in England. They were of equal severity to the case described, and were successfully controlled by the intravenous injection of morphia grain $\frac{1}{4}$.

The favourable report on the use of evipan by Bailey (1940) led us to try it in our case, and there was no doubt as to the success of this measure. The rapidity of its action appeared to be about the same as that of intravenous morphia, and it gave rise to no after-effects. It is hardly necessary to add that before intravenous drugs are tried the ether should be discontinued and oxygen, with 5 per cent carbon dioxide added, if desired, administered through an efficient airway. Also the degree of shock, always present in these cases, must be taken into account before intravenous therapy is used. To continue the anaesthetic with chloroform instead of with ether, as has been recommended in the past, is to court disaster. Hall (1940) issues this warning: 'It seems probable that more deaths have resulted from the various forms of treatment applied for this condition than for the condition itself'. Finally it should be remembered that only fresh ether should be used for anaesthetic purposes, and the ether chamber of all forms of anaesthetic apparatus emptied after use.

Aetiology of ether convulsions

The aetiology of this condition is still not fully understood. At least thirty-three factors have been suggested by various writers, some being contradictory (Lundy, 1937). The report of a case of ether convulsions accompanied by suggestions as to its causation seldom fails to stimulate a lengthy and often acrimonious correspondence on the subject (Pinson, 1927; Taylor and others, 1938; Nosworthy and others, 1937; Newton-Andrews, 1940; Logan, 1941).

The consensus of opinion seems to be that ether, or possible impurities in it, is not alone responsible for the condition. Some other factor or factors are associated. It is unjustifiable, on the strength of a single case, to try and prove that the infrequency of ether convulsions in India is due to the absence of any particular factors. But we suggest that two factors may point the way to solution of the problem.

One is that there is a difference in the relation between the patient's body temperature and local meteorological conditions in India, where ether convulsions are rare, and in temperate climates, where ether convulsions are more common. The other is that India is relatively ill-equipped with apparatus for the administration of closed or semi-closed anaesthesia, whereas these methods have been in fashion in Europe for about twenty years, coinciding with an increase in the incidence of ether convulsions.

Summary

(1) A case of ether convulsions, successfully controlled by the administration of evipan, is recorded.

(2) Factors are suggested to explain the rare occurrence of this condition in India.

Permission to publish this case was kindly given by Major G. B. Walmsley Fisher, I.M.S., Acting Surgeon Superintendent, the Presidency General Hospital, Calcutta, and by Captain V. M. Albuquerque, M.B.E., I.M.S., Surgical Specialist, P. and A. District.

A CASE OF IMPERFORATE EXTERNAL URINARY MEATUS

By A. C. ROY, M.B.

Charitable Dispensary, Balagaria, Midnapore

RECENTLY I was called to see a new-born male child who had not passed any urine since birth about 72 hours previously.

The baby was quiet and there was no bulging of the lower part of the abdomen suggesting distension of the bladder.

On examination no external urethral opening could be found. In the normal position of the external meatus a slight depression was present. The prepuce was short and curled up at the corona glandis. The glans penis was bare and not covered by the prepuce. No other abnormality was detected in the child.

A small incision was made along the depressed area and a thick membrane was incised and an opening was found. A fine rubber catheter was introduced through the opening and it went right into the bladder and about 2 drachms of high-coloured urine was drawn out.

The history of passage of urine *per anum* prior to operation could not be elicited. Therefore the existence of any communication between the bladder and the rectum could not be ascertained.

The baby is now perfectly well and is passing urine through the normal channel.

Indian Medical Gazette

OCTOBER

THE SPECIAL TUBERCULOSIS NUMBER

THIS month we are publishing our fifth special tuberculosis number. As in previous years we have received the help of a sub-committee of the Tuberculosis Association of India for collecting and selecting the articles for publication. All the original articles in this number have been approved by a committee consisting of Drs. C. Frimodt-Möller, the medical commissioner of the Tuberculosis Association of India, A. C. Ukil and B. K. Sikand, and all the matter forwarded by this committee has been included in the number. The committee wishes it to be known that approval for publication does not necessarily mean that they place their seal of personal or official approval on everything that has been written by the contributors or that they identify themselves with the views expressed, for they wish the number to be representative of expert opinion in India generally, not only of that of one body.

The outstanding feature of the year in the tuberculosis scene in India was the opening on 21st May of the Lady Linlithgow Tuberculosis Sanatorium, at Kasauli, by Her Excellency the Marchioness of Linlithgow, President of the Tuberculosis Association of India; thus has come true a dream that Lady Linlithgow has cherished since she launched her appeal for the King-Emperor's Anti-Tuberculosis Fund in 1937. A tuberculosis sanatorium with 112 beds will not solve India's tuberculosis problem, nor when it has expanded to its full scope of 250 beds will it be able to accommodate even one in ten thousand of the country's tuberculous subjects, but we should not be surprised if future medical historians did not single out this event as the real beginning of the solution of this terrible problem. The sanatorium is to be the centre in India for teaching and research in tuberculosis; both are urgently needed, perhaps the former even more than the latter.

modes of transport, with the ever-increasing immigration of the people from the rural to the urban and industrial areas in search of work, and with the insanitary conditions and low standards of living that prevail, the disease has made rapid strides within the last two decades. It is now not only prevalent in most of the towns in India but also in many rural areas. It is estimated by some workers that there are over 3 million cases of tuberculosis in India and that not less than 5 lacs of people die of the disease every year. This may be an over- or an under-estimate, but the fact remains that the disease is responsible for enormous mortality and morbidity in the country.

All the provinces in India have a tuberculosis problem and its importance is in no way less than that of any other public health problem, with perhaps the single exception of malaria. In the past, tuberculosis was regarded as a disease more common in western countries than in India but to-day it causes more deaths in India than in any of the western countries. The total annual deaths from tuberculosis in the United States of America is only 80,000, in Great Britain 30,000, in France 67,000, in Italy 60,000, in Germany 56,000, but in India it is over 500,000. A comparison of the deaths from tuberculosis in a few of the important cities in India and elsewhere will further emphasize its public health importance.

Tuberculosis deaths per 100,000 population

Another very regrettable aspect of the tuberculosis problem in this country is that the disease collects the heaviest toll from the adolescents of both sexes—the period of increasing activity and usefulness. The economic loss to the country consequent on the illness and death is thus enormous. It is on account of the increasing morbidity and mortality from the disease that a profound interest is now being shown all over the country for fighting this great scourge of civilization.

In a campaign against tuberculosis, the first thing to be realized is that considerable sums of money are required to fight it successfully. For a country like India and for a problem of the magnitude of the Indian tuberculosis problem, several crores of rupees will be needed annually and improvements in diverse directions will have to be effected before lasting good can result. An idea as to the enormous sums of money required for successful control work can be gained from the table below which gives the amounts spent by some of the western countries on anti-tuberculosis measures during 1928.

TUBERCULOSIS AS A PUBLIC HEALTH PROBLEM IN INDIA

TUBERCULOSIS is one of the most urgent public health problems in India. Although tuberculosis is by no means a new disease in this country, at no time in the history of India has it been so widespread and so devastating in its effects as it is at the present time. With the development of industries all over the country and the introduction of rapid

	Deaths from tuberculosis	Number of fresh cases	Total cases	EXPENDITURE	
				Total	State
Germany ..	55,672	146,246	?	50 to 60 million marks	30 to 35 million marks
England ..	36,623	77,881	350,000	£3,013,530	£1,613,962
France ..	60,000	100,000	?	360 million francs	87 million francs
Italy ..	60,000	59,000	?	290 million lire	45 million lire
India ..	500,000	?	3,000,000	?	?

The question that naturally arises is how can India obtain the requisite money for her campaign against tuberculosis? In the western countries the money for anti-tuberculosis schemes has been obtained not only from the state's coffers but also from private sources. The latter in fact has been repeatedly shown to be the mainstay of all anti-tuberculosis schemes. So far as India is concerned voluntary contributions have not been forthcoming to the requisite extent. Even after the lead given recently by Her Excellency the Marchioness of Linlithgow in starting the King-Emperor's Fund, the response, though good, has not been as generous as it could have been. Until and unless private donations pour in freely from all sides it will not be possible for the state to draw up a definite policy or programme best suited to the needs of the country.

When the time for starting a comprehensive campaign comes, as it surely will some day, the following questions will have to be considered and properly answered before formulating any plan and putting it into operation:—

(i) What is the extent of infection and disease in the country, and what are the special factors that are responsible for the increase in tuberculosis? (ii) What are the causes of decline in tuberculosis mortality in other countries and how may the problem be tackled in India in the light of the experience of others? (iii) What is the minimum programme of administrative preventive measures to be adopted? (iv) How can funds be obtained for anti-tuberculosis schemes?

The answer to the first question can be given only by conducting proper tuberculosis surveys in all affected areas, as recommended by the Tuberculosis Survey Committee of the Indian Research Fund Association (1940). With regard to questions 2, 3 and 4, the League of Nations' inquiry (1932) into the prevention of tuberculosis has provided appropriate answers. Their conclusions can be summarized as follows:—

Tuberculosis has declined with advancing civilization and improved well-being. It can be measured in terms of the increase in the purchasing power of wages of earning members. It is directly correlated with better food, housing, cleanliness, sanitation and education. As tuberculosis is essentially a social disease,

anti-tuberculosis campaigns are amongst the activities of social hygiene. Administrative preventive measures must utilize for purposes of detection, isolation, disinfection, and treatment, special agencies such as legislation, dispensaries, hospitals, sanatoria, preventoria, school medical inspection and health insurance. The driving power for anti-tuberculosis work must come from the state. Money must be amply provided, not only from the state but also from private donations, special taxation and suitable schemes of health and invalid insurance. The state must act as the co-ordinating agency directing the entire scheme.

The report of the Public Health Commissioner with the Government of India for the year 1932 states:—

'The only organization solely concerned with anti-tuberculosis work in India is the King George's Thanksgiving Anti-Tuberculosis Fund. This organization is ill-equipped financially and is mainly concerned with propaganda work. It may as yet be said to have only engaged in preliminary skirmishes with its subtle enemy and it is difficult to see how it can do more, until ample funds are provided in every province. But it must be realized that the way to victory does not lie, except in small part, in the provision of clinics, hospitals and sanatoria. Money spent on such institutions will be money largely wasted unless the social factors involved are studied and then attacked with vigour. In the practice of more hygienic methods of living, in the provision of ample nutritious food supplies and generally in wider appreciation of the dangers inherent in harmful social practices, will be found the way to a gradual decrease of this scourge of civilization and generally to a healthier and happier people.'

From these quotations it will be clear that the main problem in tuberculosis is socio-economic, and the remedy lies not only in the hands of the state but also in the hands of the people. Solution of the socio-economic problem will not only help indirectly to reduce the incidence of tuberculosis, but also result in the reduction of many other preventable diseases.

K.

In announcing this special tuberculosis number, we included, in all good faith, Dr. C. Frimodt-Möller's name amongst the contributors. We were at the time unaware of Dr. Frimodt-Möller's sudden serious illness from which we are glad to be able to announce that he has now almost completely recovered. It is a matter of very great regret to us that this number will appear without a contribution from India's outstanding pioneer in anti-tuberculosis work.

Special Article

RECENT ADVANCES IN OUR KNOWLEDGE ABOUT VITAMIN B₁

By N. C. DATTA

Assistant Professor of Biochemistry, Grant Medical College, Bombay

'CHEMISTRY has been of immense service to medicine and other biological sciences'. There has been an extension of knowledge in all its branches but in none have there been more spectacular discoveries than those in the field of biochemistry. Modern technique is effecting in quick succession the isolation and the synthesis of many of the accessory food factors more commonly known as vitamins. Many of these synthetic products have been put into medical practice and vitamin therapy has now been extended to all branches of the pathological field. It is, however, 'in the wider field of preventive medicine that the newer knowledge about the vitamins is proving of greatest value'.

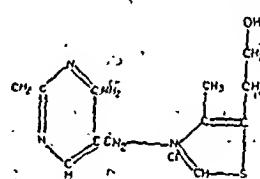

Isolation and identification of vitamin B₁

Vitamin B₁ is the most well-defined constituent of the vitamin-B complex. The existence of this vitamin was suspected by Eijkmann nearly forty years ago when his classical researches on the relation between experimental polyneuritis and human beri-beri were in progress. The earlier researches of Eijkmann, Fraser, Stanton, and Funk showed that a substance was present in rice polishings which protected animals against disorders characteristic of beri-beri. Although the early attempts on the isolation of the anti-beri-beri substance were marked in many instances by over-enthusiasm, the search for the active constituent of rice polishings was destined to last for a quarter of a century owing to the inherent difficulty of the problem.

The chemical investigations on the isolation of vitamin B₁ led workers to believe that they were dealing with a comparatively simple substance. Funk (1911) isolated from rice polishings a crystalline substance which he believed to be the salt of anti-beri-beri vitamin. From a study of its properties he placed the compound in the class of pyrimidine bases, but before long fears were expressed that the compound was not pure but contaminated with a varying proportion of the vitamin. In 1926, the position was radically altered by the announcement that two of Eijkmann's successors in the medical service of the Dutch Indies, Drs. Jansen and Donath (1926), isolated from rice polishings a few milligrams of highly active crystalline hydrochloride of the free base having the formula C₁₂H₁₀ON₂. Most of the other workers who repeated the method of isolation described by the Dutch investigators were successful, wholly or in part, in confirming the essentials but failed to establish the purity of the crystalline hydrochloride.

A profound sensation was caused when Windaus and his associates (1931, 1932) at Gottingen obtained a crystalline material with practically the same potency but differing in chemical composition. Analytical results revealed the presence of sulphur in the compound having the formula C₁₂H₁₇ON₂S. The presence of sulphur in similar products was confirmed and proof was adduced that the preparation of Jansen and Donath also contained sulphur. The serious differences in analytical results led one to suspect that all the preparations were not of uniform composition. The absorption spectra of various crystalline preparations strongly indicated that the best crystalline products were not homogeneous and that the vitamin had not been isolated.

A successful attack on the problem began with the work of Williams *et al.* (1930), who in 1935 developed a method for obtaining a consistent yield of the vitamin. They obtained approximately 5 grammes per ton of rice polishings which is about 25 per cent of the total amount present. A study of the chemical behaviour of the substance resulted in the elucidation of the nature of vitamin B₁ and eventually to its synthesis. It is now definitely known that the molecule of vitamin B₁ is built of the two-ring system, namely a pyrimidine ring and a thiazole ring, having the following structural formula:

Vitamin B₁ is now made synthetically in the laboratory from simpler compounds and is prepared in quantities corresponding to thousands of tons of rice polishings at a price much cheaper than the natural substance in the pure state.

The extraordinary achievement of the chemists in effecting the decomposition of the vitamin isolated from rice polishings and then in building up a complex molecule from relatively simple organic compounds identical with the natural product having only 'the right atoms of the right elements in just the right places', is matter of admiration and furnishes an excellent illustration of the spirit of organic chemistry.

Nomenclature.—In the older literature, the term 'anti-beri-beri' or 'anti-neuritic vitamin' was most commonly employed. In more recent literature vitamin B₁, aneurin (Jansen), or thiamin (Williams) are used. Aneurin seems to be the name preferred in Europe, whereas in the United States workers have adopted the name thiamin.

The principal effects of vitamin B₁ deficiency.—Animals deprived of vitamin B₁ show a number of symptoms of disordered function. Our knowledge about the nature and symptomatology of vitamin-B₁ deficiency was derived mostly from observations on beri-beri in man and polyneuritis in pigeons. The cardinal symptoms of vitamin-B₁ deficiency are degeneration of

nervous system, cardiac enlargement and dysfunction, oedema, gastro-intestinal disturbance, muscular atrophy and anorexia'.

A number of neuritic symptoms which arise in the deficiency of this vitamin have been attributed to nerve lesions, but are more probably due to functional interference owing, perhaps, to the accumulation of metabolic products, especially pyruvic acid, resulting from imperfect carbohydrate metabolism. Some of the nervous symptoms frequently encountered in patients with beri-beri are a feeling of numbness and a tingling sensation like pins and needles, usually associated with a gnawing pain in the arm, especially at night. Nervousness, loss of memory and a feeling of despondency are frequently observed.

Deficiency of vitamin B₁ causes disturbances of the gastro-intestinal system which include anorexia and is accompanied by hypochlorhydria and lack of tone of the muscles of the gut.

Anorexia or loss of appetite is one of the first observable and the most outstanding symptoms of vitamin B₁ deficiency. Many of the symptoms which were formerly believed to arise directly from the lack of this vitamin are in fact attributable to the wastage consequent on the partial starvation due to loss of appetite. It is assumed that interference with the intermediary metabolism of carbohydrate, due to deficiency of vitamin B₁, is the essential factor for the loss of appetite.

Cardiac enlargement is the characteristic of human beri-beri. Aalsmeer and Wenckebach (1929) have shown that the common cause of death in beri-beri is the failure of the right side of the heart and have ascribed it to the oedema of the heart muscle. The nature of the affection may be water retention with consequent swelling rather than a true hypertrophy. Newcomb (1930) was unable to note any significant increase in water content of the cardiac muscles from cases of human beri-beri and pigeon polyneuritis as required by the hypothesis that the large heart in beri-beri is due to water retention.

Birch and Mapson (1936) studied the action of adenine nucleotide on the heart of normal and vitamin-B₁-deficient animals. They succeeded in increasing further the bradycardia already present, due to deficiency of this vitamin, by injection of small amount of adenosine or adenylic acid from the muscles or yeast. Vitamin-B₁-deficient animals appear to be more sensitive to the action of these compounds and at the same time unable to render them innocuous at the same rate as the normal. These authors believe that the observed bradycardia is due to failure in the deaminase mechanism, resulting in an increased accumulation of adenylic acids in the tissue. It is known that by the process of deamination, adenylic acid is converted into ammonia and inosinic acid which have little or no effect on cardiac muscles.

There are a number of other indefinite symptoms which arise in deficiency of this vitamin. Human beri-beri is frequently accompanied by oedema. It is probable that dietary deficiencies other than those of vitamin B₁ are related to this condition.

Retarded growth often accompanied by vomiting, decreased appetite, constipation with other gastro-intestinal disturbances, restlessness, pallor, a whimpering whining cry, unhealthy and scanty hair, represent the true picture of a marasmic child and may frequently arise and be due to a deficiency of vitamin B₁.

Clinical manifestations of typical and characteristic deficiency of vitamin B₁ are very rare. A number of causes other than deficiency of vitamin B₁ operate at the same time and contribute to the clinical picture ordinarily seen in vitamin-B₁ deficiency. We have, therefore, no accurate means of detecting borderline degrees of deficiency of this vitamin by clinical examination. By proper chemical and clinical findings it has now become possible to study with more precision the biochemical significance of separate factors. There are now good reasons to believe that vitamin B₁ stands in reasonably clear-cut definition in regard to the part it plays in the animal organism.

Cause of vitamin B₁ deficiency.—The deficiency of vitamin B₁ may be due to diminished intake of the chief natural sources of this vitamin, such as milk, potatoes, bread, egg (yolk only), peas, liver and nuts, or it may be that the vitamin present in those foods is lost in the process of cooking. The vitamin is extremely soluble in water, and consequently a considerable proportion of this vitamin is lost if the water in which these foods are cooked is discarded. Besides, the vitamin cannot withstand heating to a high temperature.

In attempting to settle the question of the intake of vitamin B₁, particular attention must be paid to the intake of those foodstuffs which though low in vitamin B₁ are taken in relatively large amounts. The most important foodstuffs in this connection are cereals and their refined products. In using the refined products, it must, however, be remembered that mechanical separation of the starchy part of the cereals from germ and bran coats leads to almost complete loss of vitamin B₁. Polished rice, white wheat flour, white bread, and pearl barley consequently contain only traces of vitamin B₁.

Even when the amount of vitamin B₁ in the diet is adequate, deficiency of vitamin B₁ may arise as a result of diminished absorption and utilization from the alimentary tract. Any form of chronic diarrhoea, such as ulcerative colitis or dysentery, that interferes with normal absorption of vitamin B₁ may be associated with signs of deficiency.

Increased demand.—Vitamin B₁ is not stored to any large extent in the body so that the body requirement of this vitamin must always be dependent upon a regular intake. The minimum

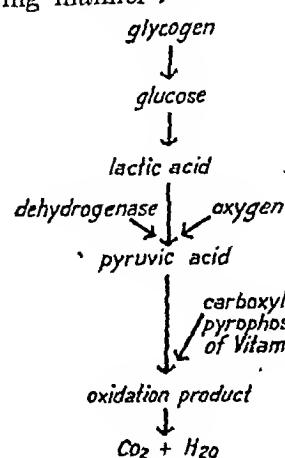

amount of vitamin B₁ required by the body is determined by the basal metabolic rate (BMR). Anything that raises the BMR will also increase the requirement of the body for vitamin B₁. Increased metabolism as a cause of vitamin B₁ deficiency is of considerable practical importance. Prolonged pregnancy, lactation and rapid growth, may each participate in clinical manifestation of deficiency if the diet contain vitamin B₁ just adequate for the minimum ordinary requirement.

The dangerously low intake of vitamin B₁, prevalent amongst the population of this country, together with the changing views regarding the serious possibility of deficiency of this vitamin, raises some interesting questions, the solution of which is of great practical importance to the general health and welfare of the public.

Physiological rôle of vitamin B₁.—Vitamin B₁ appears to be a catalyst for carbohydrate metabolism. Emphasis has been laid from time to time in clinical and laboratory work on the importance of carbohydrate intake and metabolism in the aetiology of beri-beri. Lewinson (1937) noted that vitamin-B₁ deficiency causes a derangement of carbohydrate metabolism which precedes the nervous disturbance and is manifested as hyperglycaemia. This derangement of carbohydrate metabolism has been attributed on the one hand to reduction in the amount of oxidizing enzymes, and on the other to inanition. The important contribution of Peters (1936) at Oxford has helped greatly to resolve in a highly satisfactory manner a somewhat conflicting state of affairs and has revealed for the first time the site and character of the biochemical lesions in experimental polyneuritis. The first important observation of a definite increase in lactic acid in the brains of polyneuritic pigeons and the subsequent discovery that the brain tissue of such pigeons exhibits a lowered oxygen consumption suggested that the symptoms in the pigeons might be associated with a failure of the oxidative mechanism of the brain. The addition of vitamin B₁ *in vitro* to such tissues restores the oxygen consumption of the brain of affected birds to normal levels, while at the same time the "accumulation" of lactic acid disappears. This led to the hypothesis that vitamin B₁ plays an active rôle in tissue oxidation and is quantitatively related to the metabolism of lactic acid. Subsequently, with the discovery by Peters and Sinclair of a colour reaction of pyruvic acid, it was demonstrated that pyruvic acid accumulates in the brain of vitamin B₁ deficient pigeons. Peters more recently discarded the lactic oxidase theory and concluded that 'vitamin B₁ is related specifically to pyruvic acid oxidase in its aerobic reaction'. In the absence of vitamin B₁, therefore, a block in glucose metabolism occurs at the pyruvic acid stage.

The fundamentally important discovery made by Lohmann and Schuster (1937) that in the form of a compound with pyrophosphoric acid

vitamin B₁ acts as a co-enzyme of the system that breaks down pyruvic acid in the living tissue, strengthens the view that vitamin B₁ is indispensable in the metabolism of carbohydrate. This can be shown schematically in the following manner :—

The efficiency of the pyruvate-metabolizing mechanism is lowered in the absence of vitamin B₁, with the result that the amount of pyruvate in the blood tends to rise. An estimation of the amount of pyruvic acid in blood and also the determinations of bisulphite-binding substances of the blood, cerebro-

spinal fluid and urine, such as pyruvic acid and methyl glyoxal, as suggested by Platt and Lu (1936), may be useful as a criterion in the diagnosis of vitamin B₁ deficiency.

The thiochrome reaction, which permits measurement of the fluorescence of partially oxidized thiamin, first observed by Peters and studied further by Jansen (1936), is now being most extensively employed for the estimation of vitamin B₁ in body fluids. The extent of the body's 'reserve' of vitamin B₁ is determined by estimation of vitamin B₁ in the urine. The urinary output has been found to be dependent upon the past intake, being low in beri-beri and in conditioned deficiencies associated with alcoholism, pregnancy, gastro-intestinal obstruction or faulty absorption. It seems probable that in the immediate future we shall be able, by means of these tests, to learn the limit of vitamin-B₁ concentration compatible with health. As suggested by Orr (1940) these tests may also give us an indication of the extent to which pathological symptoms noted on clinical examination may be attributed to deficiency of vitamin B₁.

Relationship between vitamin B₁ and thyroid.

—It has been definitely established that vitamin B₁ plays a direct part at least in one phase of carbohydrate metabolism. It is not surprising, therefore, to find a close relationship between vitamin B₁ and thyroid because of the marked effect of the gland on carbohydrate metabolism. Bernheim (1940) cited a number of references of experiments on animals to show clearly that vitamin B₁ counteracts the toxic action of thyroxin, prevents weight loss and loss of liver glycogen in thyroid-fed rats and is helpful in the pre-operative treatment of Graves' disease.

Interaction of vitamin B₁ with acetylcholine-

Interaction of vitamin B₁ with acetylcholine.—Acetylcholine is produced at most synapses and myo-neural junctions, and it is quite natural, therefore, that a disturbance in acetylcholine metabolism will be reflected in the tissues supplied by the cholinergic nerves. As suggested by

Bernheim there exists the possibility that, because of physical conditions, or local concentration effects, vitamin B₁ *in vivo* does control the activity of the enzyme cholinesterase which specifically hydrolyses acetylcholine. The interaction between vitamin B₁ and acetylcholine can offer a possible explanation for the cardiac and gastro-intestinal symptoms of vitamin B₁ deficiency, symptoms which can be relieved temporarily by choline esters. Also part of the protective effect of vitamin B₁ in hyperthyroidism may be, according to Bernheim (1940), due to its inhibiting action on the serum cholinesterase, which has been observed by Antopol *et al.* (1937) to be higher than normal in patients with this disease.

The therapeutic uses of vitamin B₁.—The synthesis of vitamin B₁ in 1936 has accelerated clinical investigation and made possible the application of the synthetic product in the treatment and cure of diseases which are believed to arise from deficiency of vitamin B₁. Because of its anti-neuritic properties, vitamin B₁ has been suggested for the treatment of a host of conditions varying from systemic diseases to diseases of the nerve tissues *per se*. The synthetic product has been used with considerable success in the treatment of beri-beri and of acute neuropathy associated with pregnancy, pellagra, and chronic alcohol addiction.

Beri-beri in its severe form affects the peripheral nervous and cardiovascular systems. Spies and others (1940) suggest that 'the administration of vitamin B₁ hydrochloride to persons with acute beri-beri relieves the cardiovascular disturbances, induces improvement in response of muscles innervated by affected peripheral and cranial nerves, restores the normal electrical conductivity of peripheral nerves, relieves gastro-intestinal dysfunction resulting from vitamin-B₁ deficiency, increases carbohydrate tolerance and decreases the bisulphite-binding substances in the blood. In milder cases where typical clinical symptoms do not appear, vitamin B₁ improves appetite and strength as well as the feeling of general well-being of the patients. It is believed that vitamin B₁ is most useful in clearing up efficiently the early disorders caused by the deficiency of vitamin B₁ and without which the conditions would probably remain chronic.'

The polyneuritis of pregnancy is probably a dietary deficiency disorder and has its origin in associated factors among which are anorexia and vomiting of pregnancy. The rational therapy should aim at provision of deficient nutrients, more especially vitamin-B complex.

Lewy *et al.* (1940) confirmed the premise that the incidence of neuropathy which is common among pellagrins is caused by the deficiency of vitamin B₁. Intravenous administration of 50 mg. or more of phosphorylated vitamin B₁ (co-carboxylase) was followed by quantitative improvement in the electrical irritability of a number of muscles of seven out of nine of these pellagrins. Improvement was also noted in the

pupillary and corneal reflexes and in the sensitivity to touch and pin-prick. The clinical effect of co-carboxylase was found to be identical with that of vitamin B₁.

Vitamin B₁ is specific in alcoholic neuritis. There seems to be a variable threshold at which alcoholic neuritis may arise. This may be dependent upon the state of the gastro-intestinal tract and the degree to which the absorption of vitamin B₁ is prevented by gastritis which is associated with low alcohol consumption. An early diagnosis of alcoholic neuritis is important and should always be looked for in the absence of high alcohol intake. Polyneuritis of chronic alcoholism is usually traceable to shortage of vitamin B₁, consequent on reduced food intake. Alcohol has a high calorific value. The direct relationship between the calorie intake and the vitamin B₁ requirement constitute the basis for the explanation of the efficacy of vitamin B₁ in the prevention and cure of alcoholic neuritis.

Vitamin B₁ has been tried in a wide variety of cases of inflammatory and degenerative diseases of the central nervous system. There are references to herpes zoster being tried with vitamin B₁ hydrochloride. Herpes zoster is an inflammatory disease, but its many similarities to conditions which are said to respond favourably to treatment with vitamin B₁ led Rattner and Roll (1939) to try vitamin B₁ for the pain of herpes zoster. Investigation on 16 cases showed that the treatment gave indifferent results.

Vitamin B₁ has also been used to relieve rest pain of ischaemic origin. Vitamin B₁ is now considered essential for tissue metabolism. Attempts have, therefore, been made by Naide (1939) to decrease pain by supplying tissues deficient in blood with vitamin B₁, the absence of which cause disturbance of nerve function resulting in pain. The principle is based on the assumption that injection of large quantities of vitamin B₁ into the blood stream may raise the blood concentration of vitamin B₁ to such a level that even reduced blood supply in ischaemic areas would maintain an adequate vitamin-B₁ content of such disease.

The application of the results of investigations to the cure of deficiency diseases has yielded such striking results that 'therapeutic dietetics has become an important branch of medicine'. Specific therapy in the form of synthetic products induces more rapid remission of symptoms and assures more certain recovery. Vitamin B₁ may be administered either orally or parenterally, but according to Spies *et al.* (1940), the latter method is to be preferred because of the greater ease of giving large doses and the rapid improvement which follows. Although there is indication of the therapeutic use of synthetic vitamin B₁ in a large number of cases, yet indiscriminate use is not consistent with the interest of patients.

GOVERNMENT OF INDIA'S ARP PROPOSALS

THE composition of certain air raid precautions, services and instructions for the disposition, establishment and equipment of ARP control and report centres, depots and wardens' posts are laid down in a letter which has just been sent by the Government of India to all provincial governments and the Chief Commissioners of Delhi and Baluchistan.

The Government of India have laid down scales of establishment differing in accordance with the geographical position and importance of the town.

The 'nerve centre' of the ARP system is the control centre, which in every large town will be attached to one of the report centres. The combined control and report centre is the headquarters of the ARP controller, to which all reports of damage and requests for assistance come through the agency of the warden service and of the heads of each of the ARP services—the messenger, warden, rescue, ambulance and first-aid services.

Here is a brief description of the organization of these services:

The control and report centre comprises control, message and rest rooms, an air raid shelter, sleeping and messing accommodation. In the control and message rooms are located direct-line telephones to military headquarters, the headquarters of the district or the provincial government, fire brigade and police; and exchange lines, where possible, to warden posts.

The number of report centres to be set up in a town is governed by the number of wardens' posts. One report centre, even under severe raiding conditions, can cope with the traffic of 50 warden posts, provided the wardens are trained to send only essential messages. The number of personnel required to 'man' a report centre varies with the number of wardens' posts under its control. Thus, a report centre in a town in which

there are 50 wardens' posts would need a staff of 24, while a smaller warden service would need only 12.

The staff of a report centre comprises an officer in charge, intelligence and plotting officers, chart writer, tallyboard clerk, message clerk, clerks to assist the controller and heads of the ARP services, record clerk, message superintendent and messengers and telephonists. In towns in which the personnel of these report centres are to be paid, there will be two 'shifts' and Government have decided that a reserve of personnel of 100 per cent is to be trained.

MESSENGER SERVICE

The next link in the chain is the outdoor messenger service, which provides alternative means of communication, should the telephone service break down, between the report centre and the wardens' posts, first-aid posts and ARP depots.

It is hoped that the boy scouts organization will give every assistance in providing messengers. Four messengers will be needed for each control and report centre, one for each first-aid post, one or two for each warden's post, two for each ARP depot, ambulance and other service. In addition a reserve of 50 per cent is to be enrolled and trained.

AIR RAID WARDENS

The unit of organization in the warden service is the warden's post. There will generally be four wardens for every 500 of population.

The wardens' post is where wardens allotted to the sector served by the post assemble when a warning is sounded, and from where they send their messages to the report centre. The post consists of a message room capable of affording protection against blast, splinters or the fall of debris, a store for equipment, a small shelter and, in certain towns, sleeping accommodation for wardens.

In densely populated areas, these posts will be spaced at 10 to the square mile, and in more 'open' areas the number will be smaller. A post will serve a group of sectors each of which should contain approximately 500 population.

The chief of the wardens' service and his deputy will be volunteers. Under them will be head wardens, each in charge of groups of posts covering 6,000 to 10,000 population. Each post will be in charge of a post warden with a deputy to assist him. In the larger towns, it may be found more convenient to organize groups of posts into divisions, each under a divisional warden.

A TYPICAL ORGANIZATION

The warden service in a town of 250,000 inhabitants would thus be:

A chief warden, having under him three divisions each of 80,000 inhabitants, under divisional wardens. Each division would be divided into 10 groups of 8,000, each under a head warden. The groups would again be divided into five posts of roughly 2,000 population, each under a post warden. The total number of wardens for a town of this size would thus be approximately 2,400. A reserve of 50 per cent having been laid down, the chief warden of a town of the size of Poona, for example, will have to enrol and train not less than 3,600 men for the warden service alone.

In towns in which the warden service is large enough to be organized either in groups or divisions, the chief warden will have an assistant to take charge of the routine administration and training of the service.

Special wardens will be appointed for large blocks of flats or tenements in which there are more than 100 residents. Warden services organized by industrial, commercial or public utility companies will work in close co-operation with the main service.

FIRST-AID POSTS

First-aid posts will deal only with 'light' cases, i.e., persons who are, usually, able to walk. Serious casualties will be sent direct to hospital, after preliminary attention from the first-aid party, and should not pass through these posts.

Normally, first-aid posts will be established less than two miles apart, so that an injured person will not have to walk more than a mile for attention. Each post will be in charge of a doctor, who will have under him at least one fully-trained nurse, first-aid workers and stretcher bearers. A large post, serving an area in which there are from 30,000 to 60,000 inhabitants, would have a staff of 30, and a small post, for 3,000 to 20,000 population, half that number of staff.

THE CASUALTY ORGANIZATION

The first-aid posts are only one section of the casualty organization, other sections being the ambulance service and first-aid parties.

Ambulances will be provided, as a general rule, on the scale of one ambulance to every two first-aid parties and a car to carry 'sitting' cases to every three parties. Each ambulance will have a driver and attendant and each car a driver. In addition, a reserve of 100 per cent is to be enrolled and trained. Government have under consideration methods of converting private cars into ambulances.

FIRST-AID PARTIES

For every 100,000 inhabitants of a typical town, there will be approximately 20 first-aid parties to give immediate attention to casualties. A first-aid party will consist of a leader and four men, one of whom will be the driver, who will also be fully trained in first aid and will work with the party, and will be equipped with a car. It is hoped to provide officers of the St. John Ambulance Association as heads of the first-aid party service who would also act as staff officers to the head of the casualty organization.

RESCUE SERVICE

When a warden reports a bombing incident to his report centre, he will set in motion machinery which will at once order the necessary ARP services to hurry from an ARP depot to the scene of the bombing, to extricate casualties, render first aid or deal with fires.

For example, in a demolished building a rescue party would be sent. Rescue parties will be divided into heavy and light. They will be equipped with lorries carrying lifting tackle, ropes, ladders, axes, stirrup pump, first-aid boxes and all equipment needed to extricate wounded from wrecked houses, render first aid and tackle fires. Heavy rescue parties will carry, in addition, a portable acetylene-gas cutting outfit and heavier lifting tackle.

Light rescue parties will comprise 11 men—a leader, three skilled and six unskilled men and a lorry driver. As many lorries as possible will be provided with detachable light trailers. Heavy parties will consist of nine men, but their equipment is designed to deal with buildings of heavy construction. In all parties there will be men capable of turning off gas, water and electricity supplies.

The service, as a whole, will be in charge of a technically qualified officer. In large towns, the head of the service will have one or more staff officers, qualified constructional engineers, responsible for organization, administration and training. Each group of six parties will be in charge of a technically qualified group leader. The approximate strength of rescue parties is to be 10 for every 100,000 of population. The proportion of light to heavy parties will vary with the type of buildings in the area.

THE ARP DEPOT

In order to prevent delay in sending services to a bombed area, first-aid parties, ambulances and rescue parties will be based on combined ARP depots, which will be so spaced that the rescuers can get to a bombed area within 10 minutes of receipt of the message from the control and report centre ordering them out.

The number of personnel located at one depot may be as many as 200 to 250 but will often be less. There will be a depot superintendent, who will have a deputy and a staff comprising telephonists, messing staff, sweepers, a clerk and a storeman.

SIR PRAFULLA CHANDRA RAY

THE Indian Chemical Manufacturers' Association presented an Address to Acharya Sir Prafulla Chandra Ray, Ex-President of the Association, on the occasion of his attaining his 81st Birthday, at the premises of the Association at 102-A, Clive Street. Mr. N. R. Sarkar, Member-Designate of the Viceroy's Executive Council, presided over the function.

In the course of the Address, which was read by Dr. H. Ghosh, Vice-President of the Association, the manifold services rendered by Acharya Ray to the public and specially in the field of Science and Scientific Research were eulogised and his unique service in establishing the Chemical and Pharmaceutical Industry in India was referred to. It was stated that the scientific achievements of Acharya Ray found their fulfilment in industrial enterprise and as a pioneer in modern scientific research; he was also a pioneer in the application of that research to industrial development. At a time when the country was industrially backward and scientific research in India was comparatively unknown, Acharya Ray gave a practical demonstration of what Indian talents could do by founding the Bengal Chemical and Pharmaceutical Works which had served as a forerunner of several chemical and pharmaceutical works. The address then referred to the organization of the chemical and pharmaceutical industry by Acharya Ray as the Founder-President of the Indian Chemical Manufacturers' Association, which had made signal progress in the short period of three years of its existence and whose membership now included almost all the important chemical and pharmaceutical works in the four corners of India. The members of the Association, it was stated, therefore considered it not only their privilege but also their duty to offer humble tributes of respect and love to Acharya Ray on this occasion.

In his reply, Acharya Ray expressed satisfaction at the gradually increasing strength of the Association which had become a representative organization. He stated that in order to facilitate the growth of chemical and pharmaceutical industries, the country required in the first place, a liberal state policy, to render all assistance to such enterprises, and in the second, sincere support from the public. He referred to the inferiority complex among a large section of the people, whenever the question of choosing between foreign and home-made chemicals and medicines was concerned and appealed to the manufacturers to remove this impression by propaganda, demonstration, and by raising the standards of Indian products, wherever necessary. He said that he had not been content to remain a mere theoretical man in the laboratory, but had tried to devote the best portion of his life in giving chemical research a commercial and industrial turn and although the success had not been phenomenal a beginning was made and it was now for the business men and industrialists to carry it to the final success. He thanked the Chemical and Pharmaceutical Manufacturers for the kind words in which he had been felicitated.

GROWING POPULARITY OF 'AGMARK' GHEE

With the growing popularity of 'agmark' ghee, still greater attention is being paid by the Agricultural Marketing Staff to control quality and by strict supervision to detect the activities of unscrupulous dealers who fraudulently use imitations of the 'agmark' seal on ungraded ghee.

During the first six months of this year, 36,554 maunds of ghee, worth more than Rs. 26,22,550, were graded at the various grading stations throughout India.

The checking staff collected large numbers of samples of graded ghee from different distributors for analysis at the Central Control Laboratory. In almost every case the samples were found to conform to the original grade designation.

The checking staff, however, detected a few cases in which retailers were selling ungraded ghee in tins sealed with bungs coloured to resemble the bungs used for genuine 'agmark' ghee. These dealers were dealt with under the provisions of the Agricultural Produce (Grading and Marking) Act of 1937.

MATERNITY AND CHILD WELFARE

NURSERY SCHOOL AND PARENT EDUCATION IN SOVIET RUSSIA*: A REVIEW

IN 1929, a party of educationalists drawn from almost all countries interested in kindergarten and nursery school education was invited to visit Soviet Russia. In the party was Miss Patty Smith Hill, Professor of Education, Columbia University, New York. So much was Dr. Hill struck by the developments of the work in health protection and education of the pre-school group that she persuaded the writer of this book 'Nursery School and Parent Education in Soviet Russia', Vera Fedyaevsky, to set down, in a form which would make it available to all interested in the development of the pre-school child, the principles and practices by which the Soviet Union planned and provided services for the protection of motherhood and infancy.

Now that the orientation of the war has brought Soviet Russia into the sphere of immediate interest, it is perhaps not out of place to offer a somewhat extended summary of certain portions of this very interesting book that will appeal not only to workers in maternity and child welfare but also to organizers of community health programmes.

In 1914, the infantile mortality rate in Russia was 270 per thousand live births and in the same year in Moscow one-third of all deaths were of infants under one year. Almost immediately after the October revolution a special department for the protection of motherhood and infancy was inaugurated as part of the Commissariat of Health and its first object was to determine the special causes of this very high mortality rate prevailing in Russia.

By a process which is not detailed, the special causes of this great loss of infant life were found to be, (i) lack of medical care—this was not only insufficient in the urban areas, but in most villages completely lacking, (ii) the heavy handicaps under which women worked during and after pregnancy, as well as the poor facilities and lack of care during confinement, (iii) the general illiteracy of the population reflected in ignorance regarding the need for medical care and education of infants and children, and (iv) the lack of both medical care and supervision especially in villages during the harvest months when large numbers of mothers were labouring in the fields.

The author states that so distressing were the conditions in the country that many women

were delivered 'under a hay stack or among the sheaves of grain', while in most cases no medical aid was available. The *babka* of Russia was as ignorant and ubiquitous as the most ignorant form of Indian *dai*. No regularity or modern practice was observed in the daily family routines of feeding and sanitation, and great numbers of children were carried off each year by summer diarrhoea and dysentery. As the mother had to return to work very soon after delivery, the care of the infant often devolved upon a small brother or sister, with the result that many neglected infants were devoured by wild animals.

The author states boldly that as a result of the measures taken to meet these problems the infantile mortality by 1932 had been reduced by 40 per cent. Apart from the training of staff, the Commissariat of Health set out to establish a far-reaching system of organized crèches, and consultation centres, supplemented by courses in child health and child education and, further, to inaugurate an elaborate system of propaganda, aimed at breaking down conservatism and ignorance. The scheme also included provision for research into the problems of child health, child education and maternal care. Threaded through the entire system was of course instruction in the ideology of the regime, but it is the actual developments in legislation and organization which make the book a valuable contribution to present-day literature on child health and education.

Three chief lines of approach were charted out by the Department for the Protection of Motherhood and Infancy. These were: (i) legislation, (ii) organization and work in national institutions, and (iii) propaganda.

Legislation.—One of the most important developments was the removal of illegitimacy. The Code of Laws on Marriage and Family, section 25, reads: 'Children whose parents are not married have the same right as the children whose parents are legally married'. Further sections of the same Code are designed to secure *alimony* 'for the welfare of the child' for the unmarried mother who may, during her pregnancy, or after the child is born, name the father. The court is instructed to place implicit trust in the mother's testimony, and should the father deny his fatherhood, he must disprove it. The law is planned and administered in the light of the child's 'greatest good'. This cannot be more simply and significantly stated than it is in the words of section 33 of the Code 'parental rights are put into effect in the interests of the child, exclusively'. This precludes all possibility of the utilization of the child for gain at any period during its minority.

Under the labour laws also, great privileges are granted to the pregnant and nursing mother

* Nursery School and Parent Education in Soviet Russia. By Vera Fedyaevsky and Patty Smith Hill. 1936. Kegan Paul, Trench, Trubner and Company Limited, London. Pp. 265. Price, 10s. 6d.

with the object of securing or increasing her economic independence, and to facilitate the rearing of her child. Discharge of a woman during pregnancy or while on motherhood leave is forbidden: she must be reinstated in her post after her leave, and no night work or overtime is permitted. In the case of factory workers only, there exists a unique provision for maternity. Under this system 'leave by degree' a woman is entitled to leave with full salary for a period of sixteen weeks, eight weeks before and eight weeks after delivery. If the woman or her husband is insured, in addition a sum of money will be granted for the care of the infant and also 25 per cent of the wages of the woman will be paid monthly for nine months from the time of the birth of the child. To all women workers are extended the privileges of the use of consultation centres, milk kitchens, medical advice, etc. In the case of the poor mother, money will also be provided for the layette.

Once a mother returns to work she is entitled to half an hour's rest for every $3\frac{1}{2}$ hours' work during the nursing period, and if she is employed in a factory the child is placed in the factory crèche under the care of doctors and nurses. If the child falls ill, leave is granted to the mother on full wages.

Naturally, such a system costs an enormous amount of money and there are various sources from which funds are obtained. The most important of these is a state social insurance which applies to hired workers only. These, however, include workers employed by the state, or by communities or private individuals. This tax is paid exclusively by business and industry. Fifteen to twenty per cent of the profits are utilized for this purpose, and the insurance provides not only free medical aid to all workers, but pensions for aged workmen and support during unemployment for the worker and his family. It pays also for the assistance during pregnancy, confinement and for nursing care, and for the 'leave by degree'. The budget for provision for mothers and children in 1934 was the equivalent of 120 million rupees. The rural worker (for example a worker on a collective farm) is on the same footing legally, but is not a hired worker and therefore cannot be benefited by the funds of the state social insurance. Assistance in this case can be provided from the collective farms funds only. Usually one month before and one month after delivery on half wages is the maternity leave available for the rural worker.

It is an interesting development of this programme of mother and child protection that all public conveyances give preference to expectant mothers, and mothers with infants in arms.

Consultation centres.—The development of 'consultation centres' for women and children is a feature of the programme of the Department of Protection of Motherhood and Infancy.

These centres have both curative and preventive functions related to (a) pregnancy, confinement and gynaecological disease, and (b) infant care. They also participate in the work of health centres by planning measures to protect the health of the woman worker.

The consultation centre for women may be separate, but is usually connected to a centre for children. Medical pre-natal care, health advice, and instruction are given; the diagnosis and treatment of gynaecological disease are undertaken also. In addition to these activities (which are not different from those of many maternity centres in various parts of the world), there is a section for advice in regard to birth control and one where permission may be granted for legal abortion if it is considered dangerous to the health of the woman, or when *economic circumstances make abortion advisable*. In cases where therapeutic abortion is advised *induction of abortion may be undertaken in the centre*. It is not to be assumed from this that abortion is encouraged; on the other hand, instruction on the dangers of abortion is given at all such centres.

The consultation centre for children is intended to provide health advice, medical care and guidance. Immediately a child is born it must be registered and the local consultation centre is informed of the birth. The child must be brought to the centre within two weeks of birth and from that time onwards regularly, as advised by the doctor in charge. In the event of the infant not attending the centre the visiting nurse calls to advise the mother to bring it up for consultation. Each centre has a physician in charge and although health protection is the chief purpose of the centre, medical care is also carried out. Vaccination is compulsory, and in most large cities anti-diphtheritic and anti-measles inoculations are undertaken on a large scale; in some places the von Pirquet test is also done. A milk kitchen is attached to each consultation centre, and, where artificial feeding or supplementary feeding is necessary, the doctor's prescription for the feeding is taken by the mother to the trained dietitian in charge of the milk kitchen who provides the necessary feeds. Payment is made by the parent to whatever extent is possible. Spare human milk is stored also in these milk kitchens for the use of needy infants. The author states that it is the aim of the Soviet Government to establish ultimately, nutrition stations to *provide all food for all children both in the home and in institutions*. 'Educational consultations' (child guidance clinics) are held in some centres only, but, even when these are not provided, there is a mother and child corner for self-education of the mother regarding the needs of the child both physical and mental, and the types of toys which should be provided for his play. In the newer centres specialist advice is also available. Free legal advice is given also in most of these centres, and where difficulty

arises the woman may be helped to obtain alimony for the support of the child.

Home visits are carried out by visiting nurses attached to the centre and every effort is made to help the mother to adopt her environment to the needs of the infant. Such centres really become general clinics for young children, with 'follow-up' in the home. A close connection is maintained with tuberculosis and venereal disease dispensaries and with crèches and maternity hospitals. Information on vital statistics is provided in all factory centres.

The enormous size of these consultation centres can be judged from the fact that to no. 2 centre in Moscow 61,000 visits were paid in 1934 and 200 to 250 children were seen daily. Each doctor attached to the consultation centre is responsible for a portion of the district, usually housing 400 to 500 children. His duties include visiting severely ill children in the homes and all infectious cases among children, as well as imparting health advice, and controlling all health activities in his area. He (or she) is responsible for the administration of protective inoculations in times of epidemic. The doctor is also called upon to select rooms which are to be used as nursing rooms in factories, to inspect these rooms from time to time and advise on urgent needs.

All the trained staff do teaching work, also short courses are given in child welfare and domestic hygiene.

For children who show evidence of rickets or anaemia, or have been exposed to infection by tuberculosis, there is a type of open-air playground provided to serve a group of centres; to these play-grounds children may be referred only by the doctors in charge of the consultation centres. These are 'the sanitary nursery play-grounds' where the children are in the open air under all conditions of weather for six to eight hours a day. The play-ground is equipped with all simple forms of recreation, including, in some instances, a bathing pool. The children are provided with meals and are under trained supervision.

Crèches.—Apart from the orthodox type of crèche, that is, a room or series of rooms with open-air facilities, where children are cared for and kept under supervision, this book describes types of primitive crèches; some are both original and interesting especially those in whose development the co-operation of mothers and even school children is utilized.

The ordinary type of crèche is met with in both rural and urban areas, and in the Soviet Union the crèche is expected to fulfil two objects: to liberate the woman for other duties, *social and political*, and to provide an educational background for the child and parent. Many of these crèches are financed jointly by the state, from local budgets, from state social insurance, by operatives, agricultural enterprises and industry. The parents, as a rule, contribute according to their means. No plans for a

factory will be passed unless they include suitable crèche arrangements.

Each such crèche is managed by a council to which both teachers and parents elect representatives. Members of the workers' committee and women's organization are also elected. All the members of such a council receive courses of instruction in health education and in crèche organization and management, motherhood and child care. The working hours of the crèche correspond with the shifts in the factory. These crèches may work 24 hours a day in 1 or in 2 or 3 shifts, or as a 'long-day crèche', that is, open for ten to fourteen hours. An infant may be admitted to a 24-hours' crèche for several reasons, for example, when the mother is ill, is continuously on night duty, or is found to be ailing and requires rest.

Sixty to 100 children ranging in age from six months to three years are accommodated in most of the bigger crèches. These are simply well-conducted modern crèches, under medical supervision. All children are medically inspected on arrival and facilities are provided for bathing, feeding, sleep and recreation. The nursery teacher is responsible to some extent for parental education and for making home contacts with the parents.

In the rural areas the needs of the workers on collective farms have resulted in different types of crèche service being organized. In the main, two types of crèche have been developed. The 'permanent' crèche and the 'summer' crèche. Difficulties of locality, poverty of equipment and less extensive financial support have modified the facilities provided, but the methods are the same and the crèche is expected to provide whatever the ingenuity, common sense and training of the organizers can effect. The permanent crèche is in charge of a trained nurse and is responsible not only for the supervision of the short-term crèches or summer crèches in her district, but also for conducting short courses for workers with a view to producing a supply of semi-trained nursery staff.

The problem of providing facilities for the nursing mother harvesting in the field often far from her home has been met by the introduction of travelling crèches. 'These are trucks, trains or caravans on wheels which follow the workers wherever they go.' Collective farms are encouraged to provide fruit and vegetables for sale to the workers. Primitive milk kitchens are set up and all children of workers on collective farms are provided throughout the year with wholesome food.

In urban areas certain unusual types of crèches have been established. One of the most interesting is the 'boulevard nursery groups'. These, like the railway station crèches, were established in 1932. Their object is to provide children with fresh air, exercise and play under the supervision of a trained nurse on the boulevards of the city. Boulevard groups are, as all health

activities for children, connected with the consultation centres in their area. The children go home for meals, but are otherwise in the open air from 8 a.m. to 6 p.m. The parents are expected to contribute according to their economic status. Another unusual form of crèche is a 'walk'. This is also an open-air activity planned in close consultation with the centre doctors. In essence, it is simply arrangement for supervised play in the open air with provision of a shelter for midday rest and meals managed each day by the mother of one of the children. A 'walk' is organized for the families in one house and the mothers take it in turn to spend the day with the children, supervising their play and rest under a trained nurse. The educational value of such an organization is obvious. Parents contribute towards the cost of the meals and the trained nurse is provided by the government. Older school children are also encouraged to participate in the supervision of these 'walks'. No play apparatus is available in most cases.

The railway station crèche is intended especially for the relief and rest of mothers with young children undertaking a long journey through the country. These railway crèches have a 'filter' room through which the children must pass in order that sick children can be segregated.

After the medical inspection they pass on into the room which corresponds to their age group. There are rooms for children under 3, from 3 to 7 and over 7. Cheap meals and sterilized milk are made available. There are provisions for rest, play and instruction. The mother may wash soiled clothing, bathe her baby and herself and enjoy a period of relaxation. At the railway buffet wholesome food for children is always available at cheap rates. In addition to these facilities special coaches are attached to the long-distance trains for the exclusive use of mothers with children.

Another interesting type of institution which has been evolved is the 'home for mother and child'. This corresponds to the convalescent home in other countries, and in the U. S. S. R. it represents a comfortable home where the working mother, after the birth of the child, may pass the eight weeks' leave which has been granted to her. Here she is taught infant care, she receives adequate rest, instruction in mothercraft, in the problems of social hygiene and 'legal problems of family welfare'. For orphan and unwanted children there is a *boarding-out* system similar to that which has gained prestige in the United States. Parents who accept such children are selected with great care and are known as 'patronat parents'—such homes are under constant supervision.

Research.—Research into mother and child care in the U. S. S. R. has fallen into two distinct categories, that which is conducted in institutions (and there are 20 in all of these institutions for the protection of motherhood

and infancy), and that which is related to the study of local problems in different parts of the country.

A country of the size of Russia with so diverse a population maintaining such varying standards of education and culture has naturally been compelled to consider how the far-flung units of the Republic can be brought into alignment, so that the benefits of maternal and child protection may be available throughout the Union. Expeditions therefore were planned to study the problems of workers in the Siberian coal fields and mines where coloured metals are extracted, and of those of the tribes in Central Asia; expeditions went to factories, to automobile works, etc., and studies were made in collective farms among rural communities.

Institute research.—Each institute is associated with six to twelve centres and crèches, which form its field of study and experimentation. The object of all research is 'to formulate principles by which practice can be standardized, while the excursions for the study of local problems are intended to find means to put these principles into practice under varying local conditions'. The organization and efficiency of crèches are 'intensively studied'. *The efficiency of a crèche is judged by the efficiency of the mother as a worker and as a social and political unit.* Comparative studies are made from this point of view, of mothers who are not utilizing crèche care and of mothers who are utilizing crèche care of a less official type.

With the study of children the problems of diagnosis and therapy the clinic of paedology in Moscow is concerned. Here also the development of normal and abnormal children is being studied both by records for 24 hours at a time and by the photocine method. Nursery institutions for handicapped children are also subjected to research. Norms of development and behaviour are being worked out. In the words of the author, 'one of the most important branches of research is the study of the diet and equipment for the nursery or crèche'.

When the book was written most research had been devoted to the infant and child under 3 years of age, but schemes of research on older groups were being planned. The work that has been done is on such a large scale and so comprehensive that it is almost impossible to put down the complete trends in short form even with the aid of so attractive a book as this. One of the most advanced and attractive of them is the planning and adaptation to local circumstances of the child's environment and play apparatus, with which it is impossible to deal here.

Parts of the stage upon which these welfare movements are set have counterparts all over the world in all conditions and in many countries, and a study of the results achieved and the methods of approach cannot be without value.'

NUTRITION**PUBLIC HEALTH ASPECTS OF ENRICHED FLOUR AND BREAD***A report of an address*

By W. H. SEBRELL, M.D.

The Nutrition Advisory Committee, Washington

As a physician and a health officer I am vitally interested in the health of the people of this country. The enriched flour and bread programme is one of major importance in accomplishing something constructive to meet the serious dietary deficiencies which exist in this country to-day. Many of you may think that the American public is well-fed. As a matter of fact all of the recent dietary studies made in this country indicate very clearly that a large part of our people are getting diets which are below the standards necessary to maintain health. It has been reliably estimated that not less than one-third of our entire population are getting diets which are not entirely adequate.

Another misconception which some of you may have is that the inadequate diets in this country are found entirely in the lowest income groups. While it is true that most of the inadequate diets are found in this group, it has been found that inadequate diets also extend into the highest income group. Many of you in this audience are probably eating inadequate diets, not from inadequate incomes, but from poor food selection, special diets or lack of knowledge as to what you should eat. I have seen actual deficiency diseases in well-to-do business and professional people simply because they had neglected their diets as most of us are inclined to do. They eat what they want to eat and not what they need.

American diets are most likely to be deficient in some of the vitamins and minerals in spite of the large increase in the consumption of fruits, vegetables and milk in this country in recent years. For many years many different agencies in this country have been attempting through educational means to improve the American diet. It may surprise some of you to learn that the American diet is more deficient in thiamine, which is one of the vitamins of the B complex, than was the American diet of 100 years ago. Some of you may have felt that the increased consumption of fruits, vegetables and milk has been one of the causes of the decreased consumption of flour and bread. I do not believe that this is true. One of the major causes for the decreased consumption of flour and bread in this country may be one which you have not considered very seriously or may have thought did not amount to very much, that is the fact that dietitians, home economists, colleges of home economics, and all the institutions in this country that are teaching nutrition have taught, and under present conditions must continue to teach, that white flour is practically devoid of minerals and vitamins, and that in obtaining an adequate diet one must be sure to get the necessary vitamins and minerals first from other sources and then complete the diet with any foods that suit the appetite—including white flour and white bread.

Diet and the physician

Physicians have to do just that in making special therapeutic diets. When I have to make a special diet I must first assure the vitamin and mineral intake; having secured that I can then consider the protein, fat and carbohydrates and then I can say eat enough white bread to make up your calories if you care to do so. This sort of thing has been going on for years.

In addition, whenever you hear anyone talking about reducing diets, which are so popular with the ladies these days, you almost invariably hear them advise a decreased consumption in flour and bread. This situation has been brought about by the highly refined milling processes which have made white flour such a beautiful product to look at but which have so seriously

injured its nutritive value compared with the original wheat from which it is made. I do not blame the millers for making a highly refined flour. As I see it you men in industry are trying to give the public what it wants. The fault has been that the public did not want the right thing and I think we have to educate the public to want a flour and bread of high nutritive value.

The tendency of the American public to use highly refined foods has been manifested in other ways than in flour. I wonder if you realize that if you add together the calories consumed in the average diet from white flour, refined sugar, and highly refined fats you find that these items make up more than half an individual's average daily calorie consumption. As a result he must get all of his minerals and vitamins from the remaining 1,000 calories or so which make up his diet and this is the reason that our diets to-day are more deficient in thiamine than they were in the past. The increased vitamins and minerals supplied by fruits and vegetables are not enough to make up for the loss which has occurred in eating more highly refined foods of other types. It is factors such as these, which taken together with poor food selection and low incomes are the major causes of the widespread dietary deficiencies existing in this country to-day, and I cannot over-emphasize the importance of these things from the point of view of preventive medicine.

A new concept has arisen in preventive medicine in the past few years. You no doubt think of preventive medicine as vaccination against smallpox, immunization against diphtheria, and sanitation of water and sewage. To-day preventive medicine has advanced beyond that view. The up-to-date health officer is now concerned with building the healthiest possible population with the greatest resistance to disease. A major part of such a programme is that the population shall receive a diet adequate in all respects. For this reason the widespread prevalence of deficient diets is of serious concern to the health officer and these dietary deficiencies and means for their prevention are now being studied in considerable detail.

B-vitamin and iron deficiencies

It is recognized that the most prevalent deficiencies in this country to-day are those due to deficiencies in members of the vitamin B complex and in iron. I have no intention of giving you a dissertation on the diseases produced by these deficiencies but there are a few facts with which any well informed person should be familiar. The three members of the B complex which are most important from a health point of view in this country are thiamine, riboflavin and nicotinic acid.

Thiamine deficiency in its extreme form causes a disease known as beri-beri. This was formerly thought to be a tropical disease which did not occur in the United States. We now know that this is not the case. We see many cases of severe beri-beri and we recognize that a condition known as peripheral neuritis which occurs in cases of pregnancy and in alcoholics, as well as in other diseases, is also a manifestation of thiamine deficiency which was not recognized a few years ago. But from the point of view of the entire population, even more important than these serious deficiencies has been the very recent recognition that thiamine deficiency also causes symptoms such as mental depression, easy fatigue, and undue anxieties and although the individuals with these symptoms are not sick in the sense that they do not go to bed, these things result in a lowered efficiency and possibly other more serious economic consequences. There is every reason to believe that these symptoms are widely prevalent in this country because of our reduced thiamine intake.

The symptoms of riboflavin deficiency were just recognized about two years ago. This condition is manifested by fissures in the corners of the mouth, a scaly condition around the nose and ears and disturbance in vision caused by blood vessels growing into the cornea of the eye which obscures the vision and may lead to blindness. These symptoms miraculously disappear on the addition of riboflavin to the diet. Although this

disease has been recognized only so recently it is evident now that it also is widespread in this country.

The importance of riboflavin is further evidenced by the fact that it is found in every living cell, at least in all the higher forms of life, and when experimental animals are deprived of it they invariably die as is also the case with most of the other vitamins.

Nicotinic acid deficiency leads to a disease known as pellagra which was formerly thought to be confined largely to the southern United States. We now know that it exists throughout the United States. The symptoms of pellagra have been known and recognized for a long time and I do not believe it would be an exaggeration to say that not less than 200,000 cases occurred in this country last year. The disease kills more than 3,000 people in this country each year. Yet it can be entirely prevented by nicotinic acid which is one of the members of the vitamin B complex.

It has been known for only a few years that nicotinic acid will prevent pellagra. When I use the words 'nicotinic acid' I know most of you immediately think of nicotine. It is most unfortunate that the name of the deadly poison nicotine sounds so similar to the name of this life-saving vitamin 'nicotinic acid' which is found so widely in our daily foods. This unfortunate similarity is due to the fact that although nicotinic acid was made in the laboratory in 1867 no one found any practical use for the substance until to everyone's astonishment it was discovered in 1937 that it would prevent and cure pellagra, a disease for which we had previously had no specific treatment. It may interest you to know that during all the years when I was searching for the pellagra-preventive vitamin I had a bottle of this same nicotinic acid sitting on the laboratory shelf—never suspecting that what I was seeking was standing at my elbow.

More important than the above symptoms, however, from the point of view of numbers of people involved, is that there were many thousands who had red tongues and suffered from indigestion and weakness due to a partial deficiency in this substance. In addition, there is an acute mental condition characterized by confusion and disorientation which is due to nicotinic acid deficiency.

Another point of considerable interest about these various diseases is that they are rarely found alone. We usually see an individual with symptoms of two or all three deficiencies at the same time. This is not surprising since these three factors of the vitamin B complex are usually found in the same foods. An individual does not select a diet that is deficient in just one of these things. Since his deficient diet is due to the absence of natural foods containing these vitamins the diet is likely to be deficient in the entire B complex rather than in just one of the factors, and in order to prevent the development of these deficiencies it is necessary to supply all of these factors as they would be supplied by natural foods.

One of the most important of the mineral elements for the human body is iron. Iron is necessary for the formation of the haemoglobin of the blood and if there is an insufficient amount of iron in the diet an anaemia develops. Individuals living on foods raised on soils which are deficient in iron develop anaemias, and school children have been found in this country with about one-half of the amount of haemoglobin in their blood that they should have simply because their food did not contain enough iron. These sickly, weak, under-nourished, and frail children can never be any better until this iron deficiency is corrected. Identical conditions develop whenever the diet is deficient in iron for any cause, whether it be because the foods are raised on iron deficient soils or because the iron has been removed from the food by milling or other processing.

Food vs. pills

There are other deficiency diseases in the United States in addition to the above, however, from a public health point of view they do not cause the deaths, the illnesses and the economic loss which are caused by the above.

Therefore, we are directing our attention to devising a programme which will solve once and for all the problem of continuously getting into the American diet enough thiamine, enough riboflavin, enough nicotinic acid and enough iron to prevent the development of these deficiencies. I feel that the proper way to approach this problem is through dietary means and not through the use of vitamin pills or tablets. These conditions have developed as a result of our improper handling of foods and should be corrected by changing the handling of our foods so that the vitamin and mineral content is restored to a level which will be effective for this purpose.

There is no intention to make bread or flour a medicine. We are not attempting to treat disease—that is in the province of the physician. We are attempting to prevent disease and to prevent the disease conditions which we have brought down on our own heads through improper food practices and which should be, and can be corrected, by making suitable changes in our food habits. Just a few years ago I took the point of view that the way to correct these conditions was to try to stimulate the increased consumption of foods naturally high in these vitamins. I still think that this point of view is correct theoretically. Although I recognize that such a programme if it succeeds at all will progress so slowly that it cannot meet the extensive deficiency conditions in our population to-day; therefore, as I see it the next best thing is to add these vitamins and minerals to foods which are consumed in large quantities especially by the low income groups.

We already have one example of this in the various forms of vitamin D milk that are now widely used in this country. Some of these products were introduced about ten years ago in an effort to solve our rickets problem, and to-day it is recognized that they are of the utmost value in the prevention of rickets. They have added very little to the cost of milk and yet are one of our best and most economical means of preventing rickets.

A stronger staff of life

Bread has always been the mainstay and principal component of the poor man's diet. The fact that it has become nutritionally inferior has taken away these vitamins and minerals from the very population groups which need them most. I feel that the addition of thiamine, riboflavin, nicotinic acid, and iron to flour and bread in sufficient quantities will represent a major contribution towards solving our dietary deficiency problem. There is great public interest in this subject at the present time. This public interest should be utilized and guided on a national scale in the right direction so that the public will obtain a product which will be of real health significance.

It is of equal importance that the public shall not be misinformed or misled. They should be reassured that they are receiving a food and not a medicine. The industry must take on itself the preparation and regulation of products for which you yourselves will permit no unsubstantiated claims. It is equally important that these enriched flours and breads shall reach the public at the lowest possible price. From a public health point of view it is most important to reach the lowest economic groups, and a premium price product is likely to be beyond their reach.

Again from a health point of view, it is of little importance how the necessary levels of vitamins and minerals are obtained in the flour and bread. The important thing is that the necessary substances are there in the final product in a quantity sufficient to be of value. And I would like to see this accomplished in the most economical way possible. I hope we will see these levels obtained in a variety of ways to meet a variety of tastes so that it will have the widest possible utilization. There is no reason why we should not have white flour to which the synthetic materials have been added, a lightly milled, creamy coloured flour, and a dark flour with the vitamins and minerals retained by the milling process, and also that we shall

have a variety of breads of various colours and flavours just so the vitamins and minerals are there. As far as I am concerned, I just want to know that the individual who is on a deficient diet gets into his stomach these things in the quantities in which he needs them and it is up to you gentlemen to get them to him in the best possible way.

Various nutritional programmes have been tried in the past in an effort to solve our dietary deficiency problems. We have seen years of effort spent in an attempt to get people to eat whole wheat bread. I think we all recognize that this programme has been definitely a failure. It has not solved the problem. Too many people still demand white flour and white bread, and I think we should give it to them as long as they demand it but also give them an opportunity to have their vitamins and minerals concealed in this product if they must have it that way.

As I have indicated, our deficiency problem is one of multiple deficiencies, therefore, the addition of thiamine alone is not sufficient. We have seen in recent months a number of breads appear on the American market which have been fortified with thiamine and these breads have been advertised as being a superior product on this account. This is not enough. We frequently see cases of thiamine deficiency which go on and develop symptoms of nicotinic acid deficiency or riboflavin deficiency. The addition of thiamine is only a partial answer to the problem; just as the addition of nicotinic acid or of thiamine and nicotinic acid would constitute only a partial solution to the problem. We need to put back into the flour vitamins which were originally present in the wheat, not just some of them, or you will still leave us with thousands of sick people. I want to remind you again that as a physician interested in public health I am also interested in solving this problem and that means the addition of all of the substances I have mentioned to-day. If we can make such an enriched flour and bread available we should be able to change our teaching practices and our educational activities in regard to the use of this flour and bread instead of having to relegate these items to the groups of foods which fail to supply many vitamins and minerals. Nutritionists and dietitians will be able to recommend them and utilize them in preparing adequate diets and I think the leaders in nutrition education in this country would welcome such an opportunity to utilize such an important element in our diet instead of having to tell a poor family that they must buy more expensive foods in order to get their necessary vitamins and minerals. It is much simpler to tell that family to shift to enriched flour and bread. I hope to see this enriched flour and bread promoted in a conservative educational manner on the basis of its value as a contribution to a health-preserving diet, and as a permanent programme sold to the population on the basis of this value and with no promotional flash in the pan hysteria. If this is to be of any value it must be a permanent change in the American dietary and should be approached from that point of view. It is imperative that we have co-operative action between all of the agencies concerned. If an educational campaign is undertaken by health or other authorities before the flour and bread are ready commercially it will be just so much wasted effort. If the various baking and milling companies undertake industrial campaigns without co-operation and without proper advice in regard to their advertising, exaggerated and unwarranted claims may nullify much of the work of the programme.

I feel that here is a real opportunity for a great American food industry to carry on a programme which will result in a permanent and valuable contribution to the health of this nation, and at the same time benefit our agriculture by increasing the proper utilization of one of our most valuable and economical foodstuffs.

Eagerly we look forward to the day when our children and our children's children will be armed with the armour of robust health.

SANITARY ENGINEERING

BORED-HOLE ABSORPTION PITS

By RAI SAHIB KASHI PRASAD, M.B., B.S., D.P.H.
Medical Officer, In-charge Health Unit, Partabgarh

Definition.—A bored-hole absorption pit is a hole 20 feet in depth and 16 inches in diameter, bored with a machine known as a boring outfit. A limited amount of sullage water is absorbed and disposed of by it every day.

History.—Bored holes, which were originally introduced as latrines*, have been utilized as absorption pits also. These have had an extensive trial for several years past in the Health Unit, Partabgarh, and some other places in the province.

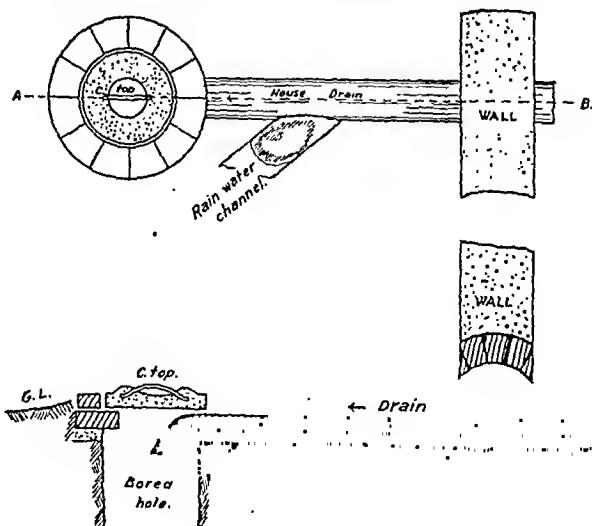

Advantages.—Bored-hole absorption pits require very little space, are easy to construct and cost less than other devices for disposal of waste water. They are well suited for village homes for a variety of reasons. The house drains usually open towards the front of the dwellings. The ground over the bored-hole absorption pits could be covered over during the life of the pits and the ground is not only left clean and dry, but is also made available for use, like the other parts of the open space in front of the houses.

Bananas or other plants, usually recommended in this connection, are soon eaten away or destroyed by cattle, unless they be carefully protected all the time. Even if they grow, they engender dampness and dirt; mosquitoes are also attracted owing to the moisture and vegetation.

Bored-hole absorption pits do not require the services of a sweeper or even attention from the householder.

Brick soakage pits mean more cost, more space, less efficiency, and their annual renewal is not a pleasant job for the orthodox villager.

Uses.—Bored-hole absorption pits are made to dispose of waste water from houses, bath

*The method of preparation of bored-hole latrines was described in some detail in the Indian Medical Gazette of April 1934 and of July 1935.—EDITOR, I.M.G.

enclosures, and wells. They can be used to dispose of urine (from a urinal), effluent from a septic tank, washings from a slaughter house or a cattle-shed, and waste or filthy water from any other source, provided the amount of such water is limited.

Limitations.—Bored-hole absorption pits can, of course, be made only where a boring outfit is available, and where the soil is not rocky or does not contain much of 'kanker' or bricks. It is inadvisable to have pits within four feet of a wall, as there is a danger of its collapse during rains. They should not be very close to drinking-water wells. There should be at least five feet square of open space on which the boring machine could work. One pit can absorb easily only 10 to 15 gallons of water per day.

Life of a pit.—If rain water is not allowed to get in, a pit will last several years. As silt and solid matter also find their way into the pits, they gradually fill up.

After one or more years there may be some caving in of pits receiving a lot of clean water. In such cases it will be advisable to throw in brick-bats to obviate collapse of the walls. The pits will, however, continue to serve their purpose after such treatment.

Construction of a silt chamber in the course of the drain, does prolong the life of the pit, but it is not desirable, since it means unclean work and only helps to retain in the drain filthy matter, which should not be there.

Construction of a pit.—Four labourers will be able to bore one hole in a day, two holes if the soil is soft or sandy. The villagers can do this themselves, if an outfit and a 'mistri' who knows how to work the borer are supplied to them. They could themselves make a drain of bamboos or country tiles.

A mason will be able to construct a proper drain and top for the pit. These will be more efficient and lasting.

The drain should preferably be of the saucer type. Unnecessary bends and angularities should be avoided. The gradient should be sufficient. For the storm water, a rain-water channel should branch off from the drain. During rains it is desirable to shut off the portion of the drain leading to the pit and to open out the rain-water channel instead.

To guard against erosion of the walls of the pit it is necessary to prevent the water in the drain from running down the walls of the pit. This can be easily arranged by having a spout or a properly-cut brick, which will project into the pit from the terminal end of the drain.

The mouth of the pit should be covered to prevent children or small animals from falling in. This may be done by thorny shrubs, by inverting a basket or clay basin over it, or by covering it with a wooden plank or stone slab. The best arrangement is to have a movable cement slab resting on a masonry ring, 9 inches wide (thick) and 6 inches deep, constructed all

MICROBIOLOGY

THE INCIDENCE OF *BACTERIUM AEROGENES* IN THE FÆCES OF PERSONS SUFFERING FROM INTESTINAL INFECTIONS AND ITS SIGNIFICANCE IN WATER ANALYSIS

By K. V. KRISHNAN, M.B., B.S., M.R.C.P. (Edin.),
D.B., D.Sc., F.N.I.

and

A. P. CHAWLA, B.Sc.

From the Department of Microbiology, All-India Institute of Hygiene and Public Health, Calcutta

WITHIN the last few years several articles have appeared regarding the significance of the *aerogenes* group of coliform organisms in the bacteriological analysis of water. The general trend of most of these papers has been that a much greater sanitary significance than was accorded in the past will have to be attached to the presence of these organisms in water. This change in the view point has been chiefly necessitated by the results obtained through

(Continued from previous column)

round the top of the pit. This top may be a few inches higher than the surrounding ground so that rain water may not get in.

Costs.—In Partabgarh district a hole 20 feet in depth and provided with a masonry top and drain costs about Rs. 3, made up as follows:—

	Rs. As. P.
Wages of four labourers for a day ..	1 0 0
Wages of a mason for a day ..	0 8 0
Wages of a coolie to assist the mason ..	0 4 0
Cost of bricks, cement, etc. ..	1 4 0
TOTAL ..	3 0 0

General.—A boring outfit costing Rs. 135 (pre-war price) is available from Messrs. Ivan Jones Limited, 8, Dalhousie Square, Calcutta. It comprises of—

'Samson' earth borer 16 inches diameter fitted with adjustable shaft to enable boring to a depth of 20 feet,

Handle for rotating borer,

Double ended jumper,

2 shackle bolts $\frac{3}{4}$ inch,

5 feet chain sling,

60 feet $\frac{3}{4}$ inch diameter Manila rope,

and can be utilized for boring small wells as also pits for plants.

An outfit, suitable for use in soft soils, can be had from the Agricultural Institute, Naini, Allahabad, for Rs. 40 (pre-war price). This is lighter and can be used by fewer labourers.

A trained 'mistri' is available in Partabgarh. He is willing to go to any district, if he is paid actual railway expenses (3rd class) for the return journey and wages at As. 12 a day for the period he is detained.

studies on the types of coliform organisms present in human faeces.

It has been found that *Bacterium aerogenes* is not uncommon in human faeces. Mollari, Randall and Reedy (1939) isolated *Bact. aerogenes* from 40 per cent of human adult faeces. Horwood and Webster (1937) from their studies of the stools of certain patients opined that the normal bacterial flora of the small intestine possibly consists essentially of *Bact. aerogenes*. Parr (1937) found that 25.2 per cent of organisms isolated from human faeces belonged to the *aerogenes* type, Sen (1938) found 9 per cent and Raghavachari and Iyer (1940) 8 per cent. Furthermore, it has been shown that a very large percentage of the coliform organisms isolated from pathological material such as urine, are of the *aerogenes* type (Burke-Gaffney, 1932). Although these observations have led American bacteriologists to believe that the presence of *Bact. aerogenes* in water is almost of the same significance as the presence of *Bact. coli* their viewpoint has not been accepted everywhere. The Ministry of Health (1940), London, while admitting that *Bact. aerogenes* may frequently be found in human faeces states that as a rule their number compared with *Bact. coli* is very small and therefore their presence is not of the same order of importance as the presence of *Bact. coli*.

In the studies on the incidence of *Bact. aerogenes* in human faeces, noted above, the samples used had all been obtained from healthy individuals. Hitherto, as far as we are aware, no one has studied the incidence of *Bact. aerogenes* in the faeces of diseased persons and especially in the faeces of those suffering from specific intestinal infections. Such studies appeared to us to be of far greater importance in assessing the true significance of *Bact. aerogenes* as indicator of faecal pollution than the studies on stools of healthy persons. The present study was therefore commenced with the object of determining (1) whether *Bact. aerogenes* is present in the stools of persons suffering from intestinal infections such as cholera, dysentery, typhoid and diarrhoea; (2) if so, what is the relative proportion of *Bact. coli* to *Bact. aerogenes* in these stools; and (3) whether the number of *Bact. aerogenes* present warrants the acceptance of the American view that the presence of *Bact. aerogenes* in water supplies is also to be looked upon with suspicion.

Samples of stools were collected from persons suffering from intestinal disorders admitted into the Carmichael Hospital for Tropical Diseases, the Medical College Hospital and Campbell Hospital, Calcutta. These were inoculated into large MacConkey's plates (directly in case of liquid stools and after making an emulsion with sterile normal saline in the case of solid stools) and incubated for 24 hours at 37°C. On an average, twenty coliform colonies were picked out from an area fairly representative of the entire plate. These were classified on the basis

of M.R., V.P., citrate and indole tests. The Eijkman test was done on a large number of the strains in the commencement of this study, but, as it gave very discordant results (as obtained by other workers in this country), it was decided not to use it for the purpose of the present classification. Tables I, II and III give the results obtained.

Results:

TABLE I
Number of stools showing *Bact. aerogenes*

Type of stools	Number of stools examined	Number of stools showing <i>Bact. aerogenes</i>	Percentage of stools showing <i>Bact. aerogenes</i>
Normal	10	3	30.0
Intestinal disorders of unknown aetiology.	34	12	35.3
Bacterial dysentery	15	7	46.7
Cholera	11	10	90.9
Typhoid	8	7	87.5
TOTAL	78	39	50.0

It will be seen from table I that the percentage of faeces showing *Bact. aerogenes* is very high in the intestinal group and that it varies from 35.3 per cent to 90.9 per cent with an average for the whole group of 53 per cent. In the

TABLE II
Ratio of *Bact. aerogenes* colonies to total colonies

Type of stools	Total number of coliform colonies examined	Number of <i>Bact. aerogenes</i> obtained	PERCENTAGE OF <i>Bact. aerogenes</i>	
			Average	Maximum
Normal	180	5	2.77	15
Intestinal disorders of unknown aetiology.	580	66	11.14	70
Bacterial dysentery	232	46	19.85	95
Cholera	200	74	37.00	100
Typhoid	114	23	20.19	35
TOTAL	1,306	214	16.4	..

cholera and typhoid stools the percentage was highest, being about 90 per cent. Another fact worth mentioning here is that almost all the samples of stools taken from cholera patients showed the presence of *Bact. aerogenes* in varying proportions, while those taken from persons

with cholera-like symptoms (which on examination proved to be non-cholera) showed either an absence of *Bact. aerogenes* or the presence of a small number.

From table II it will be seen that the ratio of *Bact. aerogenes* colonies to total colonies in the intestinal cases is not at all small or negligible. It varied from 11.14 per cent to 37 per cent with an average for the whole intestinal group of 18.6 per cent. This again is higher than the ratio in healthy stools. A perusal of the last column in this table will show that the percentage given for each sub-group is only an average and that in certain individual instances the percentage went up to 95 per cent and 100 per cent. This is a very important finding and is of special significance in the interpretation of results obtained during water analysis.

From table III it will be seen that the types of coliforms present in faeces could be arranged in the descending order of frequency thus: (1) *Bact. coli* type I, (2) *Bact. aerogenes* type I, (3) *Bact. coli* type II, (4) Irregulars type III, (5) *Bact. aerogenes* type II, (6) Intermediates types I and II, (7) Irregulars types I and II. This shows that *Bact. aerogenes* is second in importance among the coliforms present in faeces of persons suffering from intestinal infections.

Discussion

The significance of the above findings from the point of view of water analysis is indeed great. It will be accepted that pollution of water with faeces of persons suffering from intestinal infections is definitely dangerous. It has been shown that the stools of some of these persons contain *Bact. aerogenes* in very large numbers. Therefore the presence of *Bact.*

aerogenes in water supplies even in small numbers can on no account be completely ignored in all cases. In this country some water bacteriologists are of the opinion that *Bact. aerogenes* can be ignored unless present in very large numbers, but the results presented above do not justify or support such an opinion. As the coliforms in a cholera stool may at times consist mainly of *Bact. aerogenes* and as contamination of water with such a stool will only show *Bact. aerogenes*, the presence of the latter must be looked upon with suspicion also. The contention of many in the tropics is that if *Bact. aerogenes* is taken as an indication of faecal pollution then it would exclude many waters which are now being consumed with impunity for indefinitely long periods. Although the observation may be true there is no denying the fact that in passing such waters for human consumption there has always been an element of risk involved. Looked at from the bacteriological point of view, a safe water for human consumption is one which is free from pathogenic organisms. That being so the rational procedure for finding out whether a water is safe for human consumption or not would be to determine the presence or absence in it of specific pathogenic bacteria, such as *Bact. typhosum*, *V. cholerae* or *Bact. dysenteriae*. This task being elaborate and time-consuming is not ordinarily undertaken in routine work; even if it is attempted, the chances of detecting the pathogenic organisms are uncertain. It has therefore become necessary to resort to some simpler indirect method for detecting faecal pollution of water, so that one may reasonably predict the presence or absence of pathogenic organisms in it. Since the pathogenic organisms conveyed by water are primarily of intestinal

Oct., 1941]

origin, the presence of bacteria normally inhabiting the intestinal canal, such as the coliform organisms which are more easy to demonstrate, is taken as evidence of faecal pollution of water. *Bact. coli* being the commonest and most predominating type of coliform organism present in ordinary human stool, its presence in water is taken as an indication of faecal pollution. But now that it has been shown that *Bact. aerogenes* is also frequently found in stools and that it may in some cases be the most predominant organism, the necessity has arisen to revise our ideas regarding the significance of *Bact. aerogenes*. But before doing that it should not be forgotten that *Bact. aerogenes* is also found in other situations than the intestine of man and that *aerogenes* from these sources is not of the same order of importance. One of the immediate problems to be solved, therefore, is to find out some test by which we can differentiate between *Bact. aerogenes* of intestinal origin and *Bact. aerogenes* of soil and vegetable origin. Until that is done it is no doubt true that no definite opinion can be given about the true significance of *aerogenes* in water. But in view of the findings detailed above that several pathological stools may consist almost purely of *aerogenes*, it seems safe and reasonable to look upon *aerogenes* with real suspicion in water analysis. If this is not done it is indeed risky. To avoid the risk the least that can be done is to accept rigidly the Ministry of Health standard and not attempt to relax or modify it to suit the tropics. The plea that in the tropics there should be some laxity of standards does not seem justifiable or worthy of acceptance at present and in the absence of specific evidence in support of such laxity. At least with regard to filtered, chlorinated and unchlorinated pipe water supplies the evidence is increasing for the adoption of a standard in strict conformity with the English (Ministry of Health, 1940) or the American (Amer. Pub. Health Assocn., 1936) standards. Although in theory the former standard is accepted in India, in practice it is often relaxed to an extent which in our opinion is unsound.

Summary and Conclusion

1. The incidence of *Bact. aerogenes* in the faeces of persons suffering from intestinal infections ranged from 35.3 per cent to 90.9 per cent with an average of 53.0 per cent.
2. The ratio of *Bact. aerogenes* to total coliforms varied from 11.14 per cent to 37.0 per cent with an average of 18.6 per cent.
3. In cholera stools in some instances, 95 per cent of the coliforms present consisted of *aerogenes*.
4. The presence of *Bact. aerogenes* in water should also be looked upon with suspicion.

Pain in the Female Genital Tract and its Treatment

By A. C. PALMER, O.B.E., F.R.C.S., F.R.C.O.G.

(From *Medical Press and Circular*, Vol. CCV, 26th March, 1941, p. 250)

WHEN pain is due to disease in the female genital tract, it may be spoken of by the patient as ovarian pain or pain in the womb, but its site will be demonstrated as being in the hypogastric region, just above the symphysis pubis, in one or both iliac regions, in the sacral region, in the perineum or possibly in the upper part of the thighs. When pain is complained of as occurring in one or several of these regions, the patient may be neurasthenic, hysterical, or the subject of a pelvic lesion. Possibly she has two or all three of these conditions. In the majority of women a bi-manual examination will enable one to recognize an abnormality in the pelvis, in the lower abdomen, or occupying both areas, but if the patient is unduly fat, or unable to relax her abdominal muscles, bi-manual examination without anaesthetic may give no additional information, and under these circumstances the examination must be repeated under anaesthesia. In the neurasthenic or the hysterical, it is probably wise to make examination under anaesthetic the rule, rather than the exception, unless the physical signs are obvious.

NEURASTHENIA

As seen by the gynaecologist, this condition is characterized by two main features:

- (1) Over response to stimuli, especially slight stimuli.
- (2) Diminished power of resistance to pain and depressing mental influences.

This may be the result of exceptional stress in a woman whose nervous system was of good quality before she was exposed to the stress, or more commonly it is due to the ordinary stresses of life working upon an inferior nervous equipment.

The exercise of the reproductive function is a frequent cause both of nervous exhaustion and of disease of the

reproductive organs. This is why disease of the female generative organs and neurasthenia are frequently seen together. When child-bearing has produced both local disease and nervous exhaustion, the local disease aggravates the nervous exhaustion. Cure of the former will help the cure of the latter; but the cure of the nervous exhaustion requires general treatment as well as that directed to the local condition. When the nervous exhaustion is cured, the neurasthenic patient will be well and cease to complain, at least for the time being or until she is overpowered by the next stress. If the neurasthenic happens to be a hypochondriac as well, that is to say, a woman who believes without cause that she is the subject of serious bodily disease, she will not be cured.

Neurasthenia is met with in both sexes at all ages, but is rare in very young girls and old women, and I think it is no longer open to dispute that the liability of this disease is inherited with the nervous system. It is common during the reproductive period of life, and its chief cause is the strain involved in reproduction: the strain of pregnancy, the stress of labour, the exhausting effort of lactation, and the anxiety inseparable from the care of children; the disturbed sleep; the impairment of nutrition sometimes associated with pregnancy and lactation; and perhaps the anxiety of some local disease—anxiety which is out of proportion to the importance of the local condition. Most cases of neurasthenia associated with uterine disease in married women are due primarily to exhaustion of nervous energy by child-bearing and its consequences, and the uterine disease aggravates the condition.

Exertion produces fatigue, which in health is quickly repaired by rest and food.

Exertion pushed far into fatigue causes exhaustion and recovery will take longer; possibly it may not be complete. Work without rest or variety may exhaust and, in adolescent girls, overpressure at school or in preparation for examination sometimes fulfils this condition. A precocious girl may be encouraged by parents and teachers, who mistake information and accomplishments for education, to force her brain at the neglect and expense of her body, forgetting or not knowing that the first aim of education is to produce a good animal. From such training there is likelihood of producing a woman with very sensitive nerves, an active imagination, and a feeble body who is rendered unfit for her duties by slight causes, and is apt to torture herself by the dread of future disease. Physical pain may produce neurasthenia by its persistence, especially when it is severe enough to prevent or interrupt sleep. Long continued unhappiness, especially of conjugal origin, may be a cause. Sudden shock is an infrequent but occasional cause, and may be associated with cessation of menstruation persisting for years after the shock. Trivial uterine conditions are often associated with the neurasthenic; a non-tender retroversion; or possibly an unusual degree of anteflexion without dysmenorrhoea, the existence of which has become known to the patient by some unfortunate accident. These give rise to no symptoms and require no treatment, but the knowledge of their existence has added to the patient's anxiety, and it may be difficult to make her believe that they are of no consequence. Slight uterine disease, such as a small erosion; a mild degree of chronic cervicitis; or a small cervical polyp, may require treatment, and the disappearance of the symptoms will help the patient, but her neurasthenia will not be cured. This requires the removal of the cause, which may not be possible. If the cause can be removed the exhausted nervous system may never become robust, especially if part of its weakness is inherited.

Some stress has been laid on neurasthenia because patients suffering from this condition are subject to morbid sensations in the lower abdomen and pelvis as well as in other parts of the body. Sacral backache, dragging pain in the pelvic region, and abdominal discomfort or pain from flatulence may be attributed to pelvic disease, and it is important to be quite certain that the genitalia are free from disease before

attempting to convince the patient that the symptoms are due to general weakness and nervous exhaustion.

In hysteria a common feature is the presence of hysterogenetic zones or hyperalgesic spots. One of these spots is situated in the ovarian region, that is about two inches internally to the anterior superior iliac spine. Pressure over this spot causes a "sickening sensation", and not uncommonly a feeling of constriction in the throat and palpitation of the heart. In such a case it may be necessary to exclude disease of the genital organs, even though the patient is known to be suffering from hysteria, and a pelvic examination should be made under anaesthesia. Lower abdominal pain with a lump rising out of the pelvis may occur with hysterical retention of urine. Catheterization and pelvic examination should remove any doubt with regard to the condition of the genital tract.

THE CHANGES IN THE GENITAL TRACT WHICH GIVE RISE TO PAIN

The sites of pain have already been mentioned as being situated in: The sacral region, the iliac fossae, the hypogastrum, the perineum, or the thighs. Sometimes the pain will be complained of as being 'Inside, low down', the patient being unable to localize it to any definite area.

The immediate local cause of pain is increased in the tension within the tissue of origin. This change may be due to:

- (1) Inflammation.
- (2) Trauma.
- (3) Muscular contraction.
- (4) Vascular changes secondary to trauma or independent of trauma.
- (5) Fatigue of weakened muscles.

The type of pain associated with neurasthenia and hysteria in the absence of a pelvic lesion has already been described.

Any one of the five conditions mentioned may give rise to pain in several or all sites described above. I think that the explanation is that the pain complained of by the patient is referred pain, that is, pain referred to the appropriate skin area. Whether the pain remains confined to this area or spreads over into adjacent skin areas depends on the stability of the patient's nervous system and her general health.

New growth has not been mentioned as a cause of pain because I think it is not a cause. Growing ovarian tumours, be they cystic or solid, and uterine fibroids do not cause pain; nor does the growing pregnant uterus cause pain. The growth is slow and unaccompanied by change in the tension within the tissues that are growing. Something in addition to growth is necessary before pain is produced: a vascular change due to some peculiarity of the growth; a twist, an invasion of other tissues, or the onset of inflammation.

The areas where pain is referred are those supplied by nerves coming from the tenth dorsal to the second lumbar and from the first to the fourth sacral segments. Hyperesthesia may be present in pain due to any one of the causes mentioned. In pelvic inflammation it is accompanied by deep tenderness and later by a lump of varying consistency, size and shape, and usually with an indefinite outline, unlike any of the known lumps unaccompanied by inflammation. Hyperesthesia in the hypogastric region and iliac fossae is present when the inflammation is acute, but dwindles and may easily pass unnoticed as the inflammation becomes chronic.

A patient with prolapse may have widespread hyperesthesia in the lower abdomen, sacral region and thighs at the end of the day, but probably not in the morning after a good night's rest.

The pain of an acute torsion may be associated with superficial tenderness for a short time after the torsion, but it will disappear in a few hours if there is no further disturbance of the peritoneum.

In the more acute forms of dysmenorrhoea, superficial tenderness is often present in the abdomen, sacrum and thighs. It may also be present in cases of congested retroverted uterus which give rise to pain.

Oct., 1941]

History and physical signs will usually reduce the choice in diagnosis to one or two probable causes; sometimes the diagnosis will be certain only on laparotomy; occasionally only on histological examination, and rarely not even then.

PELVIC INFLAMMATION

This wide term includes pelvic peritonitis, ovaritis, salpingitis and cellulitis. In its common clinical manifestation all four are present, but peritonitis is the outstanding feature; though it is originally called salpingitis. The commonest causal antecedent of salpingitis is neglected miscarriage (77 per cent), accidental, self-induced, or criminal. Next in frequency come ascending gonorrhoea (11 per cent) and tubercle (11 per cent). Tuberculous salpingitis does not give rise to recognizable symptoms till secondary infection has occurred. An uncommon but definite cause is infection of a small ovarian blood cyst, resulting from adhesions to neighbouring gut. In the acute stage, the symptoms are lower abdominal pain, hyperesthesia, rigidity, and deep tenderness accompanied by constitutional disturbance. The treatment is expectant unless the patient is failing to respond, when the lower abdomen should be drained; or additional lumps develop, when the lower abdomen should be opened, tissue damaged beyond recovery, removed, and the pelvis drained.

Occasionally the acute attack will quiet down and not be heard of again, but most commonly the respite is temporary only, and the apparent cure will pass into the recurrent subacute or chronic pyosalpinx. Sooner or later operation and the removal of some tissue will be required, possibly a pyosalpinx only, possibly bilateral pyosalpinges, bilateral ovarian abscesses and chronically infected uterus.

TRAUMA

Trauma usually means a twist, a twist of the pedicle of an ovarian cyst or solid tumour; of a pedunculated fibroid; perhaps of the uterus, the seat of a fibroid. If not a twist, perhaps the rupture of a tubal pregnancy, or short of rupture rapid stretching of the tube due to bleeding into its lumen. At the outset the symptoms are similar in each case; lower abdominal pain accompanied by a varying degree of shock. If the cyst does not rupture, an obvious tender lump will be present. It might be a solid ovarian tumour or a pedunculated fibroid, but ovarian cysts are common, twisted solid tumours much less common, and twisted fibroids rare. If a ruptured tubal pregnancy is present, the symptoms will change to those of internal abdominal haemorrhage. If the tube becomes distended by clot, a small one may absorb, but the more usual course is the development of a low-grade pelvic peritonitis. The condition then resembles a chronic pyosalpinx, and is diagnosed as such. Further haemorrhages may occur, and give rise to another acute attack. In each case the treatment is laparotomy and removal of the damaged or overgrown tissue, with control of hemorrhage in ectopic cases.

MUSCULAR CONTRACTION

Excluding normal labour, outstanding examples of painful uterine contraction are:

- (1) The inco-ordinate uterus in labour.
- (2) Spasmodic dysmenorrhœa.
- (3) Hæmatocolpos.
- (4) Submucous pedunculated fibroid in process of extrusion.

By the term 'Inco-ordinate uterus' I mean that the lower uterine segment does not progressively and uniformly relax; and the upper uterine segment progressively and uniformly retract during labour. The uterus as a whole may contract, while the upper segment retracts and the lower segment fails to relax. A ring may develop in the lower segment perhaps at the level of the neck of the *fœtus*, or in the external os; or more rarely in the upper segment. Here it may be vertical or oblique, and appears to be associated with an error in fusion of the Müllerian ducts. This condition develops independently of obstruction outside the uterus, but it may be difficult to exclude the latter

when the ring prevents the head from descending in spite of strong uterine pains. If the two conditions happen to be present, the ring will probably not be recognized. Before the inco-ordinate uterus was recognized, women sometimes died from exhaustion in labour without obstruction. Some thirty years ago Mr. Gordon Luker and I watched a woman do this, and wondered why, speculating as to what we had missed. Fifteen years ago we were beginning to recognize what might be happening, and would then have tried antispasmodics, and if the patient did not respond quickly, we would have persisted and probably persisted too long. We should have been guided by traditional conservatism and by fear of criticism for breaking new ground. Now, if we thought this condition was present, we should try antispasmodics, give the patient a maximum of twenty-four hours in strong labour, and then perform Cæsarean section, believing that by failing to do so we should neglect our duty and deny our experience.

SPASMODIC DYSMENORRHOEA

Here the pain is probably due to inco-ordinate uterine action or spasm. In its more severe form the condition cannot be cured by medical treatment. It can sometimes be cured by simple dilatation, but more certainly by artificial labour, that is to say, by dilatation followed by packing the cervical canal with tents for forty-eight hours.

Cases of severe dysmenorrhœa are accompanied sooner or later by some degree of neurasthenia, and then the result of treatment—cure or relief—depends on how far the neurasthenia is also cured.

In hæmatocolpos the pain is due to obstruction of the menstrual flow, and the condition is cured by removing the obstruction. As a rule it is not this pain which brings the patient to hospital, but that due to retention of urine.

SUBMUCOUS PEDUNCULATED FIBROID IN PROCESS OF EXTRUSION

The pain in this condition is typical uterine contraction pain, felt in the sacral and hypogastric regions. The amount of pain depends on the size and consistency of the mass being extruded, but even so pain is not the prominent feature; it is usually masked by the bleeding.

VENOUS CONGESTION NOT DUE TO TRAUMA

A well-involved mobile retroverted uterus or a congenital retroverted uterus does not give rise to intermenstrual pain because it is not heavy and congested. A heavy sub-involved uterus with venous congestion will give rise to sacral backache and hypogastric discomfort. I think the pain is due to the increase in vascular tension and associated oedema in the body of the uterus. It disappears when the uterus is maintained in the proper position for venous drainage.

MUSCULAR FATIGUE

That muscle fatigue can cause pain is no doubt common knowledge to all who have passed beyond the stage of adolescence. It may be acute while the muscles are at work, and be graded down to the discomfort of stiffness after work has ceased.

A weakened pelvic diaphragm (levator ani and superficial perineal muscles) may find the task of supporting the abdominal contents beyond its capacity and so give rise to some pain. It has already been stated that this is one of the features of neurasthenia but it is also one of the features of the overworked mother and housekeeper who is not yet neurasthenic. It is also the primary symptom of prolapse during the period when the pelvic floor is giving way, and is felt in the back, in the iliac regions, or in all the areas of pelvic pain. It is suitably described by the term 'Girdle ache' or 'Girdle pain'. When the prolapse is complete, with the vagina inside out, pain is a much less prominent feature. The reason may be that the genital canal having ceased to fall, there is now very little drag on the pelvic tissue. Furthermore, the pendulous perineal mass prevents the patient from

being active on her legs, and she is compelled to sit or rest for the greater part of the day. For the neurasthenic or tired women general treatment and a

holiday, if it can be obtained, but when prolapse has begun a pessary is necessary as a temporary measure or support, and operation for cure.

Reviews

GLEANINGS FROM MY RESEARCHES. VOLUME I.—

KALA-AZAR: ITS CHEMOTHERAPY.—By Sir Upendranath Brahmachari, Kt., M.A., M.D., Ph.D., F.R.A.S.B., F.N.I. 1940. Published by the University of Calcutta. Pp. xx plus 461. Illustrated.

In Bengal, the immediate response to the word 'kala-azar' put by the psycho-analyst would on nine occasions out of ten be 'urea-stibamine' or 'Brahmachari', so deep an impression has Sir Upendranath's work on kala-azar and his now world-famous drug made on the mind of the man in the street. To the medical man, and especially to those who like the reviewer have been interested in kala-azar for a number of years, the word Brahmachari means much more, for we all know him as a great chemist; and every chemist in Bengal, not to mention chemists in foreign countries who are familiar with Brahmachari's work, know him as a famous physician and research worker. His book on the subject was the first book on kala-azar in the English language, and the successive editions and his more ambitious *Treatise on Kala-azar* have taken their place amongst the world's monographs on tropical diseases.

It is therefore with very great interest that we received the first volume of Sir Upendranath's *Gleanings from My Researches*. This volume is no less than a verbatim re-publication, with occasional explanatory notes by the author himself, of all the most important papers on the treatment of kala-azar contributed by him during the last 25 years. And a very formidable array they make.

Brahmachari made a special study of chemotherapy of antimonial compounds in kala-azar infection. An extensive series of chemical and therapeutical experiments with various antimoniales were carried out by him between the years 1915-1921, at the Calcutta Campbell Hospital. At first, several new inorganic antimoniales were synthesized and tried. Then later, following in the footsteps of that other famous chemist, Ehrlich, he turned to the organic antimoniales and invented urea stibamine.

The frontispiece serves to remind one of the early struggles of Sir Upendranath.

It is impossible not to see a parallel between the lives of two great research workers who made their crucial discoveries in Calcutta. Both modest self-effacing men whose thoughts were never for honour, recognition, or gain, but solely for suffering humanity. Both worked with the minimum of official encouragement, not to say against opposition, and both with poor equipment and under trying physical conditions, Ross in his small dark laboratory in the Presidency General Hospital with a microscope with a cracked lens and Brahmachari in an outhouse in the Campbell Hospital with no water or gas laid on, by the light of a hurricane lamp, both worked in the sweltering heat of Calcutta, and each described his triumph in memorable and poetic language, thanking his God or Providence rather than taking credit to himself.

Ross wrote

'God

Hath placed within my hand
A wondrous thing; and God
Be praised

* * * * *

I know this little thing

A myriad men will save.'

And Brahmachari

'I well recall that memorable night—I found about ten o'clock in a little room with a smoky dimly burning lantern that the results of my experiment were up to my expectations. But I did not know that Providence had put into my hands a wondrous thing and that this little thing would save the lives of millions of my fellowmen.'

TEXTBOOK OF GYNÆCOLOGY.—By Wilfred Shaw, M.A., M.D. (Cantab.), F.R.C.S. (Eng.), F.R.C.O.G. Third Edition. 1941. J. and A. Churchill Limited, London. Pp. viii plus 616, with 4 plates in colour and 255 text-figures. Price, 21s.

It is only five years since the first edition of Wilfred Shaw's *Textbook of Gynaecology* was published, so that it is a tribute to the author that it has been found necessary to bring out a third edition so soon.

To see the name Wilfred Shaw on the title page of a book or paper connotes that a perusal of such book or paper will repay one.

In the third edition of this book one's great expectations are fulfilled, for it is indeed a worthy successor to the previous editions. It follows the same sequence as the previous volumes; the plates and diagrams being much the same. However, the text has been elaborated and new matter has been added: the most notable addition being a chapter on chemotherapy and endocrinology, and the author has added valuable matter to the chapter on radiotherapy.

Mr. Shaw advocates douching the uterus after evacuation of the products of conception. This is an excellent recommendation which however has fallen into desuetude of late years. He also advocates the use of the Aveling repositor for treating cases of chronic inversion of the uterus, and states that the 'ingenious abdominal operations' devised for cases of this condition are hardly ever necessary as the repositor is usually successful, and the only operation justified is vaginal hysterectomy in certain cases. These opinions coming from such a savant as Wilfred Shaw must command attention; they are not however universally accepted.

The book is an excellent one and amongst the best in the literature.

H. E. M.

MEDICAL ORGANIZATION AND SURGICAL PRACTICE IN AIR RAIDS.—By P. H. Mitchiner, C.B.E., T.D., M.D., M.S., F.R.C.S., and E. M. Cowell, C.B., C.B.E., D.S.O., T.D., D.L., M.D., B.S., F.R.C.S. Second Edition. 1941. J. and A. Churchill Limited, London. Pp. ix plus 296, with 58 illustrations including 1 coloured plate. Price, 12s. 6d.

THE authors of this book had the foresight to see the likelihood of a demand for a book of this kind; they have, we hope, had their material reward, for we notice that the first edition was reprinted twice. The first edition was pre-war but post-Munich, appearing in March 1939; this second edition is post-'blitz'. Much of what was written in the first edition was theoretical, or comparative, being based on experience in Spain. That experience was very valuable, but probably those who have seen service in both Madrid and London during air raids will have found many practical differences in their two experiences.

One should perhaps not be too critical, in view of the conditions under which this book was rewritten, for one must assume that the experience of two such surgeons as the authors was not wasted during the

Oct., 1941]

autumn 'blitz' in England last year, but there is evidence of patching where rewriting was indicated. For example, the sections dealing with blood transfusion are very patchy. On p. 93 is written 'The technique of simple blood transfusion is well known and will not be described here'; it may be simple but many are unfamiliar with it and will look to this book for help. If they persist, ignoring the statement quoted above, they won't be altogether disappointed, because apparently in 1940 blood transfusion became less simple, and, if details are not given in this book, at least one is told where they are available; for the Medical Research Council apparently did not think that the procedure was so simple and gave these details in their *War Memorandum No. 1*. The authors occupy the space in which just a few of these details might have been reproduced by irrelevant, even if true, statements, such as that a blood transfusion costs £15 in Russia, and by a tall story from their Spanish friend Durán Jordá who claims to have given 7 pints of blood in 10 minutes; we question the truth of this story and certainly the advisability of recounting it without any further comment on the rate of blood transfusions. Plasma transfusion, which is now largely replacing blood transfusion in the treatment of shock, is just mentioned.

On the whole the new edition is disappointing. The book is a valuable one, and in view of the fact that there are few, if any, other books that cover the same ground, it is important and should be read widely in this country, especially in towns that may expect air raids, but the reviewer feels that it might have been better.

EXPERIMENTAL PHYSIOLOGY FOR MEDICAL STUDENTS.—By D. T. Harris, M.D., D.Sc., F.Inst.P. Third Edition. 1941. J. and A. Churchill Limited, London. Pp. xi plus 292, with 248 illustrations and plate in colour. Price, 15s.

This book, now in its third edition, is already familiar to many medical men who took their qualifying course in Great Britain, but it is, to their disadvantage, less familiar to students from the medical colleges of this country.

It is an ideal laboratory book for students doing their physiology course. In it a large number of appropriate and practical experiments, many of which can be done with the minimum of special apparatus, are described, and the lines along which other experiments could be devised are suggested.

This edition contains a very excellent chapter on experimental pharmacology (by Dr. W. A. M. Smart) which is an extremely appropriate addition to a book on experimental physiology.

This is a book that will be found very valuable for teachers of physiology and pharmacology in India. If they do not feel able to recommend it as a class book, hesitating to add to the student's already heavy book bill, they will find it very valuable for their own use, as it is replete with suggestions for experiments very suitable for students in this country.

RECENT ADVANCES IN THERAPEUTICS. PART II.—By J. R. Goyal, M.B., B.S. 1941. Published by the Manager, The 'Medical News'. P. O. Box 81, Delhi. Pp. iii plus 225. Price, Rs. 3-8

LATELY, we reviewed the first part of this book, that was entirely devoted to sulphonamide therapy. The second part, just published, deals with vitamins, hormones and various therapeutic agents, *viz.* protamine zinc insulin, dilantin, prostigmin, etc. Concise notes or abstracts from recent publications have been put together, thus affording a bird's-eye view of the subject.

The selection is fairly good, but the amount of detail often appears to be out of proportion with the relative importance of the subjects.

Cautionary comments might have been incorporated with some of the abstracts, especially with reference to the claims of 96.3 per cent cures in blackwater fever.

with *Cassia fistula*, rapid improvement following cholesterol therapy in advanced anaemia of pregnancy, and a few others.

There are many printing mistakes in the book; the errata list added at the end of the book is incomplete.

General practitioners who are not in touch with recent literature will, however, find these two booklets very helpful.

R. C.

AIDS TO ANATOMY AND PHYSIOLOGY FOR NURSES.—By Katharine F. Armstrong, S.R.N., S.C.M., D.N. (Lond.). 1941. Second Edition. Ballière, Tindall and Cox, London. Pp. xiv plus 384. Illustrated. Price, 3s. 6d.

I AM already well acquainted with the *Aids to Anatomy and Physiology*, and have circulated copies among my student nurses.

The book is unique in making these subjects interesting, and clearly summarizes all the knowledge needed by the nurses. It is simply set out, and is in my opinion adequate for the needs of the student nurse, without supplement from other books.

D. E. C.

AIDS TO MEDICAL NURSING.—By Margaret Hitch, S.R.N. 1941. Ballière, Tindall and Cox, London. Pp. x plus 375. Illustrated. Price, 3s. 6d.

Aids to Medical Nursing by Margaret Hitch is a valuable and essential addition to the series. It gives just the information on medical subjects that nurses need, with concise details of nursing care. This pocket-sized book should prove most helpful, both as a reference for those on duty, and for study for the final examination.

I shall have no hesitation in warmly recommending this book to both my student nurses and charge nurses.

D. E. C.

CORRIGENDUM

In our July 1941 number on p. 440 in the review on *Materia Medica of Pharmaceutical Combinations and Specialities* by U. B. Narayanrao, reference was made to 400 patent medicines: the figure should have been 4,000.

Abstracts from Reports

ANNUAL REPORT OF THE KING EDWARD VII SANATORIUM, BHOWALI, U. P., FOR THE YEAR 1940

The sanatorium remained open throughout the year and the accommodation available was fully occupied except during the winter months and, as usual, there was a waiting list during the season especially for the cheaper classes. Enquiries and applications for admission were received not only from the various districts of U. P. but from other provinces also.

Seventy patients remained in the sanatorium on 1st January, 1940, from the previous year and 252 patients were admitted and 274 discharged during the year under report. The daily average number of patients treated was 112.67, the largest number being 145 during the months of June, July and September, and the lowest 48 in the month of December.

The financial condition of the sanatorium remained satisfactory.

The need of water for the sanatorium has been felt very keenly for some time. While the quantity of water available has remained the same, the accommodation for patients has gone up from 18 in 1912 when the sanatorium was opened to 162 in 1940. Great difficulty is therefore being felt in supplying a sufficient quantity of water to the staff and patients. The question of sanitation is always closely bound up with

the supply of water and during the dry season when enough water is not available, it is found difficult to clean the drains and latrines thoroughly.

The urgent need of electricity in the sanatorium has been shown from year to year. The sanatorium requires electricity not merely for the sake of comfort to the patients but also from the point of view of efficiency and hygienic considerations. No sanatorium can be called up-to-date in these days without electricity when so much depends upon it such as x-ray, ultra-violet ray treatment, radio, etc.

The present generating plant consisting of an engine and dynamo for running the x-ray apparatus is showing signs of deterioration. The storage battery consisting originally of 60 cells was already small for the purpose for which it was meant when installed in the year 1931, and now it has become still less efficient owing to the disconnection of several cells on account of plate and other defects as a result of which a serious limitation has been imposed on the use of instruments and appliances dependent upon electric current, such as, the ultra-violet ray lamp, viewing boxes for studying the x-ray films, radio set, etc. During winter months the development of x-ray films has become very difficult because tank heaters cannot be used.

SECOND TRIENNIAL REPORT OF THE GOVERNMENT TUBERCULOSIS CLINIC (COLVIN HOSPITAL), ALLAHABAD, U. P.

DURING the year 1940, 1,139 patients were visited and 409 contacts were examined. The 'home' and not the 'family' was considered as the basis for investigation of contacts. From amongst the contacts about 25 per cent were found suffering from tuberculosis. These figures are high compared to English and other Indian figures. There may be some divergence on account of the standards of diagnosis; for instance a child contact aged 6 years with Mantoux (++) and having a few deep glands in the posterior triangle but not having any rise of temperature above the normal will be diagnosed scrofulous at one clinic and healthy at another. It is not always possible to observe the contact for a period before making a diagnosis. However in future it might be a better plan to separate a group of suspicious cases from those found definitely suffering from tuberculosis. A majority of cases disposed of their sputum in a satisfactory manner though a minority continued to be unsatisfactory.

SECOND ANNUAL REPORT OF THE TUBERCULOSIS ASSOCIATION OF INDIA FOR THE YEAR 1940

In presenting this second annual report, we would express at the outset our pleasure at the thought that circumstances have made it possible for Her Excellency the Marchioness of Linlithgow to remain with us for another year and that the Association will continue to derive the benefit of her inspiration and guidance for that period. Her Excellency's close and personal interest in the anti-tuberculosis campaign gives momentum to the work of planning and establishing anti-tuberculosis institutions at the centre as well as in the Provinces and States.

In spite of the fact that the country's interest and energies have been concentrated upon the successful prosecution of the war, the year 1940 has seen a consolidation of the Association's existing activities and of progress in several new directions.

The establishment of a Central Anti-Tuberculosis Clinic in Delhi, which was envisaged in the appeal launched by Her Excellency for the King Emperor's Anti-Tuberculosis Fund, is now an accomplished fact; the Kasauli Sanatorium project has been accepted, the estate has been taken over, and the construction is well advanced; the number of Provincial and State Tuberculosis Associations has increased; while a number of new institutions for the treatment of tuberculous

patients have opened or are in course of construction throughout the country. An account of the activities generally of the Tuberculosis Association of India is recorded.

[This report, only in its second year, has grown to a volume of 131 pages, including the appendices. This in itself is clear evidence of the steadily increasing activities of the Association, but its size prevents adequate abstraction so we have confined ourselves to reprinting the introduction which gives a broad outline of its main advances. All workers on tuberculosis in India and others interested in the subject are recommended to obtain a copy of the report and read it for themselves, for in its pages they will find much information and encouragement to continue and still further increase this valuable work.]

REPORT OF THE MAYAVATI CHARITABLE HOSPITAL, MAYAVATI, ALMORA, HIMALAYAS, FOR 1940

THE Mayavati Charitable Hospital came into being as a sheer necessity—in fulfilment of the local needs. The regular dispensary was opened in 1903. Since then it has been growing in size and importance. Now quite a large number of patients come from a distance of even 50 or 60 miles, taking 4 or 5 days for the journey.

The hospital stands within the precincts of the Ashrama, and is in charge of a monastic member qualified for the task. There is also a medical graduate who was appointed to increase the efficiency of the work. Service is done in a spirit of worship, and as such irrespective of caste or creed. The efficiency with which the work is done has elicited admiration from one and all. Especially medical persons having the practical knowledge of running a hospital have appreciated the management of the institution situated in such a distant corner of the Himalayas.

In the hospital there are 13 regular beds, one extra bed being added this year. But sometimes we have to make arrangements for even 30 or more indoor patients.

The operation room is fitted with up-to-date equipment and almost all kinds of operation can be done here.

We have also got a small clinical laboratory.

There is arrangement for the amusement and recreation of the patients through a gramophone. There is also a small library for those who can read.

The following figures will indicate the gradual growth of the hospital:—

Year	NUMBER OF PATIENTS	
	Outdoor	Indoor
1915	1,173 ..
1925	3,162 35
1930	5,014 203
1935	14,344 189
1940	14,312 286

THE ASSAM MEDICAL RESEARCH SOCIETY, SHILLONG: A RÉSUMÉ OF ITS ACTIVITIES DURING 1931-41. ILLUSTRATED. PUBLISHED BY MESSRS. THACKER, SPINK AND COMPANY (1933), LIMITED, 3, ESPLANADE EAST, CALCUTTA

The introduction to this publication gives a short account of the genesis of the Society which we quote in full:

'The Society was the result of negotiations which had been going on since 1927 between the Assam Branch, British Medical Association, and the managing committee of the Pasteur Institute, under the Government of Assam with the Government of the Medical Research work in the province. In its final form the Society owes its inception to Sir Egbert Laurie Lucas

Oct., 1941]

CORRESPONDENCE

Hammond, K.C.S.I., C.B.E., I.C.S., the then Governor of Assam, who was pleased to become its first Honorary President and to Lieut.-Colonel J. Morison, C.I.E., M.B., M.R.C.P.H., I.M.S., who was then Director of the Pasteur Institute, Shillong.

An informal conference was held at Shillong on Tuesday, the 16th September, 1930, under the chairmanship of the Hon'ble Minister, Local Self Government, Assam (the late Rai Bahadur K. L. Barua), to discuss the possibility of forming a Society to press forward the investigation of malaria and other epidemic diseases. Members of the legislature, representatives of the Government and of the agricultural, industrial, transport and other interests and of the non-official public attended the above conference and discussed the scheme formulated by Colonel Morison, the (then) Director of the Pasteur Institute, for the above purpose. After further consideration both by the industrial interests and by the Government, a communiqué was issued by the Government of Assam on the 17th February, 1931, notifying the formation of a Society registrable under the Societies Registration Act of 1860 under the name of the Assam Medical Research Society the objects of which would be the prosecution and assistance of medical research and investigation in connection with the causation, mode of spread and prevention of communicable diseases in Assam (and adjacent parts of India) and malaria in particular, the dissemination of knowledge acquired and the furtherance of experimental measures against these diseases. Members of the first Governing Body representing the various interests were nominated by His Excellency the Governor of Assam.

The Society has now been in existence for about 10 years and a report on its activities from year to year has been furnished to the Governing Body and its constituents. As the future of the Society is rendered somewhat uncertain owing to the termination of the grant from the Government of India made through the Indian Research Fund Association with effect from 1st April, 1942, a brief résumé of the activities of the Society covering its period of existence over the last 10 years is now submitted for the consideration of the Governing Body and the constituents in order to enable them to arrive at a decision as regards its continuance in its present or modified form or the maintenance of the continuity of work by other means.

Then follow two parts giving a summary of the work performed throughout this period. The principal work has been in connection with malaria control and cholera prevention, "and as we have regularly abstracted from the annual reports every year we do not propose to refer to them further here. There is a fourth part headed 'Conclusion' giving a further account of certain special aspects of the work, and finally in an appendix there is a summarized statement of receipts and expenditure.

It is an interesting record of valuable work and in later years will undoubtedly prove of historical interest when the Society is older and its origin and early work is less well remembered than it is to-day.

ANNUAL REPORT OF THE MALARIA ADVISORY BOARD, FEDERATED MALAY STATES, KUALA LUMPUR, FOR THE YEAR 1940. BY A. NEAVE KINGSBURY, CHAIRMAN

PRELIMINARY findings by the Malaria Research Division, Institute for Medical Research in regard of M3—a preparation manufactured by the State Biochemical Institute of Milan—were included in the previous report. The manufacturers claim that the drug has a curative action in chronic malaria and that its prophylactic value is greater than that of quinine. They allege that a single course of a month's duration confers immunity from malaria for six months. The Senior Malaria Research Officer reported the final results of M3 prophylaxis on a population of 100 over a period

of six months. Briefly, the preventive action was less than that of a single weekly dose of 1.0 gm. of quinine—a known inefficient dose. Furthermore there was no evidence that the drug stimulated the development of malaria immunity.

'ALEBRIN'

The preparation 'Alebrin' was also brought to the notice of the Board. This synthetic compound, manufactured by an Indian firm, is claimed to be of value in malaria. It is a yellow solid said to be a derivative of benzodihydrochloride-methoxydiamino-acridine. The trade leaflet issued by the manufacturers states that it is twenty times stronger than quinine. The appearance is very similar to that of atebrin in the form and colour of the tablet, the type of packing, the leaflet of instructions and the design of the package. A supply of 'Alebrin' sufficient for three courses of treatment was received in October last from a local drug house; two cases of acute *falciparum* malaria and one case of acute *vivax* malaria were given the full course of 0.3 gm. X 5, recommended by the manufacturers. The Senior Malaria Research Officer found that the response to treatment was slow; in the two 'Alebrin'-treated cases of *falciparum* malaria, asexual parasites persisted in the peripheral blood for eleven days—their elimination then was probably due to the quinine which, on account of the increasing number of parasites, it was necessary to give from the eighth day onwards. Fever disappeared during alebrin treatment, but more slowly than with quinine; in one case fever recurred on the eighth day. In the *vivax* malaria case, parasites remained in the peripheral blood for three days longer than in the quinine-treated case; fever for one day longer. This action is not that of an efficient drug. With efficient quinine treatment parasites very rarely persist beyond the seventh day. Three cases do not provide a sure basis for a dogmatic statement on the efficiency of a drug in malaria but there can be little reasonable doubt that whatever may be the value of 'Alebrin', it is much less effective than quinine.

Correspondence

A NOTE ON COMPLEMENT-FIXATION TEST IN LEPROSY AND KALA-AZAR WITH WITEBSKY, KLINGENSTEIN AND KUHN (W.K.K.) ANTIGEN

SIR.—In your August number you publish 'A note on complement-fixation test in leprosy and kala-azar with Witebsky, Klingenstein and Kuhn (W.K.K.) antigen' by Greval, Chandra and Das in which the authors indicate that the test with the W.K.K. antigen is of considerable value in the diagnosis of leprosy, and possibly in prognosis and in studies of aetiology and epidemiology. A thorough study of this test carried out in this department has led to very different conclusions.

The work on this antigen was initiated in 1938 after the report of various workers chiefly in South America that the W.K.K. antigen frequently gave complement fixation in cases of leprosy and also in cases of kala-azar. In the early phases of the work we had the collaboration of Colonel Greval. The technique of the test was modified (Greval, Lowe and Bose, 1939) and the results of the test were studied in 250 cases of leprosy, 20 cases of kala-azar and 92 cases of other diseases (Lowe and Greval, 1939). Later, Dharmendra and Bose (1941) working in this department thoroughly studied complement fixation in leprosy with antigens prepared from various acid-fast bacilli by various methods including that of Witebsky, Klingenstein and Kuhn.

The article by Lowe and Greval reported that the results of complement-fixation test were found to

correspond very closely with the results of ordinary bacteriological examination for *Mycobacterium leprae*, but since bacteriologically-positive cases form only a small proportion of the total, and since diagnosis of such cases by other methods is easy, the value of the test in diagnosis was little. The article also reported positive results in 18 of 20 cases of kala-azar and doubtful or negative results in nearly all of 92 cases of other diseases.

The article by Dharmendra and Bose showed that complement fixation could be obtained in bacteriologically-positive cases of leprosy with a large number of antigens prepared by various methods from almost any acid-fast bacillus, pathogenic or otherwise, and that there appeared to be little specificity about the reaction.

Further work on immunological tests in leprosy (allergic skin tests, and complement-fixation tests after absorption) has suggested that the complement fixation seen in leprosy with various antigens may not be a true immunological reaction at all.

I will outline the bearings of these findings on the use of the W.K.K. antigen in leprosy.

(a) *Diagnosis*.—The W.K.K. antigen gives results in bacteriologically-positive cases, which here form only about 20 per cent of the total, and in which diagnosis by other methods is much easier, quicker and more generally practicable. Its value in diagnosis therefore appears to be very little, and we have never even thought of using the test for this purpose.

(b) *Prognosis*.—Our limited observations in the possible prognostic value of the test has demonstrated marked limitations. It will not even differentiate between the bacteriologically-positive neural cases with a good prognosis, and the lepromatous cases with a bad prognosis. We have therefore not undertaken a further study of this matter.

(c) *Aetiology and epidemiology*.—It has been shown that the test is of no value in establishing the genuineness of organisms isolated from leprosy material. It is therefore of no value in studying aetiology from the bacteriological aspect. In studying the wider aspects of aetiology and epidemiology, the lack of specificity and the doubtful significance of the test would appear to render it of little value. Already simpler and better immunological methods are available.

So far I have dealt only with the main lines of the article by Greval, Chandra and Das as far as they apply to leprosy. There are many details which call for comment but I will deal with only one, namely, the statement that in diagnosis, doing a complement-fixation test is easier than 'removing bits of tissue for the microscope'. In cases that give a complement-fixation reaction, clinical diagnosis is usually very easy, and if microscopic confirmation is needed, a 'slit smear' can be taken and examined in a few minutes. The above statement is therefore very misleading.

The finding that complement fixation can be obtained in bacteriologically-positive cases of leprosy with antigens prepared from acid-fast bacilli by a variety of methods, and used in high dilution, is an interesting observation, but its practical value is very little.

JOHN LOWE.

VIPER VENOM IN A CASE OF RECURRENT HEMORRHAGE IN THE VITREOUS

Sir.—In the *Indian Medical Gazette* for April this year (p. 221) I reported a case in which viper venom was successfully used in the treatment of recurrent haemorrhage in the vitreous, the treatment ending in August 1940.

In April 1941 the patient insisted on a second course of viper venom as a preventive against relapse. I consented and gave him a first dose of $\frac{1}{2}$ c.c.m. of diluted viper venom intramuscularly. Within 10 minutes he exhibited a strong allergic reaction—flushed face, general urticaria, rapid pulse, etc.

Adrenalin was not administered because it is contraindicated with viper venom (see notes from Haffkine Institute on viper venom in tooth bleeding).

He recovered in about an hour with rest, applications of cold water and lying under an electric fan.

No after effects were reported to me, but I have since been notified by his family physician that the man died in May of this year from uremia. His vision was good until his death.

CONGENITAL MALARIA

Sir.—In the *Practitioner* for May 1941 on page 339, Dr. Cooke, Physician in charge of out-patients, Hospital for Tropical Diseases, London, states 'it should be remembered that malaria can be transmitted via the placenta'. On page 135 of the third edition of combined *Textbook of Obstetrics and Gynaecology*, 1939, published by Livingstone, it is stated 'The malarial parasite never passes from the mother to the foetus'. Which statement is one to accept and believe? Since there is at no time any connection or continuity between the maternal and foetal circulations, and the interchanges between them (mother and foetus) take place through the thickness of the villi and the walls of their vessels, is it usual (normal), or possible for the malarial parasite to pass from the one to the other through healthy intervening tissue?

One is perplexed at the above contradictory statements, so perhaps you or some other authority would clarify things through the medium of the *Gazette*.

J. CHINAL, M.D., D.T.M.

P. O. BASDEOPUR,
MONGHYR DISTRICT,
E. I. RAILWAY,
31st August, 1941.

[Note.—Whilst Dr. W. E. Cooke's statement is strictly correct, it is, we consider, misleading; on the other hand, the statement in the gynaecological textbook, if it is unqualified by its context (we have not looked it up), is not true, but conveys the correct idea, namely that under *normal* conditions the malarial parasite does not pass from the maternal to the foetal circulation.

We refer our correspondent to a paper by Professor B. M. Das Gupta that appeared in this journal in July 1939 (page 397). The question is very well answered here.

Many cases in which the child was quite evidently infected before birth have been reported, though it is relatively a very rare occurrence. There is no evidence at all that the parasite is capable of penetrating the membrane that separates the maternal and foetal circulation, but, as this membrane is very thin and very extensive, its rupture, as a result of trauma or some localized lesion, is not an unlikely accident.—EDITOR, *I. M. G.*

Service Notes

APPOINTMENTS AND TRANSFERS

The services of Lieutenant-Colonel R. N. Bhandari, Superintendent, Central Prison, Agra, have been placed at the disposal of the Government of India, Defence Department, with effect from 6th July, 1941.

Lieutenant-Colonel N. S. Jatar, C.I.E., D.S.O., returned to duty before the expiry of his leave and resumed charge of the office of the Inspector-General of Prisons, Central Provinces and Berar, on 7th July, 1941.

Lieutenant-Colonel A. S. Garewal, officiating Inspector-General of Prisons, Central Provinces and Berar, has been reposted as Superintendent, Central Jail, Nagpur, from 8th July, 1941.

The services of Lieutenant-Colonel M. A. Jafary, Superintendent, Central Jail, Lucknow, have been placed at the disposal of the Government of India, Defence Department, with effect from 8th July, 1941.

The services of Lieutenant-Colonel J. B. Vaidya, Civil Surgeon, Benares, have been placed at the disposal of the Government of India, Defence Department, with effect from 13th July, 1941.

The services of Lieutenant-Colonel J. C. Bharucha, Principal, Medical College, Agra, have been placed at the disposal of the Government of India, Defence Department, with effect from 15th July, 1941.

Lieutenant-Colonel S. L. Bhatia, M.C., Principal, Grant Medical College, and Superintendent, J. J. Group of Hospitals, Bombay, has been appointed as Additional Deputy Director-General, Indian Medical Service, and has been transferred from this Province, with effect from the afternoon of 7th August, 1941.

Lieutenant-Colonel J. M. Shah, M.B.E., I.M.S. (Retd.), has been re-employed and appointed as Superintendent, J. J. Group of Hospitals, Bombay, with effect from the afternoon of 7th August, 1941.

On his reversion to military duty Lieutenant-Colonel D. R. Thomas, O.B.E., Chemical Examiner to Government, Punjab, made over charge of his duties to a non-I.M.S. officer on the afternoon of the 12th August, 1941.

Lieutenant-Colonel S. L. Patney, Superintendent of the Presidency Jail, Alipore, made over executive charge of the Jail to Mr. Chas. A. W. Luke on the afternoon of the 16th August, 1941.

Lieutenant-Colonel K. S. Thakur made over medical charge of the Alipore Central Jail to Dr. Bankim Behari Roy on the afternoon of the 23rd August, 1941.

On his reversion to military duty, Lieutenant-Colonel P. A. Dargan, Civil Surgeon, Amritsar, made over charge of his duties to a non-I.M.S. officer on the afternoon of the 14th August, 1941.

Lieutenant-Colonel B. Z. Shah, I.M.S. (Retd.), has been re-employed and appointed as Superintendent, Central Mental Hospital, Yeravda, with effect from the forenoon of 21st August, 1941.

The services of Major D. MacD. Fraser, Civil Surgeon, Naini Tal, on return from leave, have been placed at the disposal of the Government of India, Defence Department, with effect from 7th June, 1941.

The services of Major J. H. Boulbee, Civil Surgeon, Agra, have been placed at the disposal of the Government of India, Defence Department, with effect from 8th July, 1941.

Major R. I. Reid is appointed as Director of Production, Instruments and Appliances, in the office of the Director-General, Indian Medical Service, with effect from the forenoon of the 19th July, 1941.

Captain H. B. Wright, Deputy Assistant Director-General (Medical Stores), Karachi, will continue to officiate as Additional Assistant Director-General, Indian Medical Service (Stores), until further orders, vice Major R. I. Reid, appointed Director of Production, Instruments and Appliances.

Captain F. R. Cawthorn is confirmed as an Agency Surgeon, with effect from the 5th May, 1941.

The undermentioned Lieutenants (on probation) are confirmed in their rank, subject to His Majesty's approval:—

RETIREMENTS

Major-General (local Lieutenant-General) W. H. Hamilton, C.B., C.I.E., C.B.E., D.S.O., K.H.M. Dated 12th July, 1941.

Lieutenant-Colonel H. Chand, m.c. Dated 26th August, 1941.

Lieutenant-Colonel N. J. Gai. Dated 26th August, 1941.

Lieutenant-Colonel C. M. Ganapathy, m.c. Dated 1st September, 1941.

Notes

DEXTROSOL

THE place of dextrose (d-glucose) in health and disease has of late received considerable attention in the medical press; the following three booklets that have been issued by Corn Products Company are sure to prove useful:

'The Therapeutic Use of Dextrose' by Gaston Levy.

'Dextrosol in the Pathology of Digestive Disorders.'

'Advances in Treatment with Dextrosol.'

The three booklets give a very good idea of the protean pathological conditions in which glucose can be used with advantage. The sceptic might suggest that these include the whole range of human ailments, but this would be an exaggeration. It is however no exaggeration to say that in the very great majority of acute diseases the administration of glucose will help the patient. The remark also applies to many sub-acute conditions.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints gratis; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more, after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributors should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

OBSERVATIONS ON THE NAKED-EYE MANIFESTATIONS OF CHRONIC INFECTIVE PROCESSES IN THE ABDOMEN

By A. INNES COX

LIEUTENANT-COLONEL, I.M.S.

District Medical Officer, Madura

'READ not to contradict and refute; not to believe and take for granted; nor to find talk and discourse; but to weigh and consider.'—BACON.

It is unfortunate, but true, that many of us in India handle medical and surgical material of intense interest, and yet after years of experience have little to show for it, except official annual returns and mental impressions. It is not wholly our fault, for the pressure of work is immense, change of district, and frequent change of assistants necessitated by the exigencies of service tend to retard good intention. I plead guilty of this failure, yet feel constrained to set forth my mental impressions as they have grown strong by frequent repetition. I also gain encouragement by the knowledge that many respected colleagues over a number of years have confirmed my observations and agreed to the probability of the conclusions drawn from them.

Case records and scientific laboratory reports, I have none. To delve into the records of headquarter hospitals no longer in my district is to call upon others to do the work that I should have done myself. However, if the reader will condone this unscientific approach, maybe what follows will not be without interest as it offers a fresh explanation for some common abdominal diseases, and endeavours to explain others that are still obscure. The reader must take, with me, a very general view and regard the patient, his surroundings, habits and customs as an entity, and all that, against a time background. I wish particularly to emphasize the time factor, for I talk of chronic infections and not of the acute infective processes that are sudden and dramatic, although the chronic may become dramatic at any time, and so obscure the chronic origin. It must also be realized that all diseases have a degree of local variance, and I speak of south-west India, particularly of Malabar and Coimbatore.

I will discuss my observations in the order in which they have impressed themselves upon me.

1. The naked-eye appearance of old-standing inflammation of the appendix and of its effect on the intra-abdominal organs.

2. The naked-eye appearance of old-standing inflammation in the lower abdominal cavity other than that of appendicular origin and its apparent results.

3. The origin and scope of these different infective processes.

4. Deduction.

1. The appendix itself varies in appearance from a sclerosed dry strand of tissue to a long thick turgid oedematous structure. It may be of any shape and in any position, but, whatever its condition may be, there will be found, taking origin from it, a degree of lymphangitis which gives rise to a membrane formation. This membrane is highly vascular in the active stages, tough, and in places unyielding in the later stages; it is loosely applied to the surface of all the viscera that it encounters in its upward path; but it forms strong ligamentous attachments between the viscera. New glandular formation and enlargement of normal existing glands will be found according to the degree of inflammatory activity encountered during the laparotomy. It is not usual for the people of south-west India to resort to hospital for discomfort that does not incapacitate them, so the early stages of this membranous formation are not so commonly seen; what is usually seen is the result of years of a chronic inflammation which has resulted in complications.

I have attempted to sketch the general appearance (figure 1). The whole of the right

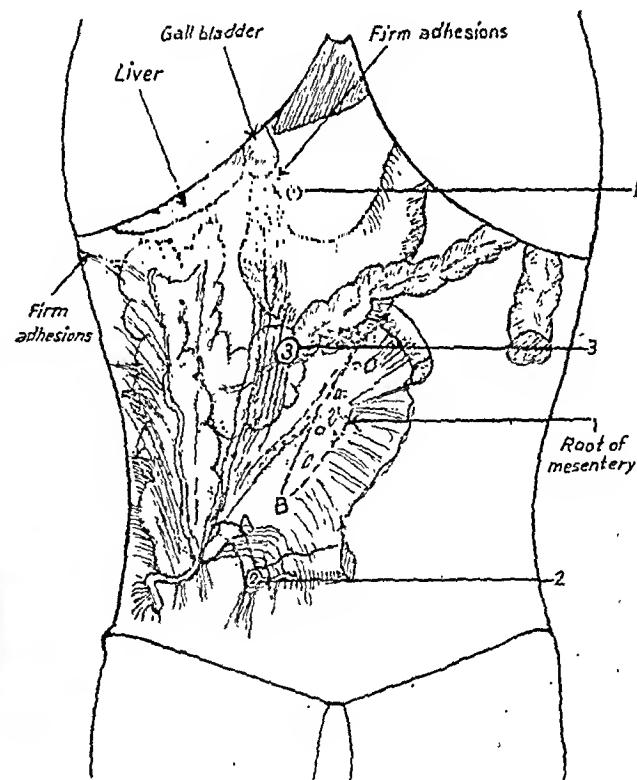

Fig. 1.—Sites marked (1), (2), (3) represent the three main sites of obstruction.

side of the abdomen is invested by a membrane, so tough in places as to appear ligamentous. This although closely applied to the underlying viscera, does not appear to be part of their peritoneal covering, for it can be separated from them to demonstrate its adventitious nature.

The terminal ileum is bound down, often to a degree that renders it unrecognizable until freed by Mayo's scissors. The cæcum ascending colon, hepatic flexure and the first third of the transverse colon are all invested. The pyloric end of the stomach and the first part of the duodenum are firmly bound to the under surface of the liver and gall bladder, and strong bands bind the large gut on the right side of the abdomen to the adjacent para-colic gutter. As this membrane toughens, the pyloro-duodenal junction becomes first fixed, and then kinked. The site of the kink is often the site of a so-called pyloric ulcer. This is obstruction no. 1 (figure 1).

The exaggerated Lane's kink due to the approximation of points A and B in the figure, by sclerosis, in the presence of a bound terminal ileum, is obstruction no. 2 and where the strong bands of membrane cross the junction of the first and second thirds of the transverse colon is obstruction no. 3. It must however be realized that the whole length of gut from site 2 to site 3 is hampered in its activity. It is often turgid and oedematous from lymphatic obstruction, and the exudation escaping from this part, added to the little free fluid usually found in the dependant parts of any abdomen, often amounts to some ounces and this on exposure to the air forms a gel, testifying to its inflammatory nature. So this too must be considered to be endowed with the power of adhesion formation, and the possible reason why an intra-abdominal lymphangitis gives rise to a sheet-like membrane.

This is the usual naked-eye picture encountered during the routine gastro-enterostomy for pyloric obstruction in a man of 45 years and over, with symptoms of 15 to 20 years' duration and whose condition is now rendered intolerable by virtue of obstruction no. 1. May the apparently large number of failed gastro-enterostomies not be due to the failure to appreciate, or permanently to overcome, obstructions at sites 2 and 3 whereby, undigested food, short circuiting obstruction no. 1, is held up at obstructions 2 and 3, giving rise to discomfort which the patient can no longer relieve by putting his fingers down his throat?

I have tried to find reference to this common state of affairs but the nearest approach to a description that I have been able to trace is a passage in Binney quoting Moynihan under the heading 'Cæcetomy'. I quote from memory as that reference is not available and so may be forgiven for not reproducing that lucid fluidity of writing that characterizes Moynihan. He says in effect that 'Sometimes the whole of the right side of the abdomen is found turgid and oedematous, affecting the cæcum, ascending colon and the first half of the transverse colon and for this I can think of no effective treatment other than hemi-colectomy'. I think that at some time Lord Moynihan must have recognized what I describe as commonplace in

South India, but what is in England, I presume, much less common. I have been tempted to do an ileo-transverse colostomy in such extreme cases, as such appears reasonable, but the patients are poor surgical risks and dislike operation by stages.

I am satisfied that the kinking described as obstruction no. 1 can be, and is, the site of ulceration. Ulceration behind an obstruction is a habit in the alimentary canal. I am also equally satisfied that the thickening behind the kinked, bound obstruction is taken for pyloric ulcer with sclerosis even when there is no ulceration, for I have followed operated cases to the post-mortem room on several occasions and found no ulcer, but with the relaxation of death, a free passage. This error is more likely to occur with spinal and general anaesthetics than with local, although I hasten to add, it is not necessarily bad surgery to perform gastro-enterostomy if there be obstruction even in the absence of ulceration, so long as obstructions 2 and 3 are appreciated.

Now all that is said above will explain another common condition, namely, chronic gastric dilatation. I had one extreme case whose stomach during x-ray examination obscured every organ in the abdomen and pelvis. I kept him in hospital for over 10 months, when he died. Autopsy proved that there was no ulcer, but he did have a very tough membrane formation and evidence of long-standing appendicitis. Another such extreme case treated by gastrostomy and the passage of a tube through the pylorus remained happy until the tube came out and could not be replaced, and so he too died. But between the slight and the extreme, many cases of simple chronic gastric dilatation are seen in this part of India, and while painless because free of ulcer, yet give rise to extreme discomfort which the patient tries to relieve by belching and air-swallowing to enable him to belch more freely. (Perhaps the home practitioner may not realize it, but this is classical conduct in the part of India I speak of.) This too, I believe, is the result of the membranous lymphangitis rising from a chronic appendix, thickened into ligamentous attachment between the pyloro-duodenal junction, and the under surface of the liver.

The name volvulus is a loose one. If what I describe below is volvulus of the small intestine, then 4 out of 5 cases of intestinal obstruction (other than hernial strangulations) are in my experience, on the Western side of South India, volvulus of the small intestine.

The condition appears to be this. The appendix shows evidence of chronic inflammation resulting in sclerosis. The membrane described above is marked, and, as the lymphangitis is no longer active, it is now a contracting scar. The appendix may lie across the terminal ileum, either in front or by artifact, behind (the ileum being bound down and dragged down by scar contraction on top of it). The appendix and

cæcum are drawn up towards the root of the mesentery which, in its lower part, is puckered and contracted, more below near the appendix than above which is the root of jejunum. There is a degree of small intestinal obstruction in the lower reaches of the ileum at the site marked obstruction no. 2 in figure 1, while above, the gut is hypertrophied and dilated. As a result there is a longer mesentery to the jejunum than to the ileum, the latter being scarred and puckered by its proximity to the appendix and old-standing lymphangitis at its base. Some day after a big meal, the weight of the upper gut bears it down and to the right, and the base of its mesentery lying over the scarred, fixed, lower mesentery *cum* appendix brings the jejunum towards, and even into, the pelvis. In this way the mesentery makes a half-turn anti-clock-wise that is clear to the eye at operation and is corrected only by complete eventration, when, the fixation of the cæcum *cum* appendix *cum* lower ileum having been relieved, the bowel resumes its normal position, the contents pass on and the patient (temporarily at all events) is cured (figure 2).

A highly situated appendix is at times described as due to failure in descent of the cæcum and ascending colon. This developmental failure cannot be considered a common occurrence as it is not commonly found in abdomens innocent of the pathology I shall shortly attempt to describe.

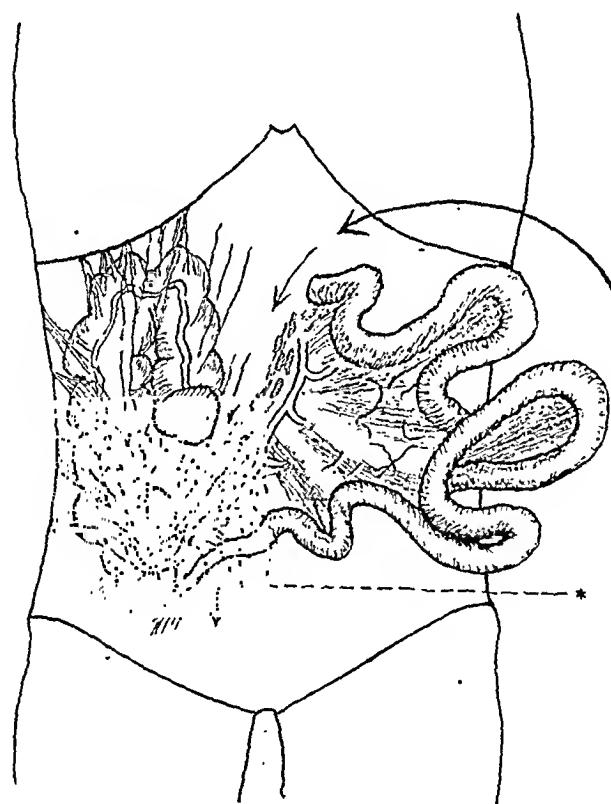

The appendix is, at times, plastered down on to the ascending colon, and so covered over by this lymphangitic membrane that it looks like one of the longitudinal striae, and is only demonstrated to be the appendix by the surgeon dissecting it out.

The tip of the appendix may be right up under the liver and attached to it by a ligamentous thickening of this membrane. It may even be so attached to the gall bladder, that, by contracture of this membrane and the adhesion caused by it, the whole of the large gut in the right side of the abdomen is drawn up, so that to effect visualization and removal of the appendix the incision must be extended upwards to the maximum, and woe to the surgeon who has started work through the grid incision.

Once this state of affairs is acquired it is very doubtful if a patient is materially benefited by removal of an appendix that has itself long

since prohibited the ingress of any bowel content, for on slitting it up it is found to be thick-walled, tough, and innocent of any faecal content or of naked-eye evidence of active inflammation. But it has materially interfered with the free movement of the right half of the large intestine, duodenum and pylorus by virtue of the membranous formation resulting from years of chronic inflammation.

Appendicular gastralgia conveys the idea of a nervous reflex. I do not refer to this form of upper abdominal discomfort secondary to appendicitis, but to gastric or upper abdominal discomfort amounting to pain in the absence of obviously active appendicitis. One knows that a patient treated gently under a local anaesthetic does not greatly complain, but directly an organ is pulled upon he immediately resists or even cries out. In the condition described above with the pyloro-duodenal junction fixed to the liver and gall bladder, the colon fixed to the liver, and hypertrophy of these organs secondary to their hard work in overcoming obstruction,

* Terminal ileum bound down by sclerosed membranous adhesions. Strangulation over this fixed point.

Fig. 2.—Diagram showing the shortening of mesentery of the terminal ileum and the relatively long mesentery to the jejunum predisposing to volvulus.

it is easy to imagine a stomach contracting in its length as it goes into peristalsis so pulling on the gall bladder, wave after wave and pull after pull. Naturally, the patient resents this pulling on an organ. So I suggest that constant upper abdominal discomfort after food may be due to the stomach or, alternatively, the colon constantly pulling, as it were, on the gall bladder door bell. It is not unduly difficult, but laborious, to work through these tough

adhesions, but having done so how are they to be prevented from reforming? Hence, after removing a 'chronic appendix' for a gastralgia (there being no evidence of pathological lesion of the stomach) the patient complains that his old pain is still present, and so it will be, for all time, unless removal of the cause permits of stretching and elongation of the adventitious attachments this possibility I very much doubt, because they are seen so many years after, on re-opening what is diagnosed to be a failed gastro-enterostomy. In explanation of this discrepant diagnosis I advance my second point, which is essentially an attempt to show the similarity between the symptoms usually associated with the macroscopic appearances of abdominal pathology of appendicular origin, and similar appearances which, I suggest, arise from causes other than chronic appendicitis, so :—

2. When what is described above apparently affects both sides of the abdomen, where does the inflammation come from and what is the picture?

One sometimes finds evidence of a chronic inflammatory process more in the left side of the abdomen than the right, and in this case, the pelvic colon suffers the maximum change, and the change is identical with what is seen in the root of the mesentery of the small intestine as described above. The limb of the inverted 'V'-shaped root of the mesentery that extends lower into the pelvis bears the brunt of the change. It is scarred and contracted and has a watered-silk appearance. There may even be a bunch of hard glands as its base, which, invading the root of the mesentery, further shorten it. Above, the gut deriving attachment from the other and higher limb of the 'V' is dilated and hypertrophied and one recognizes the same predisposition to volvulus of the pelvic colon as described above as volvulus of the small intestine. In the later decades of life volvulus of this part of the gut occurs, and what I have described above are the naked-eye findings sketched in figure 3.

On the right side of the abdomen one sometimes finds the appendix in a pocket of its own which is bounded laterally and below by the para-colic gutter and medially by the cæcum and terminal ileum. The roof, cut through to expose it, is formed by a false membrane often of surprising thickness. It is as if the appendix, squeezed out of the way, took no part in the proceedings, and, as if the cæcum contacted the para-colic gutter above it, the lymphangitic membrane jumped the potential gap, missed the appendix, and continued on its upward path towards the pre-aortic glands and upper and side abdomen.

Now, if one holds up the anterior abdominal wall and throws in a light, not infrequently one will see strands of vascular adventitious membrane arising from the internal inguinal ring on one or both sides. At times one even

finds that the omentum is adherent here, and when it is peeled off, a broken-down gland wedged in the internal inguinal ring, is easily delivered. The appearance is reminiscent of the fundus of the eye with all vessels radiating from the disc.

From one or both internal inguinal rings the same type of intra-abdominal naked-eye picture as described for the 'chronic appendix' is reproduced, and the same upper abdominal pathology faithfully copied, with fixation of the pylorus,

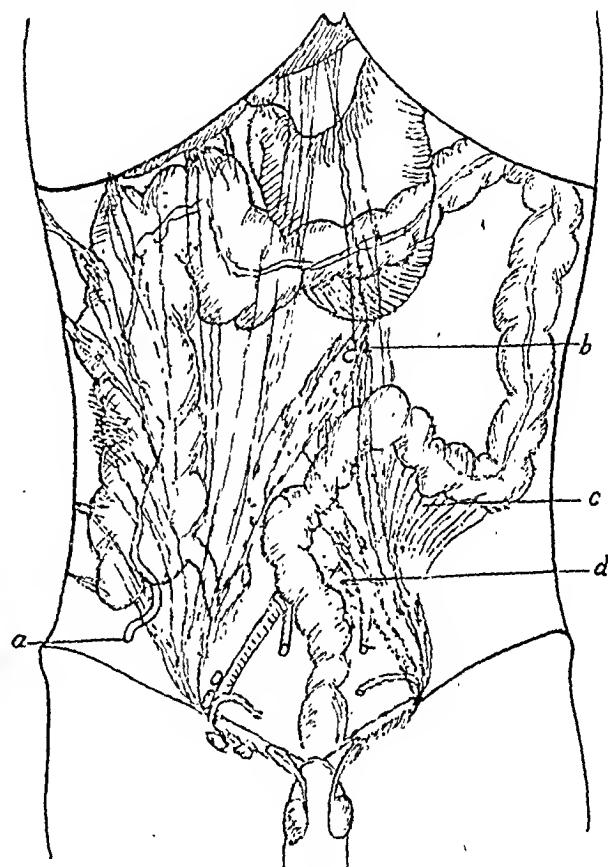

Fig. 3.—Diagram of appearance when infection apparently enters the abdominal cavity through the inguinal canal. The pelvic colon suffers in the same way as the small intestine shown in figure 2, and the same ultimate effect on the whole abdominal cavity is apparent.

a—Appendix apparently normal beneath the membrane.
b—Root of mesentery.
c—Normal long mesentery.
d—Shortened scarred mesentery.

and the picture is as represented in figure 3, with all the signs and symptoms of chronic appendicitis and pyloro-duodenal ulcer or obstruction. That the infection originates at the internal inguinal ring is further supported by the common association of a mass of glands in the inguinal and even femoral regions, or for that matter the tell-tale scar, and also clinically one knows that acute gonorrhœa can simulate intra-abdominal disturbance, temporarily at least.

Now chronic infection arising from this site sometimes shows a state of affairs not seen in

that arising purely from the appendix. It may come from either or both sides. I refer to masses of glands which follow along the spermatic and iliac vessels to the pre-aortic glands and which seem to have a predilection for causing a massive adenopathy in part or all of the root of the mesentery. These glands, the size of pigeon eggs at the root of the mesentery, get smaller as they reach the free margin of gut and, blocking lymph flow render a section of gut oedematous and wooden, so much so that the state of affairs may go on to ulceration of the gut although this is comparatively rare, except in the cæcum. In other words the condition is indistinguishable by the naked eye from the various descriptions of regional ileitis or Crohn's disease, and this may occur anywhere from the pylorus to the cæcum, and again in the lower sigmoid and rectum, in fact in all the sites said to be commonly attacked by Crohn's disease (figures 4 and 4a).

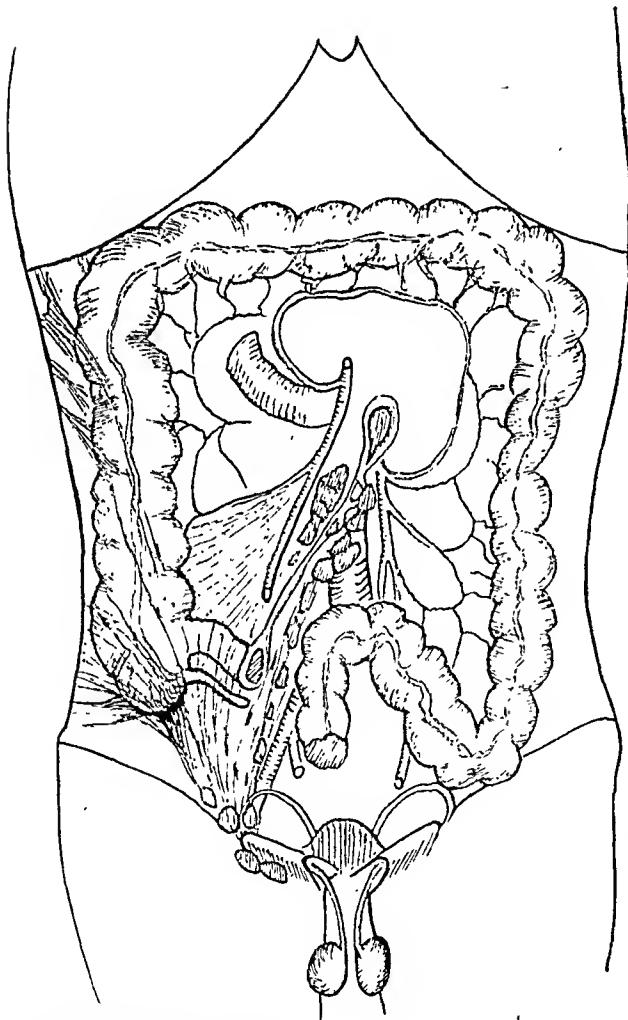

Fig. 4.—Mass of glands in part or whole of the root of mesentery giving rise to what looks like Crohn's disease.

In the cæcum the appearance is characteristic. The clinical history and diagnosis will certainly be tuberculous disease of the cæcum, and laparotomy will show a thick vascular membrane investing the terminal ileum, cæcum and

appendix, the whole, woody, hard, and intensely oedematous. It almost 'breaks' away from the cellular tissue of the posterior abdominal wall, and when slit up afterwards shows an inch or so of gut with a wall like ulcerated cartilage. Sent to the pathologist for cancer or tubercle, the result is neither. It looks, in fact, like the excised rectum of a non-malignant stricture of that organ. The resistance of the patient, unlike that in cancer and tubercle, is so good that death is rare, so further verification by post mortem is rarely possible, even if local eustom permitted it.

When this state of affairs is found, the membranous formation is dense, and if the examining hand puts tension on the ascending and first third of the transverse colon and pylorus, dense thickenings of the membrane stand out as in figure 1. Any glands and tissue excised for biopsy do not disclose the true pathology, but do exclude active tuberculosis and cancer.

More rarely, frank tuberculous adenitis from a tuberculous lesion of the lower limb will give rise to similar membranous formation and moderate glandular enlargement, but this is more understandable, as the primary disease is

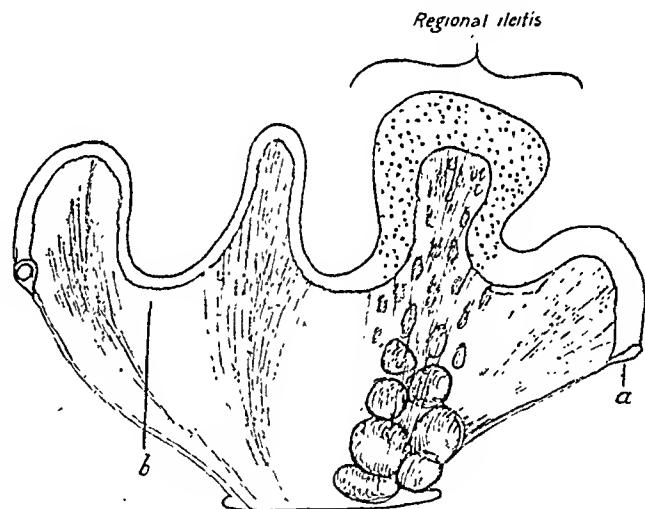

Fig. 4a.—Regional ileitis? A segment of intense oedema from lymphatic obstruction of part of the base of the mesentery.

a—Simple dilatation of healthy gut above the obstruction.
b—Collapsed gut below obstruction.

recognizable. Mycetoma may show glands in the femoral and inguinal region which on section show characteristic discoloured areas, and so these give rise to no surprise. But my point is this:—Whatever the chronic infective process at work, the naked-eye appearance is similar, in general, namely, a more or less developed membrane formation investing the viscera in its path from the chronic infective focus, upwards, embarrassment of movement, lymph stasis and fixation of the viscera, especially the colon, to the side wall of the abdomen. Also fixation of the pylorus and first part of the duodenum to the under surface of the liver and gall bladder, kinking at the site of junction of these latter,

and all the symptoms of chronic appendicitis and pyloric ulcer with obstruction.

Moreover, and in particular, certain specific chronic infective processes may give rise, not only to the above, but to a variety of complications varying from Crohn's disease, to hydro-nephrosis from obstruction to the ureters where they enter the bladder.

3. The origin of these different infective processes. From the frequency with which people in this part of India suffer from chronic appendicitis, I suggest the following, more evident on the west coast where the disease is commonest. No one article of diet or vitamin can be blamed, nor hookworms nor water, but, I do think, adenitis can be blamed.

Diet in that part of India is almost devoid of protein. It is true many claim to be meat eaters, but on questioning them it is found that they get very little meat, or fish either. They get even less fish in the monsoon except a local dried variety, but few, however, will eat that.

Might it not be that the simple absence of protein from the diet means the absence of sufficient urea, that natural diuretic. In consequence there is water retention, water-logging of tissue, susceptibility of water-logged tissue to low-grade infection, and hence the almost universal granular pharyngitis, chronic infection and hypertrophy of adenoid tissue, adenoiditis, enlarged tonsils, tonsillitis, Peyer's patchitis, appendicitis, all chronic not acute. This is only a suggestion, but it certainly is very striking to the doctor working amongst these people. It is rarely if ever possible to pronounce an appendix innocent when there is a typical pyloro-duodenal ulcer, or the symptoms of it without ulcer, and then the membrane described with its adhesions is invariably present. But in true gastric ulcer, which is much less common, it is equally rare to be able to find fault with the appendix. The pathology of the two conditions must be different.

Can this membrane and glandular hypertrophy be attributed to chronic amebiasis? I doubt it, for the splenic flexure escapes so consistently, and why only the right half of the abdomen? Chronic inflammation of the appendix must bear the blame for all the diseases above described as attributable to it, but not for the others.

What is the origin of the infection described as entering the abdomen by the internal inguinal ring and possibly the femoral canal, giving rise to anything attributable to chronic appendicitis, and, in addition, to much more, for instance, 'regional ileitis', tuberculosis of the caecum that is not tuberculous, scarring of the mesentery and intestinal obstruction.

Climatic bubo heads the list, the tell-tale scar or history of bubo is the rule rather than the exception, although the history is not easy to obtain. A climatic bubo that failed to break

down is soon forgotten, especially if it occurred 30 years previously.

Occasionally on opening an abdomen for chronic obstruction, one finds a mass of glands occupying part or whole of the root of the mesentery. The segment of hard oedematous bowel overlying the mass may be so great as to present a danger to life if removal be attempted, yet this mass is apparently cleared by treatment with Fouadin or Fantorin, and the patient is relieved of his symptoms. This seems further clinical evidence incriminating climatic bubo.

As I write this article, I have been sufficiently fortunate to have 2 such cases admitted into hospital. These cases illustrate my point. Both were classical of high intestinal obstruction.

The first came under the care of my colleague Dr. Vadamalayan. Early operation was clearly necessary. On opening the abdomen two short lengths of jejunum were seen to be involved in an intense oedema, and the gut being stretched over masses of hard glands suffered a mechanical interference with the blood supply as well as obstructed lymph drainage.

The local involvement in the pathological process was so advanced that even the gentlest manipulation caused rupture, so two short resections were necessary.

As much of the gland mass as could be removed with safety was dissected out and a specimen sent to Madras for pathological report. The report was non-tuberculous chronic inflammatory tissue, suggesting regional ileitis. Thereafter Fantorin was given.

The second case was identical, except that the gut was not so seriously damaged by pressure of the gland mass on the vascular supply. The oedema was however very firm.

The sketch, figure 5, was made immediately after the exploratory laparotomy and is self-descriptive.

In this case no surgical procedure was carried out, and after demonstration, the abdomen was closed.

The patient was given Fantorin on alternate days and by the time that the stitches were removed, the hard mass, formerly visible through the thin abdominal wall, was no longer even palpable, and the patient was completely symptom-free.

The first, a female, could give no history.

The second, a male, admitted that he suffered 20 years ago from a swelling in the groin that lasted more than a year.

In this part of India, particularly on the coast, lymphogranuloma seems almost endemic. One meets with it in the neck, axilla, tonsil, floor of the mouth, bladder, lower ureters, rectum, penis, inguinal glands, in fact one is not surprised at any fresh manifestation. Many of these extraneous lesions are variously diagnosed as tuberculosis, cancer, or gummata and are treated for years with the usual remedies,

but are cured in as many weeks by Fouadin. If this external manifestations of lymphogranuloma be so varied, why should lymphogranuloma be excluded as a possible cause of intra-abdominal manifestation?

In paddy-growing areas men get cracked heels and chronic lymphadenitis from tuberculosis, mycetoma, and many unknown infections, all through their feet. May not such cases of chronic lymphadenitis of femoral and later also of inguinal glands, also be contributive to the prevalence of pyloro-duodenal ulcer and of all the lesions above described? It seems a long

query of what is that gland mass in the radiogram which is so unlike pulmonary tuberculosis?

One often sees a mediastinum showing massive 'glands' but no evidence of tuberculosis anywhere in the body, and no fever nor toxic quickening of the pulse. If the inner third of the lung field be covered, the outer two-thirds are seen to be clear. What then has drained into the mediastinal glands and from where? Certainly not from the lung tissue. There may be no evidence that the infective process travelled down from the deep cervical lymph glands, but, knowing that similar gland masses are stimulated to growth in the abdominal cavity, why not suggest that the same pathology may repeat itself in the mediastinum? This observation may escape the chest specialist for he seldom has the chance of seeing inside the abdomen. Neither does the abdominal surgeon think in terms of mediastinal glands and venereal diseases.

One occasionally does an exploratory laparotomy in a case of ascites from a medical ward if the patient be young, thinking that it is tuberculous and that the release of fluid and the inclusion of air will both establish diagnosis and be of therapeutic value.

These cases are occasionally surprises. The abdominal wall may be lined like the pleura is lined after years of effusion. The spleen may be enlarged, and attached by its margin to a similar lining membrane, quite different from anything above described, for here the membrane is hyaline in appearance and lines the parietes and not the mobile viscera. The liver also taking its part, is enlarged, or if later, contracted and cirrhotic. Glands may be present in abundance but on section they have not the naked-eye diagnostic features of tuberculosis. Such cases I have treated with Patterson's buttons, and because of success am an ardent supporter of Patterson's buttons. Perhaps I am not dealing with a tuberculous peritonitis at all but with a sarcoidosis. This introduces a fresh name.

Recently a highly-educated patient on full duty up to the day of admission came to the hospital with all the classical signs of high intestinal obstruction. He did not look as if he had suffered a long illness, his appearance was against a diagnosis of tuberculosis or cancer, but examination showed a protuberant abdomen and the presence of free fluid. Through this free fluid solid masses could everywhere be 'ballotted', the condition was considered hopeless but to satisfy conscience, the abdomen was opened to see if anything could be done.

Free fluid, innocent of any blood staining, escaped and the abdominal contents were as firmly fixed as if set in plaster of Paris. It did not look like tuberculosis of the abdomen, and if cancer, how did the patient survive so long? Exploration was impossible as everything was fixed. A small mass of this tissue was

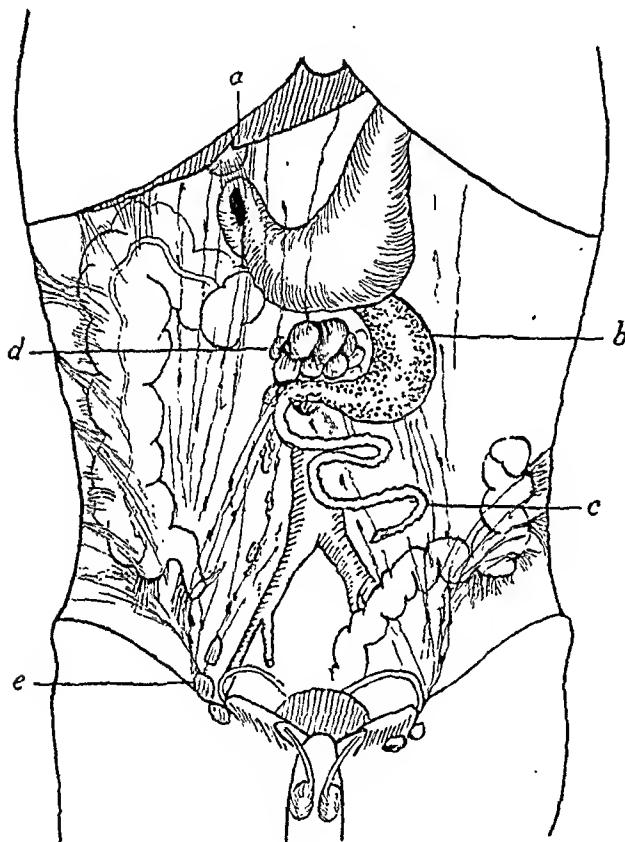

Fig. 5.

stretch from heel to duodenum, but, one sees the foot infections, the adenitis, the spreading intra-abdominal pathology, the hitching and fixation of pyloro-duodenal junction, and remember I said at the outset I am viewing the patient as a whole and not through a microscope.

This statement prompts me to make a further suggestion. If masses of glands be found in the abdomen, and if macroscopically at least, they appear to derive their origin from the internal abdominal or femoral ring, why should not the virus of infection extend to the mediastinum and answer the tuberculosis specialist's

broken off—not cut—it did not bleed. It proved to be a piece of omentum. Next day the patient died. Unfortunately Indian ideas and customs precluded a post mortem. So further investigation could not be made. The pathologist's report from General Hospital, Madras, was 'sarcoids', not cancer nor tuberculosis.

Now I am sure that pathological report was right. Very little attention has been paid to this disease, but the similarity between the manifestation of sarcoidosis as described, and the various manifestations of lymphogranuloma are very striking to the clinical observer. Of the microscopic differences, I know nothing, but for the benefit of those who see less of this condition than, I believe, we in the south-west India see, I will make a brief description.

Said to have been described by Jonathan Hutchinson in 1869, re-described by Besnier in 1899, more concisely described and in more detail by Boeck in 1899, ocular manifestations were described by Harfordt in 1909. Cutaneous manifestation reported from 1915 onwards, and since, practically every organ of the body has been found liable to suffer.

In an article in the *American Journal of Roentgenology* of April 1941 by Donald S. King, sarcoidosis of the spleen is described in which the spleen weighed 52 oz. and in the same article Teuben Schutz, pathologist, describes sarcoids in the lung, lymph nodes, and liver.

Sarcoidosis is a disseminated disease and the lesions are granulomatous, to all naked-eye appearance like lymphogranuloma in that there is gross lymphatic alteration and an oedema of wooden hardness.

The common occurrence of sarcoid-like diseases in this part of India in association with regional ileitis which looks like local sarcoids or alternatively lymphogranuloma, and the extreme frequency and variety of manifestations in which lymphogranuloma is met with is so striking, that it should be voiced even if only to stimulate the pathologist to classify these diseases and put them in their places. Clinically they appear to be one and the same disease.

Now and then a doctor hits on a new cure for cirrhosis of the liver. I cannot help thinking that he may have had the luck to run up against a small series of sarcoidoses, for this strange disease seems capable of a degree of resolution.

But since I am in my third section of this article dealing with origin of the infective foci, I put it as possible—indeed from a clinical point of view probable—that all forms of regional ileitis, woody caecum, ano-rectal syndrome and so forth, together with sarcoids intra-abdominal and thoracic adenopathy associated therewith are none other than manifestations of the virus of lymphogranuloma inguinale (*alias* climatic bubo) mostly acquired but not infrequently congenital.

4. Deduction.

The reader will have appreciated the general trend of ideas:—

(a) That in the abdomen, any low-grade infection over a period of time will give rise to permanent mechanical interference with the intra-abdominal organs, resulting in anything from pyloro-duodenal ulcer, to volvulus, and should therefore be eradicated early.

(b) That the same basic picture is reproduced whatever the exciting cause, whether the origin be in the appendix, or inguinal, or femoral canals.

(c) That in addition to this basic reaction, common to all chronic infective processes, certain specific organisms such as the tubercle bacillus or the virus of lymphogranuloma entering the lymphatic system of the lower abdomen will give rise to specific pathological pictures, such as tuberculous peritonitis, or woody caecum and regional ileitis.

In result I suggest that the prevalence of chronic appendicitis, gastric complaints, volvulus, the disease identical with the description of regional ileitis, tuberculous caecum and similar chronic abdominal disease in the south and west of India is due to the following:—

(1) Faulty modes of dieting, often of religious origin, predisposing to chronic infection of the appendix and the sequence of misfortunes that follow.

(2) The prevalence of venereal disease, which gives rise to the same sequences of disease as the appendix, also lymphogranuloma gives rise to intestinal obstruction of the type described as regional ileitis.

(3) That working bare-footed in paddy-fields and walking on infected ground will also set up the same intra-abdominal naked-eye pathology as that consequent in chronic appendicitis, the only difference being that entry is from the inguinal or femoral canals.

(4) That the vague disease sarcoidosis may possibly also be a late manifestation of lymphogranuloma.

It is therefore necessary that each patient be viewed in association with his habits and environment, the result of chronic low-grade infection plus time be given due consideration, and the possible value of Fouadin or its substitutes be kept in mind.

I hope in due course to lay some pathological evidence on the table to support these clinical observations, but the life of a district officer is too full and varied for that attention to detail so necessary before arrival at any conclusion. In the rush of life records are apt to be few, while mental impressions are apt to be fallacious.

However, others may be in a position to confirm, refute or follow up some of the above suggestions, and once the extreme prevalence of lymphogranuloma becomes appreciated, perhaps some of the Indian manufacturing

A TRANSFUSION SET FOR USE IN HOSPITALS OR IN THE FIELD

By S. N. HAYES, O.B.E., F.R.C.S., F.R.C.O.G.
LIEUTENANT-COLONEL, I.M.S.

SANT RAM DHALL, M.B., M.S.
MOHD. ABDUL SAMI, M.B., M.S.
and

SISTERS P. BAMFORD and V. K. RAO
(From The Lady Willingdon Hospital, Lahore)

BLOOD, plasma and serum transfusions are now universally accepted as being an essential part in the treatment of haemorrhage, shock, burns and a number of chronic diseases. What is not so well known or appreciated is that, in an acute condition, the best results are obtained by the early transfusion of the appropriate substance. It is at present impossible, and beyond the scope of this article to lay down the exact time at which a transfusion should be given. Allowing that there are other essential and routine methods of treatment which must be employed, our own experience is that we are constantly regretting delay.

Providing reasonable care is taken, there should be no mortality resulting from a transfusion. On the other hand, we have seen many patients die that would in our opinion have been saved if we had not delayed.

We visualize the time when in certain cases transfusions of the appropriate substance will be given almost as a routine and to prevent, not treat, shock and other conditions, and would plead for their wider and earlier use in this country.

In order to provide for prompt transfusions, it is necessary to have a complete set of apparatus ready for immediate use. Transfusion substances should also be ready or within easy reach. This article is concerned only with the description and use of a transfusion set which can be used for any substance, and fulfils the following conditions :—

- (1) Portability.
- (2) To be ready for immediate use.
- (3) Be capable of being used under any conditions.
- (4) Conform to the special conditions required by the Army on active service.
- (5) To provide for transfusions, using one or more bottles of one or different solutions.

In the set described, in order to provide for Army requirements the number of spares may be considered excessive for a civil hospital. We would, however, point out that our experience shows there is no harm in having an adequate supply of spares, and it is imperative that the set should be looked after by a responsible person and kept under lock and key until required,

(Continued from previous page)

chemists will endeavour to produce a cheap substitute for Fouadin or Fantorin in response to demand, for these two drugs are of immense value in this part of India, but expensive and difficult to obtain, especially in time of war.

otherwise various items of the equipment are certain to disappear.

The set is contained in two boxes, an upper metal one designed as a water sterilizer, and a lower wooden one, containing items not requiring sterilization, and spares.

Contents of upper box (metal)

This box contains all the items required for a single or double bottle transfusion.

(1) Metal transfusion can fitted with lid (for use as a bowl, or small sterilizer), filter funnel, and hanging hooks. The can is for use in case the simple method of transfusion is desired, or in the event of blood clotting in the bottle.

(2) Bottle fitted with blood-withdrawing cork and tubing, and containing blood-withdrawing component (rubber tubing 10 inches with glass window, metal adaptor and intravenous needle). A piece of thread is tied to one end of the component, the other end hangs outside the bottle, providing for easy withdrawal. The bottle, wrapped in a towel with the ends well projecting to prevent trauma to the glass, is placed in the metal transfusion can and covered by the lid. If space is available, the filter funnel is placed inside the can, otherwise elsewhere in the box.

(3) Bottle fitted with blood-giving cork and tubing and metal hanging cage wrapped in a towel.

(4) Blood-giving component, single bottle (figure 1) consisting of—

- (a) Drop regulator;
- (b) Rubber tubing 3/16 inch and two glass connections;
- (c) Intravenous needle and metal adaptor;
- (d) Pinch cocks 2;
- (e) Monel metal gauze filter.

(5) Double bottle component (figure 2) consisting of—

- (a) Metal Y piece;
- (b) Rubber tubing, 2 pieces;
- (c) Pinch cock, one.

Both components are wrapped in a towel.

(6) Glass filter—for use with wool or beads. A spare drop regulator is provided for this purpose and, if required, is inserted above the drop regulator in use.

(7) Set of instruments in bag consisting of—

(a) Sharp pointed scissors 5 inches	..	1
(b) Dissecting forceps	..	1
(c) Mosquito forceps	..	2
(d) Aneurysm needle	..	1
(e) Blunt hooks	..	2
(f) Scalpel 1½ inches	..	1
(g) Infusion cannula	..	1
(h) Half circle cutting needles no. 12	..	2
(i) Linen thread—thin, or any suture material desired, feet	..	20

(8) Blood matching set in bag consisting of—

(a) Microscope slides	..	4
(b) Test-tubes 2 × ½ inch	..	2
(c) Hypodermic syringe, 2 c.c.m.	..	1
(d) Hypodermic needles	..	2

Contents of lower box (wooden)

(Containing items permanently sterile or not requiring sterilization)

1. Sodium citrate, 4 per cent, ampoules of 80 c.c.m.	..	8
2. Sodium citrate tablets, gm. 1, packets of 12	..	12
3. Bandages, loose-wove uncompressed, 2½ inches × 6 yards	..	4
4. Wool, 2-oz. packets	..	2
5. Gauze—surgical, loose-wove—unmedicated, 25 inches wide × 3 yards, packet	..	1
6. Ampoules procain, 2 per cent, 1 c.c.m.	..	6
7. Knife, glass cutting	..	1
8. Tape—narrow, yards	..	18

9. Linen thread—thin—or any suture material desired. 50 feet	1
10. Methylated spirit, ounces	4
11. Syringe cinema, fitted with 3 inches rubber tubing at valve end, for use as vacuum producer	1
12. Adhesive plaster 3 inches \times 10 yards	1
13. Rubber tubing 5/16 inch for tourniquet	1
<i>Spares</i>	
(1) Drop regulator—complete	1
(2) Drop regulator spare cork and glass connection	1
(3) Glass beads 1½ ounces	3
(4) Adaptor for wide mount needle	1
(5) Needles, blood-withdrawing and giving	2
(6) Needles, blood-withdrawing adaptors	2
(7) Pinch cocks	2
(8) Needles, hypodermic	2
(9) Needles, cutting half circle no. 12	2
(10) Test-tube 2 \times ½ inch	1
(11) Rubber drainage tubing 3/16 inch, feet	5
(12) Glass tubing 9 inches, pieces	10
(13) Corks, rubber for blood-containing bottle	2

Vein seeker

This is not provided but can be improvised out of the items in the set (see figure 3).

Care of apparatus.—The care of the apparatus should be in the hands of a responsible

person. It is important that each item of the apparatus should be kept scrupulously clean. There is ample evidence to show that a higher incidence of reactions results from unclean than from clean apparatus. All new glassware should be boiled in soapy water for 15 minutes, washed in tap water and immersed in the following mixture for 24 hours:—Potassium dichromate (commercial) 100 gm., sulphuric acid concentrated (commercial) 250 c.cm., water 750 c.cm. Then wash thoroughly in tap water until water is neutral to litmus; finally wash in distilled water. If the above is not available, commercial nitric acid can be substituted. Following blood and plasma transfusion, glass and rubber becomes coated with albuminous material

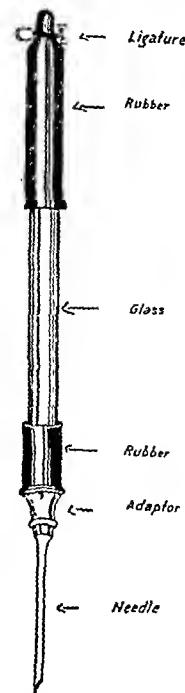

Fig. 3.—Vein seeker.

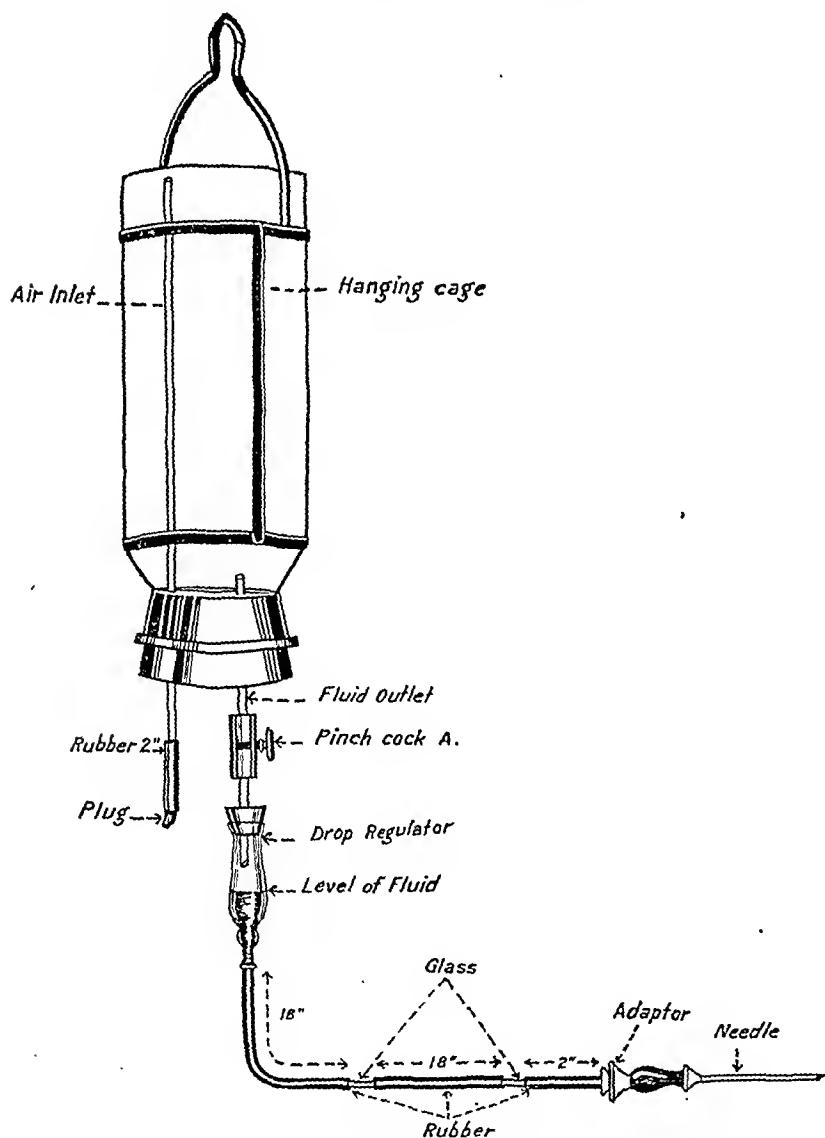

Fig. 1.—Giving bottle and component.

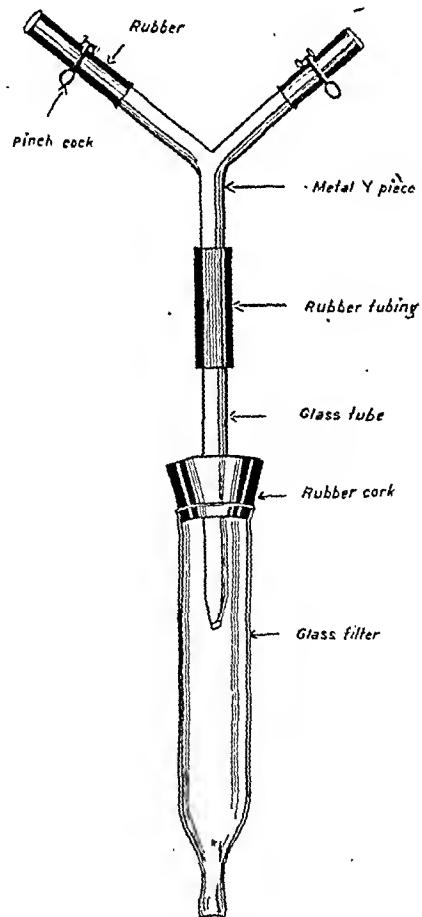

Fig. 2.—Two-bottle component with filter.

which should be removed. Immediately the transfusion is completed, the apparatus should be taken to pieces and thoroughly rinsed both inside and outside in cold water. (Hot water coagulates the protein and forms a deposit difficult to remove.)

If possible, complete the cleaning by passing tape through each tube—under running water. If this cannot be done immediately, soak in cold water and clean later. Water and friction are necessary. Rinsing without friction is useless.

It is better after the preliminary rinsing to boil all glassware and rubber in 0.1 per cent NaOH for half an hour and rinse in distilled water. This removes all debris, clots and plasma. Particular attention should be paid to the bores of needles and cannulae. Wash through with cold water using a syringe, and boil frequently in 0.1 per cent NaOH followed by distilled water. Oil the stilettos with liquid paraffin before inserting in the bore.

N.B.—After cleaning and before re-using, each piece of apparatus should be rinsed in distilled water.

Assembling apparatus

Assemble the items according to the details given under contents of box A. Note that rubber tubing should be moistened before insertion on to glass, and, as it is apt to stick to glass, fit loosely when assembling and tighten before use.

Sterilization of apparatus

Rubber perishes with repeated sterilization in a high-pressure sterilizer. It is advisable when possible to boil rubber articles in distilled water and fit to the apparatus under aseptic condition. All other articles are sterilized in a high-pressure sterilizer.

The box lid is then fastened with adhesive plaster.

Instruction for use

A. Blood matching.—Even when typed serum is used for grouping donors and patient, direct matching is advisable. The latter will be the only method available in the field. The equipment for blood matching is contained in a small bag in the upper metal box.

Method.—Withdraw 2 c.cm. of patient's blood, place in a small test-tube and allow serum to separate.

Place 2 drops of serum on a glass slide and add one drop of donor's blood. Mix and rock

gently. If agglutination occurs, the donor's blood is incompatible and a fresh donor should be tested.

Note.—Do not allow more than 2 minutes for the test. If the mixture dries within that time, repeat the test using 3 drops of serum and 2 of blood.

B. Blood withdrawal.—See figure 4 for details. The donor should lie down with his arm supported. Place the receiving bottle below the level of the arm, to assist the flow of blood. Remove withdrawing bottle from metal can and spread sterile towel under the arm. Prepare citrate solution in can lid (2 tablets to 100 c.cm. distilled water). Remove blood-withdrawing component from bottle and place in citrate solution. (Fill the rubber tube with the solution and hold up by the end until solution drips from needle); this will obviate clotting. Add 80 c.cm.

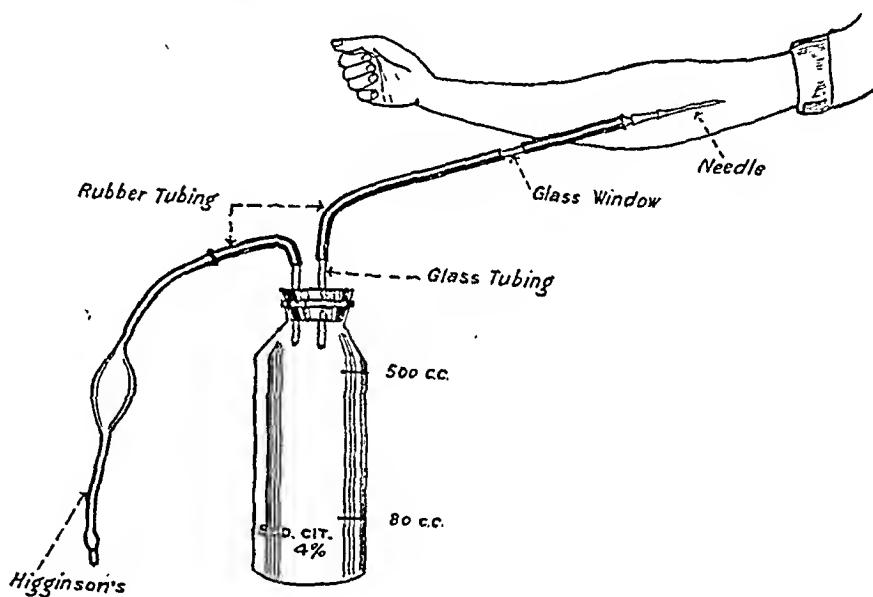

Fig. 4.—Blood withdrawing.

of 4 per cent citrate (ampoule in lower box) to bottle. Cork and rotate bottle on its side to coat the inside with citrate.

Apply tourniquet of soft rubber—or syhygrometer cuff (inflated to 80 mm. Hg.) to donor's upper arm. Clean skin area in bend of elbow with spirit. Instruct donor to open and close his hand several times. Attach blood-withdrawing component to bottle. Select suitable vein and insert needle. As blood flows, gently rotate the bottle to mix blood with citrate.

If flow slows down—attach Higginson's syringe by its reversed end to the bottle and pump gently to create a vacuum.

When sufficient blood has been withdrawn (maximum 500 c.cm.), remove tourniquet and needle—apply gauze and bandage to the arm. Give the donor a hot drink and allow him to rest.

for 15 minutes. He can then resume his ordinary occupation.

C. Blood giving.—(See figure 1).—The blood-withdrawing cork should now be replaced by the blood-giving cork and the hanging cage attached to the bottle. The blood-giving component with the upper pinch cock closed is attached to the fluid outlet tube and the bottle inverted and suspended by the hanging cage. (As rubber corks are liable to fall out, it is advisable to tie a piece of tape to the bars of the hanging cage and across the cork.) Evacuate the air from the part of the component below the drop regulator as follows.—Hold the needle in such a manner that the rubber tubing forms a U. Remove air inlet plug and open the pinch cock 'A'. Move the needle and tubing up and down until all air is expelled. Regulate flow by upper pinch cock until it is one drop per second. Close lower pinch cock.

During this time an assistant should be distending the patient's vein by applying the tourniquet. The needle is then inserted into a suitable vein and strapped to the limb by adhesive plaster.

If the veins are too collapsed for a needle to be used, a vein in the arm or leg is exposed and the intravenous cannula inserted and strapped to the limb by the tape.

Drop regulator—rate of flow.—The average rate of flow suggested is :—

Severe haemorrhage cases—500 c.c.m. in 30 minutes.
Later 40 drops per minute.

Moderate haemorrhage cases—500 c.c.m. in 45 minutes.
Later 40 drops per minute.

Slight haemorrhage cases—500 c.c.m. in 1 hour. Later 40 drops per minute.

Shock haemorrhage cases—500 c.c.m. in 45 minutes.
Later 40 drops per minute.

The safest rate is 40 drops per minute as with it reactions are fewer, the transfusion fluid need not be warmed, and, when the myocardium is affected, danger is minimized.

Keep the level of fluid to that shown in drop regulator (figure 1). The level can be adjusted by loosening the cork of the regulator to allow air to enter. To prevent the cork from falling out, apply a strip of adhesive plaster around the cork and the upper portion of the regulator.

Fitting glass tubing to corks.—Glass tubing at present available is somewhat brittle and breaks easily. To avoid cut fingers, great care should be used. When inserting glass tubing into rubber corks—thoroughly wet the cork and the tubing. Smearing with soap is also useful. Insert the tubing as far as possible with the fingers, then place it on a hard object, such as a table, holding the cork with both hands, and press through the cork as far as is desired. Tubing can be removed by holding the cork with one hand, pulling and turning the tubing with the other, and at the same time pressing the other end of the tubing against a hard object.

PLASTER OF PARIS

By F. V. STONHAM

MAJOR, I.M.S.

Surgical Specialist, British General Hospital, Poona

PLASTER OF PARIS is manufactured from gypsum by calcining it at a moderate temperature. Pure gypsum is a white crystalline mineral which consists of hydrated calcium sulphate $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$. On heating it to a temperature ranging from 107°C. to 130°C., it loses water and is converted into plaster of Paris $(\text{CaSO}_4)_2\text{H}_2\text{O}$. Excessive heat converts it into anhydrous calcium sulphate CaSO_4 which takes up water very slowly and does not harden and set. $2\text{CaSO}_4 \cdot 2\text{H}_2\text{O} = (\text{CaSO}_4)_2\text{H}_2\text{O} + 3\text{H}_2\text{O}$. $(\text{CaSO}_4)_2\text{H}_2\text{O} = 2\text{CaSO}_4 \cdot \text{H}_2\text{O}$. Commercial plaster of Paris is manufactured from impure gypsum and therefore contains the impurities present in the gypsum such as alumina, iron, silicates, carbonates, lime, etc., which can be recognized by appropriate chemical tests. These, together with traces of undehydrated gypsum, or anhydrous calcium sulphate, do not interfere with the proper setting unless they are present in excessive amounts. Traces of gypsum, in fact, accelerate setting.

The same effect can be observed when plaster bandages are soaked in water which has been contaminated by having been used to wet previous bandages and has become milky with plaster. (Calcium sulphate is soluble in water, 1 part in 372 at 26°C.) Various grades of plaster on the market possess different rates of setting. Admixtures of alum, or borax, retard setting, while common salt and sodium phosphate accelerate it. We have not found, however, that the practice of adding these substances to the water used to wet the bandages serves any useful purpose when the plaster is of poor quality and lacks setting properties. Neither does the previous roasting of tins of defective plaster cause any appreciable improvement of setting properties as can be understood from the chemical considerations already alluded to.

There appears to be much defective plaster of Paris on the market at present and those grades which set very slowly or become powdery and crumbling after the mould has set are of no use for surgical purposes. Good surgical plaster of Paris should set quickly and hard under all conditions of temperature and humidity and should remain hard permanently. It should be of fine texture and free from grit. Any samples which are not pure white in colour should be regarded with suspicion. The conversion of gypsum into plaster of Paris is an endothermic

(Continued from previous column)

The boxes and infusion can contained in a teakwood box can be obtained from Raghunath Rai and Sons, Ravi Road, Lahore. All other components can be obtained locally and fitted up with the aid of the diagrams.

Nov., 1941]

reaction, and heat is given off when the plaster is again wetted. Heat is also given off if the sample is adulterated with lime. Surgical

produced slabs which sagged or bent into a curve when similarly held. The results of these experiments are given in table I.

TABLE I

Serial number	Plaster used, sample number.	Origin	Cloth used	Evidence of setting	Rigidity	Remarks	Culture	Whether found satisfactory in actual use
1	1	Indian	Thick muslin.	None. Soft after 15 minutes.	Did not become rigid.	Remained permanently soft and crumbling. Colour greyish.	Non-pathogenic spore forming bacilli.	No.
2	1	"	Surgical gauze.	Some setting in 10 minutes.	Remained soft for 30 minutes.	Pseudo-setting in dry weather, became crumbling and powdery later.	"	"
3	2	"	Crinoline Surgical gauze.	Did " set	Did " not become rigid.	Plaster " yellowish and gritty.	"	"
4	2	"	Crinoline Surgical gauze.	Set in 1 minute	Hard in 13 minutes.	Remained " hard and rigid several weeks.	"	Yes.
5	3	Indian packed.	Thick muslin.	Set in 4 minutes	Hard in 10 minutes.	"	"	"
6	3	"	Crinoline	Set in 2 minutes	Hard in 12 minutes.	"	"	"

plaster of Paris is sold in a variety of packings, but that preferred is the moderate-sized square tin which is easily stored and packed for transport.

We have recently received certain brands of plaster which have proved unsatisfactory in that they have failed to set properly and had a tendency to crumble afterwards. Some samples did not set at all and casts prepared from them remained in a wet partially-set condition for several days during wet weather. In hot dry weather only pseudo-setting took place—the plaster merely dried as mud dries.

Samples of various grades were subjected to the following test. Bandages were carefully prepared to eliminate any possibility of uneven incorporation of the powder and were carefully and thoroughly soaked without agitation. When quite sloppy they were rolled into a slab about 20 inches long, and each layer was carefully smoothed down as the bandage was unrolled. When complete, one-third of the slab was folded over and pressed down, and the whole allowed to dry. This produced a short slab half of which was 20 layers thick and the remainder 10 layers. With good plaster the slab in a few minutes became rigid enough to enable it to be held in the hand by the thin end, as a rigid board. Those specimens of plaster which had been found unsatisfactory in actual use

Plaster of Paris is rolled into bandages by smearing the dry powder over the cloth with the hand and rolling up from the opposite end. The powder should be evenly and smoothly incorporated and the correct amount can only be learned by experience, since it varies slightly according to the cloth used. If the completed bandage is rolled too tightly it takes a long time for water to soak in and properly wet it, and if rolled too loosely the centre slips out of the bandage as it is being applied. If the proportion of plaster to cloth is too high a brittle cast results, and if too little the resulting cast is soft and tends to disintegrate rapidly. Various cloths are in vogue. If the cloth is too heavy and of too fine mesh it lacks docility and it is difficult accurately to apply it round prominences like the ankle. Moreover, with fine-meshed cloth the bandage must be prepared with meticulous care because the wet plaster cannot so easily come through the interstices as the bandage is wound on, compensating for any unevenness. Bandages prepared with fine-meshed cloth are much more difficult to wet evenly and quickly. If the cloth is too open in texture, much of the plaster escapes into the bucket from the outer layers of the rolled bandage when it is immersed in water.

The cloths available in India comprise crinoline (put up for Government use in

compressed form, three inches by six yards); ordinary surgical gauze, muslin, *pagri* cloth, and 'book' muslin. Excess of starch in the cloth interferes with proper setting. We find there is little to choose between any of them, but we dislike muslin which is too closely woven or too heavy. Sackcloth is occasionally useful in the preparation of very heavy casts such as plaster beds and spinal jackets.

It seems customary to use bandages six yards long and six or eight inches in width. In the fracture department of the British General Hospital, Poona, we prefer the five-inch width as the most generally useful, especially for moulding round the foot and ankle in the case of thin legs, and about five yards long to facilitate cutting, because we use principally surgical gauze which is provided in bulk in sixteen-yard rolls. The compressed crinoline is mainly used for the forearm since the narrowness of the bandages provided render them of limited value for lower limb casts. To obviate the nuisance of the centre falling out of these bandages each is unrolled and cut into two before incorporating the plaster to make them of convenient size.

The correct wetting of a bandage is a point of importance. The bandages should be placed in a fairly deep vessel such as a bucket, by gently immersing them end on and leaving them until no more bubbles of air appear. They are then ready for use and should not be wrung out at all. Within limits, the more sloppy the bandage is when applied, the harder and more durable will be the resulting cast. The water should not be more than two inches deeper than the width of the bandage, because deeper immersion causes the bubbles of air to agitate the water with resulting loss of plaster from the exterior layers. It is neither necessary nor desirable to use hot water. When the plaster cast has been completed its appearance and durability may be enhanced by polishing it with wet hands, and if necessary by smearing on a little freshly-made plaster cream to obliterate any ridges and depressions which might be potential sites of cleavage. Definitely weak spots should, however, be reinforced by means of an extra bandage.

Modern plaster technique aims at making the mould as light as possible consistent with strength and the avoidance of padding. Padding tends to reduce the immobilizing effect and also renders removal by any method other than cutting through it with a knife or saw more difficult and tedious. There has been a tendency for 'plaster technique' to become extremely complicated and develop almost into a speciality. We find that the custom of employing a multiplicity of slabs and cut-up pieces of slab as 'strengthening bands' to be of little use, since, unless applied with meticulous care, this makes the casts actually weaker. Practically all the casts consist of a simple single slab and circular bandage, and these are perfectly satisfactory and consume less time. The

methods used in the arm, leg and spine plasters will be described in detail.

The forearm plaster

Two suitable bandages are selected and soaked. One bandage is rolled out into a flat slab of suitable length on a table or bench. It is convenient to have the edge of the table marked with saw cuts to indicate the average lengths required. The arm has of course already been prepared by reduction of any fracture, or appropriate treatment of any wound. The slab is placed along the dorsum of the forearm and should extend from just below the knuckles to the elbow. The proximal end is suitably folded over in an oblique manner to clear the bend of the elbow. Commencing at the wrist the circular bandage is then applied and worked up the arm to the elbow and back over the dorsum and palm of the hand, encircling only the base of the thumb. The bandage should not cross the palm more distally than the proximal crease. If it does it can be pushed down while still soft and the patient instructed to clench his fist and flex his elbow. The cast is then accurately moulded and allowed to dry. In applying the circular bandage there should be no folds or ridges to irritate the skin, and any tucks required to facilitate even application of the bandage should be made where the bandage crosses the slab. Any edges of the mould likely to irritate the hand or the base of the thumb can if necessary be smoothed or cut away later.

If the plaster is to be carried up to the axilla either a second slab is applied to the lateral or dorsal aspect of the upper arm, or a U-shaped slab is applied, and a circular bandage completes the cast.

A very small pad of wool is placed over the bend of the elbow to prevent circulatory interference and to facilitate removal. We do not pad the olecranon and have no trouble. To prepare an arm spica, a second slab passes from the elbow, along the inner side of the arm to the axilla and down the side of the chest to the iliac crest where it is padded with wool or sponge rubber. The spica is completed with circular bandages passing round the arm and around the shoulder and chest and under the opposite axilla. The spica should be supported until it has thoroughly set and then reinforced by means of a piece of metal or Cramer wire previously bent to a suitable shape.

The same forearm plaster can be modified for fractures of the metacarpals, phalanges, etc., by incorporating suitable wires, and, if necessary, by placing the slab along the volar aspect instead of the dorsal. Dorsiflexion of the hand is seldom indicated.

Common errors in arm plaster

1. The cast extends distal to the proximal crease of the palm, and finger movement is impeded.

2. The cast includes the fingers. This is rarely indicated even if there is paralysis. In the case of fractures or wounds, only the injured finger should be fixed.

3. The cast impedes elbow movement. A U-shaped slab from the forearm around the elbow gives no additional immobility, but it causes a stiff elbow.

4. Reinforcing an arm spica with metal before it sets causes pressure sores. We have seen several of these.

5. Insufficient bandage around the proximal forearm results in early breakage of the cast since this part is easily damaged when the patient rests his arm on the table or on his knees.

6. Failure to mould the plaster accurately around the palm where the bandage tends to be thrown into folds results in loss of immobility. Insufficiently wet bandages are also responsible for this defect which permits the hand to move slightly at the wrist.

7. The incorporation of wooden 'pencils' with the object of separating the forearm bones is apt to cause muscle weakness and pressure sores. It is doubtful if this manœuvre is of any real value. Pressure on the pronator teres is just as likely to approximate the bones.

Leg plasters

A five-inch slab is rolled out equal to the length of the leg *plus* double that of the foot. The slab is then folded to make the sole-piece of double thickness and nicked with scissors opposite the heel. The slab is then accurately moulded to the leg and foot. The sole-piece, where nicked, is moulded over the remainder of the slab superficially. The cast is completed with one or more circular bandages. If the plaster is to go above the knee we first complete the leg and then apply a second slab and complete the thigh portion. The patella is padded with a little wool for comfort and to facilitate removal, since when cutting down it can be pulled out when the patella is reached. With the patient suitably supported, extra slabs, padding over bony prominences, and extra circular bandages, convert the cast into a spica.

For closed plaster treatment of wounds two five yard five-inch bandages suffice, but for fractures and walking casts extra bandages are required according to the build and physical development of the patient. It is sometimes of advantage to fit a U-shaped slab passing down one side of the leg, across the heel and up the other side to strengthen the cast laterally, especially when the plaster is to be relied upon to prevent redisplacement of bony fragments, and also when Steinmann's pins are employed, in which case the slab is cut to receive them.

Common defects in leg plaster

1. The sole-piece projects unduly. This catches in objects when the patient is walking, in the bedcloths, etc., in addition to being likely

to break. It should be trimmed off immediately distal to the toes.

2. The sole-piece is too thin and it soon breaks. This can be prevented by increasing the thickness of the dorsal slab or by making the sole-piece of double thickness as described.

3. Foot drop is very common and indicates perfunctory application or lack of assistance. In the latter event the plaster can be applied with the patient sitting on a table with the foot resting on the seated operator's knee.

4. Excessive inversion is the result of well-meaning attempts to prevent flat foot. It results in claw foot.

5. Walking casts which are too flimsy to be durable are commonly seen, and occasionally unduly massive casts are encountered which not only impede walking but are very laborious to remove.

6. Too short casts are very common. If a fracture is in the upper two-thirds of the leg the plaster should certainly extend to the groin. Plaster 'shoes' for fractures in the foot are uncomfortable and are not recommended. It is better to continue the cast almost up to the knee, and not bother about the theoretical disadvantages of immobilizing the ankle.

Walking irons

The Böhler type which is curved on the tread results in a tendency for the patient to rotate his leg on it when walking. This results in torsion of the fragments and delayed union. It also prejudices the maintenance of proper muscle tone, and irons with a flat tread are preferable though they do not entirely solve this difficulty. Those with a flat wide rubber base are better still. We can make inexpensive and satisfactory iron in a few seconds by bending a piece of mild steel bar in a vice. If accurate contact with the ground is not secured the iron is bent with Lane's plate benders. It is conventional to fix the iron so that it projects two or three finger-breadths beyond the heel. In cases when already developed foot drop cannot be corrected completely and where the patient is likely to walk anywhere but on a hard surface, we find it expedient to allow almost double this amount of clearance.

Spinal jackets

The patient is placed in the position advocated by Watson-Jones either by means of two suitable tables, or by means of a table and pulley with sling. With the latter method it is easier to get at the patient. A cotton vest is applied, or else a piece of lint is placed over the back and nicked with scissors at suitable places round the edges to mould it to the contour of the body without folds. Two large scissor-cuts are required opposite the concavity of the lumbar curve. Padding by wool or sponge rubber is needed over the anterior superior iliac spines. The pubic hair is protected by a piece of jaconet. The sternum, if necessary, can be padded after

the cast is complete. We do not find it necessary to pad elsewhere. It is important to observe that the aim of a spinal jacket is to immobilize by a three-point suspension.

Injuries and diseases commonly occur in the dorso-lumbar region where the plaster should accurately fit. The plaster prevents any tendency for the already fully-extended spine to extend further by its contact, while any flexion is prevented by contact with the sternum and pubis. Hence it should be carefully applied to impinge on these two bones.

The jacket is commenced with circular bandages, reinforced with slabs, and completed with more circular bandages. Slabs of suitable size can be prepared dry and *folded*, not rolled. They merely require wetting and unfolding prior to application. Slabs are placed on either side of the spine, along the sides of the body, and one is placed over the sternum. Pieces of sackcloth thoroughly impregnated with *fresh* plaster cream can be used instead of slabs. The plaster over the abdomen can be left fairly thin, and some cut away when the plaster is completed. A small pad of wool may be placed over the umbilicus, before the jacket is started, to facilitate cutting. The window should not be large, and in fact some authorities are opposed to making any window at all. However, it definitely does add to the patient's comfort in breathing, and dispenses with some unnecessary weight. It is advisable to reinforce rather heavily the upper and lower ends of the jacket with bandages, paying special attention to the pubic and sternal regions. It is usually necessary to trim the plaster in the axillary and inguinal regions to allow unimpeded movement of the arms and sufficient flexion of the thighs. Plaster beds are made in much the same way, but it is an advantage freely to employ plaster-soaked sackcloth. It is advisable to make them much heavier and of more even thickness. The bed should extend a little more than half way round the body. It is then removed and allowed to dry in the sun and is trimmed with a saw and the edges bound with adhesive plaster, subsequently.

Common defects in plaster jackets

1. The jacket is too short and does not fix the sternum and pubis, and considerable mobility of the spine is permitted.

2. The jacket is too flimsy and does not survive the rather long period—often many months—for which spinal jackets are usually needed.

3. The aperture cut over the abdomen is too large and too wide and this causes the sides of the jacket to break or buckle.

4. Insufficiently wet bandages are used, or stale cream out of the bucket is smeared on, and the result is dehiscence of the layers.

The closed plaster treatment of wounds

Advocates of this method advise against too early removal of plaster casts. It is found,

however, that a tendency exists for this to be interpreted too literally. When the cast becomes soaked with pus and highly offensive not only does it soften and fail to perform the function for which it was fitted, but it results in the patient developing anorexia and neurotic symptoms. The nuisance of the stench to other occupants of the ward cannot be altogether disregarded. Moreover, the outside of the cast becomes infectious and I am of the opinion that pyocyaneus and other infections can be conveyed from the exterior of these casts to other patients by flies. When used for injuries to the soft parts and the wounds have granulated they often heal rapidly when the plaster is discarded and the wounds are suitably dressed. It is ridiculous to assume that pus can be completely innocuous when it is seen to be capable of excoriating healthy skin.

The value of the closed method of wound treatment is beyond dispute, but it must be applied intelligently. The closed plaster method must, however, be used with caution in cases where secondary haemorrhage from a large vessel is to be feared and in cases of deep wounds which are likely to close over. If the patient is likely to be sent on a journey soon after the application of plaster, the cast should be completely split. Wounds should not be packed with dry gauze because it is a powerful foreign-body irritant. The abscess-producing effects of the forgotten swab in the abdomen need no emphasis. We find that wounds which have been packed with plain gauze heal slowly with the production of excess of pus, while those packed with gauze impregnated with vaseline or B.I.P.P. do much better.

The Spanish method

Trueta (1940) recommends the application of plaster by impregnating a piece of flannel, cut to the size of the part, with plaster cream and bandaging it on. This is a simple and quick method, and the resulting casts are of surprising strength considering their lightness. The difficulty is in making the flannel lie evenly and without ridges and folds. It requires practice. We do however occasionally employ this method, especially for wounds and fractures of the forearm.

Trueta claims that by this method casts can more quickly be applied and removed and that the maintenance of a stock of prepared bandages is unnecessary. It must be admitted that these advantages are very formidable.

Removal of plaster casts

Contrary to common belief, unpadded casts are not more difficult, but actually easier to remove. There is no padding to obstruct the shears. Padding however affords some protection if a knife or saw is employed. In modern plasters made by means of the slab and circular bandage there is a thin part to cut. The most efficient implement is the ten-inch size Still's

pattern shears. The larger shears are cumbersome and awkward for routine use, though occasionally they are needed to cut very thick parts where the extra leverage is called for.

Cutting with the knife is tedious and commonly results in cuts in the patient's skin, though the use of the knife is difficult to avoid, especially where there is a thick tight band of plaster across the ankle, which defies the insertion of shears. The application of such substances as acetic acid or peroxide of hydrogen with the

brace it is simply twisted through the cast while the key holds the other end. It is not always necessary to include it in the cast to begin with, since a guide can be made from a steel tape measure, one end of which is blunted with a smear of solder and it can be slipped under the plaster after the fashion of a Gigli saw guide and pulled through, drawing the wire attached to the other end with string. The approximate strength of the various wires available is given in table II.

TABLE II

Stainless-steel piano wire	..	Gauge ..	0.016	0.018	0.022	0.026	0.030
		Breaking strain in pounds ..	50	70	100	150	200
Steel piano wire	..	About 25 per cent stronger.					
		Diameter ..	1/32"	3/64"	3/64"	1/16"	
Stainless-steel cable wire	..		21	21	49	49	
	Strands ..	110	235	270	480		
Aeroplane cable	..	Diameter ..	1/32"	3/64"			
		Strands ..	7	19			
		Breaking strain in pounds ..	185	400			

object of softening the plaster is futile. The removal of plaster is always laborious and an ordeal to the patient especially if there are open wounds, and this should be foreseen and the plaster should be applied in such a manner that it can be removed as expeditiously as possible.

Various other means have been devised to cut it, such as the incorporation of metal strips to cut down on, or the introduction of Gigli saws under the casts. Neither has proved very satisfactory nor do the power-driven circular saws depicted in certain instrument-makers' catalogues appear to have become popular. A recent development is the incorporation of a piece of wire under the plaster which is simply torn through in the same way as a box of ampoules is opened by tearing a piece of string through the label. The method works best with proprietary bandages which are thinner and harder than ordinary made up bandages, and it does not work well if there is too much cloth in the cast. Galvanized iron wire and piano wire are unreliable. Piano wire can only be depended upon to cut through about 5 mm. of ordinary plaster bandage without breaking. Piano wire must be insulated from moisture by wrapping it in a spiral of greasy paper. Stainless wire can be used but it is not so strong. Aeroplane cable is much better and we have been able to cut strong plasters up to 2 cm. in thickness, though it breaks if it is asked to do any more than this. It is much less likely to snap than solid wire of equal tensile strength.

The tools to use with the wire can be made by any engineer from one-quarter-inch mild steel rod. One key is made like a large sardine tin-opener and the other is shaped as a brace. Each has a small hole to receive the wire and a small flange to prevent it rolling off the end. The aeroplane cable is soldered at the ends to prevent the strands from fraying, and by means of the

Summary

1. The chemistry and properties of plaster of Paris have been given.
2. The more important points in the preparation of plaster bandages to be observed, have been discussed.
3. Simple yet efficient methods of applying the commoner plaster casts have been given in detail.
4. The commoner faults observed in plaster casts have been enumerated. This has been based upon actual experience in base hospitals (B. G. H., Poona, I. M. H., Poona, I. G. H., Kirkcc).

PLASTER OF PARIS IN THE TREATMENT OF WOUNDS AND FRACTURES

By P. C. DATTA, M.B., Ch.B. (Edin.), L.R.C.P. (Lond.), M.R.C.S. (Eng.), F.R.C.S. (Edin.), D.P.H. (Edin.)

and

B. S. AGARWAL, M.B.

*Assistant Surgeon, E. B. Railway, Formerly Surgical Registrar, Medical College Hospital, Calcutta
(From the B. R. Singh Hospital, Calcutta)*

THE present war has shown that many war wounds are best treated in plaster of Paris; this medium, unfamiliar to some surgeons, has peculiar advantages and calls for special craftsmanship. It is an attractive medium and much depends on correct technique which is the subject of this paper. When the plaster is in good order a creamy bandage or fabric makes a rigid shell in

a few minutes, passing progressively from almost perfect pliability to rigidity at a rate which conforms favourably with the needs of the surgeons and thus provides the most suitable and perfect splint. With good team work little time is wasted and no movement need be hurried.

A trained plaster-room team of sisters, nurses and orderlies is essential to the smooth running of a long sequence of plasters. In a hospital the best way of initiating and organizing an efficient plaster-room team is to send a carefully chosen sister and orderlies to an orthopaedic hospital for training in the plaster room. Unfortunately, the surgical hospitals in our country seldom give special training in this work.

Material and instruments

A second need is the provision of the correct materials and instruments and an exact knowledge of their preparation and handling. The first essential is the fracture table, and Hawley's table is one of the most suitable for this work. The instruments commonly used include several Still's plaster cutters, plaster-cutting saws, scissor-like cutters for cutting soft plaster, strong scissors for cutting felt, strong scalpels (second hand from the theatre), a glove stretcher for opening the plasters after cutting, wire cutters, a tape measure, a pint measure, pails, bowls, and a trough or bucket for soaking large fabric plaques.

The materials needed are as follows:—

Plaster of Paris 'superfine' such as supplied by Terry Bros., book muslin, 32 threads to an inch, wool bandages, white felt, $\frac{1}{4}$ inch thick, white adhesive felt $\frac{1}{2}$ inch thick backed with zinc oxide, malleable iron wire, 10 to 20 a.w.g., flat strips of malleable iron, 2 feet long, $\frac{3}{8}$ inch wide, $\frac{1}{8}$ inch thick, Cramer wire, 3 $\frac{1}{2}$ inches \times 24 inches, 1 inch \times 4 inches, and glacial acetic acid.

We have never come across a case in which infection has been due to the plaster, but it is advisable that bandages should be prepared under conditions as free as possible from risk of contamination by pathogenic organisms.

The white felt is all passed through the autoclave to eliminate any possibility of tetanus from plaster sore. The plaster and plaster bandage should always be kept in air-tight containers wrapped in newspaper in a dry place otherwise they absorb moisture and become useless.

Two distinct methods of applying plaster of Paris are available (1) with previously prepared bandages purchased or home-made and (2) with creamed fabric, a method originally described by Thorncroft and subsequently adopted in various ways most recently by S. Trueta, in which a suitable fabric cut to measure is passed slowly through plaster cream, spread out and rubbed on a board, and then quickly applied to the limb.

Technique of plaster bandage and bandage plaque method

Making of bandages.—The muslin is supplied in rolls about 1 yard wide and 12 yards long. This is torn into strips of various widths and lengths from 6 inches \times 4 yards to 3 inches \times 2 yards. From each strip of muslin the outer 3 threads on each side are drawn, otherwise

these threads tend to fray and hamper the application of the bandage. The strips are then rolled loosely. The process of changing this muslin strip into a plaster bandage is best learnt by watching and practice. The bandage is unrolled foot by foot and passed through a heap of dry powdered plaster on a smooth board and re-rolled as the plaster bandage. About 12 to 15 inches of the bandage lies exposed on the board at a time, and into it powdered plaster is rubbed (Figure 1). Just the right amount of powder must be rubbed into it and retained in the mesh or left as a very thin even layer on the surface of the muslin as it is rolled up into the bandage. This rolling, too, must be done rather loosely and very evenly. If the bandage is too tight, as is often the case when a novice rolls it, water cannot soak into it; if it is too loose, the powder tends to escape before, during, and after the soaking, and the bandage tends to run out in a 'tail' during its application. The rolling of bandages is indeed a very important part in the technique and is only learnt by experience and watching.

For the limbs, bandages of 6 yards long \times 5 inches wide are preferable whether for adults or children. Bandages for the pelvis and spine should be wider about (20 cm.) 6 $\frac{1}{2}$ inches. The rolled plaster bandage 5 inches (15 cm.) wide should weigh about 400 gm. and 20 cm. about 500 gm. Plaster bandages made with starched muslin are not so good because they are slow in drying.

Soaking.—Everything must be ready beforehand. A likely number of bandages should be set out on a tray; this is advisable because, if bandages are picked out of the stock tin with wet hands, drops of water get on to the other bandages and ruin them. Plenty of warm water should be set out in two deep basins for small plasters or two pails for large ones. A smooth wooden or marble board 36 inches \times 26 inches should be handy for making plaques. When all is ready, the first two bandages are gently lowered into the water, and there is a right and wrong way of soaking a plaster bandage (figure 2). It should be lowered gently to the bottom of the pail in the horizontal position, to avoid unnecessary loss of plaster powder, and left undisturbed at the bottom of the pail until all bubbling has ceased. It is then lifted clear of the water, still in a horizontal position, and gently squeezed by holding it at the two ends and giving it a twist (figure 3). It is very important to keep in mind that the bandage should never be held in the hand and squeezed like a sponge. The squeezing is only meant to drive out the excess of water, and the bandage should still be dripping wet after the excess of water has been driven out. This method avoids any unnecessary loss or disturbance of the plaster powder in the bandages. If the bandage is lowered or lifted in a vertical position or handled carelessly, powder is lost unevenly and the bandage is spoilt. The nurse unrolls 3 inches of the

bandage and hands it to the surgeon in such a way that it comes naturally to application.

Making bandage slabs or plaques

Each slab varies according to size and length of limb where it is to be applied. An average plaque, say of 30 inches \times 6 inches size, is easily made from a single bandage. Smaller plaques made from smaller bandages are used for the forearm and hand; and to strengthen the plaster covering the back of the pelvis or the thorax broad plaques 2 feet square made from several bandages are used. The plaques are made by running the soaked plaster bandages to and fro on a smooth board; the bandage is run naturally on the board in one direction, then lifted and unrolled by the fingers as it passes back, dropped down, lifted and unrolled and so on. The whole process is immensely quickened if an assistant puts an index finger on each corner of the plaque as the lifting and unrolling of the bandage is carried out.

Application

Here it is well to remember that the characteristic virtue of the plaster is the combination of great pliability while it is being applied, with rigidity when it is fully set, and that the period between these phases is critical. It is necessary to hold the limb exactly in the desired position before the plaster is applied, and to maintain this position undisturbed during the application of the plaster and till it is set (becomes rigid). If the position is altered after the application of the plaster or even after a part of the thickness of the plaster has been applied, unsuspected internal ridges will result, causing pain, and are liable to produce what are called plaster sores. The comfort and safety of the patient depend on the even smoothness of the inner surface of the plaster and its accurate and comfortable fit around every bony prominence. A plaster that looks fine on the outside may have a sharp ridge inside. Therefore the position of a limb should never be altered during the application of a plaster. If the position is wrong, the plaster must be stripped off and re-applied. The surgeon should never hesitate to re-apply the plaster if he has the least doubt, keeping in mind that the patient is likely to be discharged from hospital soon after the application of the plaster, and will probably return after several weeks, during which time he may develop plaster sores.

We always prefer unpadded plaster splinting. Padded plaster casts should only be used for transport not for treatment, as it is not possible to provide uniform padding with the result that bony fragments become displaced, and plaster sores often develop over prominent bony points. By careful application of unpadded plaster casts, the pressure is exerted evenly over the whole area of the enclosed limb, so that no one point is subjected to injurious skin pressure. Before applying plaster it is very necessary to be sure that effusion of blood

and swelling has subsided and after the plaster is put on, the position of the limb should never be altered or this will cause creases and pressure points. The skin should not be shaved or greased before the plaster is put on. The plaster attaches itself uniformly to hairs and holds more firmly. Pain is not caused by this as the pull on all hairs is uniform and hence not felt. If the skin is greased, the case loses its grip and the plaster is destroyed as well. The removal of the unpadded plaster case is not painful, because the short hairs of the limbs are changed every four or five weeks, and so these will have been shed when the time comes for the removal of plaster.

When the part to be put in plaster is ready in the desired position a plaster slab or plaque is well moulded over the part and kept in position by a plaster bandage. The plaster bandage should not be drawn tight and only lightly applied. This bandage must never be put on in a circular manner round the part, but should always be applied obliquely. In many fractures, such as the lower end of the radius, a dorsal plaque is sufficient. In putting the bandage on, all creases must be carefully avoided, and, in modelling the plaster to fit round the neighbourhood of the joints, pressure should not be made by the finger tips over bony prominences but evenly over the whole surface with the flat of the hand (figure 5). In certain places it becomes necessary to reinforce the plaster by additional plaster slabs or even metal strips, for instance both in front and behind the hip.

Polishing.—Some surgeons prefer to polish the outer surface of the plaster with thin plaster cream with a wet hand. If the cream is thickly laid it often cracks during the next few hours as the plaster hardens and sweats. This also entails dipping the hands many times alternately in the cream and in water—in the cream to fetch it and distribute it over the area to be polished, then in water because the polishing can only be done with a freshly wet hand. The best way in our opinion is to rub the plastered area with a thin wet towel or lint all round by a to-and-fro movement of the towel as shown in figure 6. There is always some excess of plaster of Paris on the bandages, and, when they have been properly applied, the to-and-fro movement with a piece of wet lint gives an excellent polish and finish to the plaster. The plaster thus put on is much stronger, and cracks less frequently than when thick cream coatings are applied.

Patching.—When, during the service of the plaster, a part requires reinforcement, it is patched with bandages or with bandage plaques, but a patch will not adhere to a dry plaster unless it is pasted on. The process is as follows:—

The part to be patched and an area round are scratched and roughened with a saw or a file, some thinnish plaster cream is rubbed into

the roughened area and bandages or slab is quickly applied before the plaster cream has had time to set.

Creamed-fabric method

The creamed-fabric method has been strongly advocated by Trueta. In this method there is no need for a very large stock of plaster bandages; it takes less time because a skilful assistant, experienced in the method can cut out the fabric, while the surgeon is completing the operation. The cutting of the fabric of the proper size is done on a table, other than the operating or fracture table, the cast sets more quickly and uniformly; the even and known thickness of the shell permits better radiography and a vertical gap exists from the first, saving the delay and difficulty of cutting. This method evidently requires most skilled assistance and is not advisable for a beginner.

To cut out the fabric of a proper size, measurements of the part are taken on the sound side and 10 per cent added to allow for the shrinkage of the fabric when dipped in the water. The proper outlines are then pencilled on the top sheet of the proper layers of the fabric and the pack is cut out. The required number of layers varies with the thickness of the fabric and the size and weight of the part to be splinted. Trueta prefers thick soft flannellette with a loose mesh, but we cannot now obtain this fabric, and use standard plaster-muslin. Three sheets of muslin replace one of flannelette; thus, the wrist requires six of muslin or two of flannelette, the legs nine of muslin or three of flannelette, and an arm or hip spica fifteen of muslin or five of flannelette. Big spicas should also be reinforced with buttresses at the axilla or hip.

The proper amount of warm water is put into a shallow basin, then plaster powder is quickly sprinkled over the whole surface of the water until it ceases to be absorbed and lies on the surface (for a leg 2 pints of water and 4 lb. of plaster). The assistant quickly stirs and rubs the mixture into an even cream, then passes the muslin pack slowly through the cream, making sure that it is fully soaked, lifts it up to drain for a few seconds, and finally spreads it out on the table, making sure that the sheets correspond. If flannelette is used the sheets are soaked separately and then assembled before application.

Before the plaster sets, it is moulded to the surface and a thin layer of cream is spread evenly over it. Some turns of bandage may be used to hold it in position. It is important to see that edges of the fabric do not quite meet, or if they do they are turned back to make rounded rims $\frac{1}{2}$ inch apart. The narrow channel left facilitates any adjustment of the circumferential hold and the ultimate removal of the plaster.

Windows and bridges

Sometimes it is desirable to have access to a wound or to a bony prominence. This can be achieved by leaving the skin or wound unsupported locally and by reinforcing the plaster round this unsupported area by plaques or ropes of plaster, thus making a window. The wound can be dressed through this window as desired. Sometimes large areas of a limb, or even its whole circumference, may have to remain uncovered or be uncovered daily. In such cases the area is bridged over with ropes of plaster or with plaster with a length of malleable iron within it. Plaster with iron strip is easier to apply, but it may be a nuisance when it is desired to enlarge the window because this cannot be cut with a saw to modify the position. It is therefore often better to use plain solid plaster ropes for bridging buttresses; then with a saw and a few plaster bandages the area to be exposed can easily be increased or otherwise altered.

Another method is to complete the plastering all over and then to outline the area of the window with an indelible pencil; the plaster round this area may be strengthened and when the plaster is just set but not rigid the outline of the window is incised with a sharp scalpel right down to the dressing or padding exposing the wound.

Traction or skeletal fixation

A combination of plaster and traction is sometimes invaluable. Plaster control of the proximal part provides a solid basis for an extension bow, which may vary from the whole length of a Thomas splint to a small loop of wire providing traction for a finger. So, too, can plaster provide a rigid hold for Steinmann pins or for Kirschner wire.

Special plasters

Arm abduction.—This should always take a broad padded bearing on the crest of the ilium. The angle of abduction varies with the indications, but flexion and rotation are such that the hand would reach the mouth if the elbow could be flexed. This is important when parts of the humerus have been shot away or removed; for, if ankylosis of the shoulder takes place, a standard position of the arm would cause the hand to be carried past the mouth. The ulnar border of the hand should be supported; otherwise the hand will droop over the edge of the plaster. In most cases the hand is also maintained in slight dorsiflexion by a short extension of plaster into the palm, giving the effect of a short cock-up.

Lower limb.—When the whole limb is included in the spica the plaster over the dorsum of the foot should be cut out almost completely, and the plaster should always extend beyond the toes on the plantar surface, holding the toes in dorsiflexion at the metatarso-phalangeal joints and with their inter-phalangeal joints

straight. With this adequate plantar extension of the plaster, wool can be inserted from time to time under the tips of the toes, and steps taken to make sure that the correct position is maintained. The importance of this is great otherwise there will be stiffness of the ankle or the foot, for then hallux rigidus is most painful and crippling.

The plaster is thickly applied where the strain is great. This saves plaster and labour in putting on and even more in taking off the splint. But nurses cannot have it drilled into them too often that they must not lift the plaster by the lower end.

Hip spica.—The spica is applied on a fracture table with a fairly small pelvic support. Whenever possible the patient should be lifted from the supine position on the table to a prone position on a layer of pillows on his bed. In any case the back of the plaster must be looked over and any unevenness left by the support corrected. Fingers are passed as far as possible between plaster and skin, to make sure of an even, deep surface, and sufficient plaster is removed in the form of a narrowish inverted U to allow of clean nursing. While the patient is in this position, one should make sure that plaster is of adequate strength between the back of the thigh and the back of the pelvis, and reinforcement can be added if necessary. This region is subjected to a concentration of stress and strain in front and behind. This is caused by the patient trying to flex his body forwards or by a nurse mistakenly trying to lift the patient by the lower part of the plaster, perhaps to put a pillow under the knee. Extra strength is supplied behind by several plaques running obliquely from the back of the pelvis down the thigh. In front the strength should be further increased by using batwing plaques with a raised ridge at the point of antero-posterior strain.

Assurance of good circulation

A danger much more acute and disastrous than that of pressure sores or of paralysis from pressure on a nerve is that of the general compression of a limb which impairs or abolishes circulation. Compression, complete and not quickly relieved, causes gangrene; compression less complete may provoke ischaemic contracture or lead to a prolonged disturbance of the sympathetic control, associated with oedema, stiffness, and extreme osteoporosis. Compression almost always arises from subsequent swelling of the limb within the shell. It is desirable that compression should never be allowed to develop and it is essential that it should never remain unrelieved. Every plaster put on soon after a fracture or an operation should be split vertically from end to end; it is indeed a good policy to make this a standing order, though it is very often ignored by the young house surgeon. It is the practice with skin-fitting plaster to put a folded woolly bandage vertically along the limb

in the line on which it is to be cut. Then, when the plaster is just set but not yet rigid, two cuts in the plaster are made with a sharp scalpel about $\frac{1}{4}$ inch apart until the bandage is reached. The narrow strip is completely cut out; short strips of bandage are tied round the plaster at two or three levels with a bow, thus the nurse can easily loosen the tie to allow of further expansion if necessary. Later, the plaster edges can be brought closer together if the limb shrinks inside the plaster. If necessary a further strip of plaster can be removed. Trneta attains the same end by the plaque method, which is quicker.

Points in nursing

Position.—When the patient is put back into bed, difficulties arise unless the ward staff is well trained in certain points. First, the lower limb must always be so well supported that no pressure ever reaches the plaster over the tendo achillis or the heel; as a rule a few pillows under the limb, with nothing under the heel, is all that is needed, and it is a good plan to take a fracture board from the lower end of the bed and put it as a second layer to raise the mattress under the knees.

Secondly, if the patient is in a spica plaster, a common mistake is to pack up his head and shoulders so that his chest or abdomen is forced against the upper rim of the plaster with very unpleasant results. The pillows should be so arranged that the body lies evenly supported on the plaster and on pillows just above it. With the patient lying in bed there should always be room for the whole hand to be inserted between the front of the body and the plaster.

Drying.—The plaster sets in a few minutes and then sweats for twenty-four hours. If the plaster is exposed during this period or covered with a porous blanket, the sweating is imperceptible and all is well; but if the plaster is covered up in bed it will be softened and ruined. No amount of heating and drying immediately after the application can eliminate the need for this precaution.

Plaster sores.—Sores are almost unknown with good plaster work and quite unknown if a good plaster is followed by good nursing. A patient in a big plaster can almost always be turned from side to side, often right over on his face: on such points the ward sister will be given directions by the surgeon. A change of position may be necessary to relieve the discomfort of a very thin patient, a patient who is tender, or one whose skin is poor from age or illness. Good nursing of this sort may even enable a patient to escape harm from a bad plaster.

The warning signs of a sore are often far from obvious, and there may be only a brief period of warning. First, the skin becomes reddened over the point of pressure: this is almost always associated with pain, though at times the patient will not mention it, or may

not even notice it during the hours of the day; almost always, however, the night nurse will observe a change from previous quietness to restlessness. Commonly a probationer has the best opportunity of observing her patients from night to night, and therefore it is a primary essential for the junior nursing staff to be taught the importance of the least nocturnal restlessness of any patient in plaster, to note it, and to underline it in the night report. This may be the only warning of a plaster sore, and the information should always be passed on to the surgeon so that he may have the opportunity of intervening.

The second phase within the plaster is the necrosis of the skin, and, since this deadens the sensitive nerve endings, the patient becomes more comfortable (*of gangrenous appendix*).

The third phase is the deepening necrosis of the underlying tissues. By this time some discomfort will again arise, and a characteristic smell may be noticed, which, however, will have little chance of recognition where the plaster covers an open wound.

The development of plaster sores can only be prevented by the proper collaboration of the surgeon and his nurses. It is the duty of the surgeon to make his plasters even, smooth, and well-moulded inside; to arrange with his nursing staff that the patient be given frequent changes of position, if they make him more comfortable, and to insist that watch is kept for any localized discomfort or any nocturnal restlessness, and that he or his resident be immediately informed of any such warning symptoms.

Conclusion

We have tried to write a practical account of plaster of Paris as a splintage medium; once its use is understood, it is easy to adapt it in all sorts of ways and we think that the creamed-fabric method needs first-class assistance. At the same time, the bandage and water are the bread-and-butter of plaster work; if a man is to plaster, he should be ready to go anywhere and do anything with a big tin of bandages and a bucket of water.

The observation of Trueta and Barnes (1940), that immobilization in plaster minimizes lymph flow, and therefore decreases the chances of absorption of bacteria and their toxic products, has been confirmed during treatment of hundreds of cases of wounds of limbs immobilized by plasters after air raids in England (Ross and Hulbert, 1941) and this should be regarded as an additional point supporting the treatment of septic wounds with plaster of Paris splintage.

Our thanks are due to Dr. C. D. Newman, Chief Medical Officer, E. B. Railway, for kindly allowing the publication of this paper.

GRANULOMATOUS ULCERS OF SMALL INTESTINE CAUSING ANNULAR STRICTURE AND INTESTINAL OBSTRUCTION

By M. G. KINI, M.C., M.B., M.Ch. (Orth.),
F.R.C.S. (Edin.)

Surgeon, King George Hospital, Vizagapatam
(S. India)

STRICTURE of the intestine causing acute intestinal obstruction is rare in Northern Circars and when it occurs is usually due to tuberculous or malignant ulcers or to sarcomata causing an annular stricture. The contents of the small intestine being fluid, obstructive symptoms occur in the later stages of the disease; at first they are of the nature of colic, with symptoms of chronic obstruction. Acute obstruction supervenes as a late symptom in these conditions. References to annular strictures due to granulomatous ulcers with no definite specific aetiology causing acute intestinal obstruction are rare. Out of 30 cases of intestinal obstruction from 1932 to 1940 only three cases of annular stricture due to granulomatous ulcers were found. In 1932 Crohn described a condition of regional enteritis with four distinctive phases in its clinical manifestation; this is now described in the literature as Crohn's syndrome.

- (1) The acute inflammatory stage resembling acute appendicitis.
- (2) The stage of ulceration causing enteritis associated with diarrhoea.
- (3) The stage of sclerosis resulting in obstruction as in tuberculous conditions.
- (4) The stage of sinus and fistulous formation resembling actinomycosis and tuberculosis.

In most of the cases described by Crohn he found the pathology limited to the ileo-cæcum region, but later he found the same pathology

EXPLANATION OF PLATE XXXVIII

- Fig. 1.—The plaster must be well rubbed evenly and retained in the meshes of the bandage when preparing plaster bandages.
- Fig. 2.—The correct way of putting a plaster bandage in warm water.
- Fig. 3.—After all bubbling has ceased in the bucket the bandage is taken out and held between the index finger and thumb of both hands and given a twist. This deprives the bandage of excess water.
- Fig. 4.—The plaster must always be applied obliquely and never in a circular manner. Obliquely applied plaster bandages are less liable to cause compression of the limb.
- Fig. 5.—The plaster cast should be moulded with the flat of the palm and not with fingers otherwise internal ridges will result and cause pressure sores.
- Fig. 6.—Polishing the plaster with a wet towel.
- Fig. 7.—Showing a circular window in the plaster, a case of open fracture of the medial malleolus and infected ankle joint.

Note that the plaster on the sole must reach up to the tips of toes otherwise the toes are kept plantar flexed due to gravity, and stiffness results. On the dorsal aspect it must cover up to the knuckles.

occurring in any part of the small or large intestine. In all these cases the obstruction is due to thickening of a segment of a bowel and not to annular stricture. The ulcers have been described as resembling granulomatous ulcers. Granulomatous ulcers have also been found in the region of the stomach and they resembled malignant ulcers clinically (Kini and M. N. Rao, 1938). Three cases of granulomatous ulcers causing acute intestinal obstruction on the top of a chronic progressive obstruction were found in the small intestine. In these cases the ulcers caused an annular stricture resulting in obstruction. In two cases the stricture was found in one situation of the ileum and in the third in two situations, 3 feet apart in the course of the ileum.

Case 1.—Mohammedan male, aged 19 years, was admitted on 18th February, 1928, with a history of colic of six months' duration. Six months before admission he had a dragging pain in the right inguinal region. Now and then he noticed slight swelling in the same region with distension of the abdomen. At the time of admission he was found to be moderately nourished with pyorrhœa alveolaris and angular stomatitis; the tongue was raw, moist and flabby. The conjunctivæ were pale and anaemic. The pulse was regular, of low volume and tension. Heart and lungs were found normal.

On examination, a swelling was found in the right iliac fossa and there were a lot of borborygmi. There was no external hernia. There were no glands palpable and nothing else abnormal was found. He constantly complained of colic which used to grow in intensity at intervals and was associated with distension of abdomen.

X-ray examination showed marked dilatation and hypertrophy of the small intestine, and obstructive changes (figures 1, 2, 3 and 4). The barium enema showed no abnormality.

One day he got acute obstruction and he was operated on under local anaesthesia supplemented with ethyl chloride and ether sequence. On opening the abdomen, the small intestine was found dilated. It was found difficult to isolate the cæcum. There were large mesenteric glands at what appeared like the ileo-cæcal angle, and a stricture was found in the lower part of the ileum. It was done proximal to the cæcum and isolated in layers. He was

The patient was re-admitted on 4th December with marked œdema of the feet and anaemia. He was treated on the medical side for his anaemic condition and sent home, and it is reported that he is keeping fair health.

Case 2.—A Hindu male, aged 41 years, was admitted on 4th December with a history of colic and inability to pass faeces and flatus, of four days' duration.

The complaint started six years before admission. It started with a feeling of fullness in the stomach three hours after the meals; he used to vomit undigested food obtaining some relief. The pain became severe after meals lasting three to four hours and was relieved by vomiting. One year prior to admission, flatulence became a noticeable feature; it was relieved by fomentations, the passing of wind and vomiting of bile. He had lost considerable weight and was admitted for continuous pain of a severe type of about four days' duration.

An ill-nourished individual of 40 years, anaemic, tongue moist and clean, teeth dirty, and pyorrhœa alveolaris present. Heart and respiratory system were normal, but the pulse rate was 102 per minute, moderate in volume and tension.

The abdomen was scaphoid with rigidity in the epigastrum and peristaltic waves were found in the epigastric, umbilical and left lumbar region. The wave started in the right half of the epigastric region and

travelled down across the umbilical region to the left lumbar region.

Blood Wassermann—strongly positive.

Blood pressure—110/88 mm. of mercury.

X-ray showed marked hypertrophy and dilatation of the small intestine (figure 5).

A diagnosis of Crohn syndrome or tuberculosis of the intestines with obstruction was made, and he was operated upon under local anaesthesia by a right para-umbilical incision, on 13th September. On opening the abdomen, the proximal part of the jejunum and ileum was found hypertrophied and dilated.

About the middle of the small intestine a marked annular stricture was found with no tubercles on the peritoneal surface. The intermediate group of glands was removed.

The large bowel was found remarkably dilated; the stomach was normal. The abdomen was closed in layers.

The patient had a slight cough for a few days after the operation. He recovered. The specimen showed an extensive granulomatous ulcer (figure 6) which on histological examination was found to be infiltrated with plasma and lymphatic cells in the wall of muscular and serous coats. The mucous membrane showed extensive ulceration, and in places a perivascular reaction was found; no acid-fast organisms were found. The glands showed chronic inflammatory changes, but without evidence of tuberculosis.

He was discharged from the hospital and he reports on 20th March, 1940, that he is keeping perfect health. He had put on about 20 lb. weight since he left the hospital.

Case 3.—A Hindu male, aged 60 years, a fisherman by occupation, was admitted on 28th June, 1940, for chronic intestinal obstruction with acute symptoms supervening. He was admitted on the medical side for colic and later transferred to surgical side for acute obstruction. He gave a history of venereal disease.

EXPLANATION OF PLATE XXXIX

Fig. 1.—A radiographic picture of the gastro-intestinal tract taken 5 minutes after administration of the barium meal. It shows the jejunum dilated and hypertrophied.

Fig. 2.—A radiographic picture taken 3 hours and 40 minutes after the administration of the barium meal showing obstructive phenomena.

Fig. 3.—Marked ballooning of the small intestine taken 6 hours and 30 minutes after the administration of the barium meal.

Fig. 4.—Taken 24 hours after the administration of the barium meal. Note the barium in the cæcum and the residue in the small intestine which is ballooned out to the size of a distended large bowel.

Fig. 5.—A barium meal picture taken 5 hours and 30 minutes after the administration of the barium meal showing the residue in the small bowel and the barium meal is found in the large bowel.

Fig. 6.—A picture of the mounted specimen. Note a large shallow ulcer with undermined edges at the periphery. At one place the ulcer was cut for taking a block for histo-pathological examination. Note the dilatation of bowel stricture.

Fig. 7.—A barium meal picture taken 1 hour 15 minutes after the administration of the meal showing marked obstruction of the small intestine. Note enormous dilatation of the lumen of the small intestine.

Fig. 8.—Taken 48 hours after the operation of lateral anastomosis shows the barium has passed into the large bowel.

The duration was given as two months. It started as a pain in the umbilical region with gradual increase in intensity. The pain later was all over the abdomen and increased on taking food; there was a very uncomfortable sensation of something moving inside his abdomen. He used to obtain relief after vomiting, but since admission to hospital he had no vomiting. Appetite was poor and he had no history of haematemesis.

Abdomen distended and tympanitic; no free fluid, visible peristalsis found; coils of intestine were found to stand out in the ladder pattern; tenderness was present.

The urine was normal. Barium meal examination showed marked intestinal obstruction (figures 7 and 8).

He was operated on as an emergency under local anaesthesia by a right paramedian and para-umbilical incision. On opening the abdomen, dilated loops of small intestine were found to stand out. On exploration, two strictures were found in the middle of ileum about 3 feet apart and the rest of the bowel was found to be normal. There was no evidence of tubercle at the site of stricture or anywhere in the intestinal region. A lateral anastomosis of small intestine between each stricture was effected and the abdomen closed in layers. Resection was considered dangerous because of the poor condition of the patient.

The patient made an uneventful recovery and on re-examination by barium before he was discharged, it was found that the anastomosis was functioning very well. He has been re-admitted on 18th August, 1940, with marked anaemia and swelling of his feet. He was found to suffer from deficiency of vitamins for which he is being treated and he shows marked improvement.

Summary

(1) Three cases of chronic obstruction were admitted and the radiological picture of these three cases showed obstructive phenomena of the small intestine.

(2) They developed acute obstructive symptoms during the course of the investigations and so they were operated on as emergencies.

(3) At operation in case 1, the obstruction was found to be due to annular stricture, but excision could not be done as the patient's condition did not warrant such a procedure, so an ileo-transversostomy was done and he was discharged cured. The patient was re-admitted for anaemia for which he has been treated and now he is keeping fairly good health. Case 2 was operated upon, one and a half feet of the small bowel was excised, and an end-to-end anastomosis was done. The annular stricture was found to be due to a granulomatous ulcer which was responsible for this condition. The histopathological section and the naked-eye appearance showed that the intestine was markedly hypertrophied and dilated above the line of annular stricture and the bowel beyond was found collapsed. In case 3 there were two such strictures about 3 feet apart and this case was in such a bad state that excision of the strictures could not be done. He was re-admitted for anaemia for which he was treated with fair results. He is still under observation.

(4) Granulomatous ulcers causing strictures and obstruction whose specific origin is unknown

HEAD INJURY AND ITS MANAGEMENT

By P. C. SANYAL, M.B. (Cal.), L.R.C.P. (Lond.), F.R.C.S. (Eng.)

Honorary Surgeon, Medical College, Calcutta

It was common with the older writers to focus the attention to the effects of severe injury mainly to the calvarium, but, with the better understanding of the underlying physio-pathology of these injuries, our attention is now more drawn towards the effects of such injuries on the intra-cranial contents and less on the skull bones themselves. After all, sequelae that follow a severe head injury are always due to damage to its contents, and the treatment, if it is going to improve the prognosis, must of necessity be directed towards such effect. For brevity I will not discuss the mechanism and distribution of various fractures of the skull bones.

Broadly speaking, any severe violence on the head will produce deformity of the skull.

(1) If the area of impact is limited, it may produce localized fracture (depressed fracture), with or without local laceration of the underlying brain.

(2) If the deformation is diffuse, it may produce fracture of the skull and as the base is the weaker area, often the line of fracture runs through it. The meningeal vessels being intimately adherent to the skull may also be torn with the fracture (middle meningeal haemorrhage). Although middle meningeal haemorrhage may occur without a fracture, in the majority of cases they are associated, a point worth remembering. Mention may here be made that incidence of middle meningeal bleeding is rather rare though the associated lucid interval has caught the imagination of many medical men.

In the last consecutive 100 cases that I have observed only three were suspected—one proved by operation and the last two by post-mortem examination.

(Continued from previous column)

are rarely described. The question of its being tuberculous has been considered. The naked-eye and histopathological section showed no evidence of tuberculosis (see case 2).

My thanks are due to the Radiologist Dr. P. Kesavaswamy and to Dr. Pisharoty for case 3 who kindly transferred the case for surgical treatment and to Dr. T. Bhaskara Menon for the photomicrograph and the histopathology.

(Concluded at foot of next column)

The effect of general deformation of skull on the brain.

The force of impact is transmitted through the brain substance and hence any injury that may follow is to be found along the track of transmission of such force. Thus there may be local laceration of the brain substance, or there may be major contusion on the opposite side, where it violently comes in contact with the skull (*laceration by contre-coup*). The injury being furthest from the site of injury, if not thought of, may altogether be missed. Furthermore along the track of force there may be microscopic injury to the brain substance, and also around the ventricular walls.

Based on this known pathology of the condition we may group the cases clinically as follows, remembering all the time the limitation of such stereotyped grouping.

Concussion.—Following a severe injury the patient loses consciousness; this is immediate and complete. During this period, with the exception of vital centres, all functions are

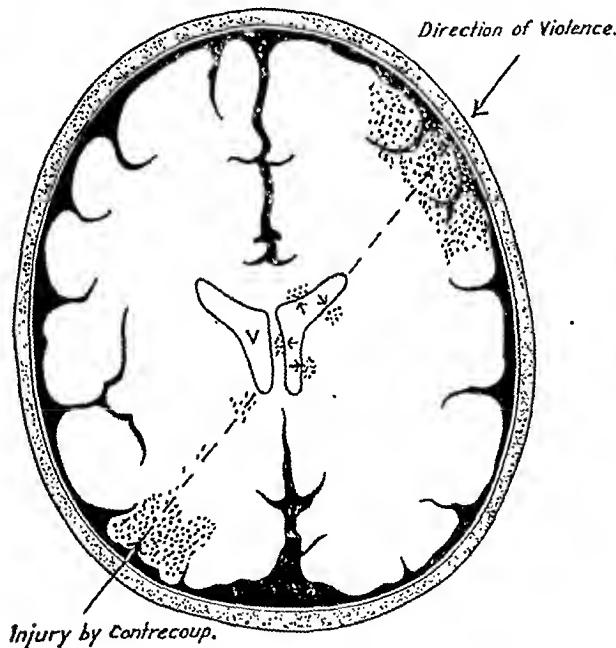

Fig. 1.

paralysed. After a short interval the patient recovers completely from its effect without any residual damage.

This is the clinical picture of a typical uncomplicated case of concussion and any prolongation or deviation of the symptoms or alteration in the recovery stage is due to added complications such as minute haemorrhages or neural damage.

Trotter's explanation for this condition has been universally accepted, namely, that owing to energetic decompression of the skull there is hyper-acute cerebral anaemia and the resultant paralysis of most of the cerebral functions. This is the only understandable explanation of the condition and one on which we can base our treatment. But as the period of concussion is only a momentary phase of the

effect of the injury, naturally one should be on guard for the train of symptoms that may follow it, proving more severe organic damage to the underlying structures.

Traumatic delirium.—The patient after a prolonged state of concussion passes into a state of incomplete unconsciousness marked by heightened excitability. The patient lies on his side, resents light or any disturbance, and the reluctance to answer questions is often noted as unconsciousness, and he may even show exaggerated rage phenomena when disturbed. There is complete absence of any focal signs and symptoms. Often there is regular alternation of drowsiness by day and delirium by night. The pulse is full and the rate is variable but more towards the slow side. Temperature may or may not be raised and then only by a degree or so. The condition reaches its maximum on the second and third day and gradually subsides, if not interrupted by further complications.

Although this is the usual clinical picture, there are often present innumerable variations of symptom groups, and as the mental condition

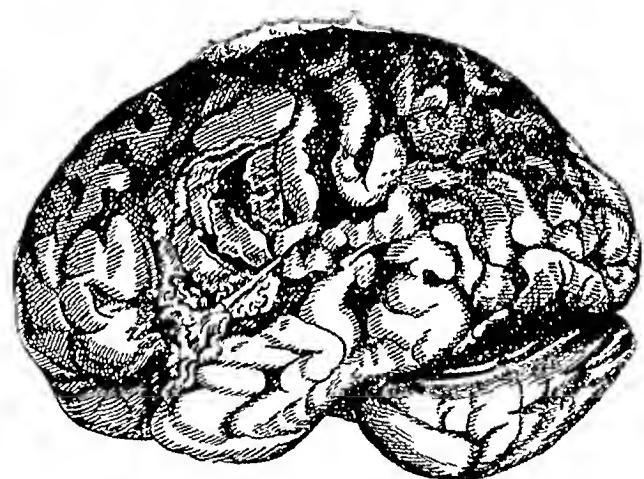

Fig. 2.

is of non-co-operation it is all the more important to take particular care in eliciting any signs of focal damage and recording progress of symptoms of clot compression.

The underlying path is explained by the occurrence of oedema following a severe injury, which is a natural result of all injuries. But there is very little space for accommodation of extra fluid without affecting the cerebral circulation; and as oedema follows, the increased pressure impedes the venous outflow in the surrounding capillaries and thus produces congestion of the part. It has been assumed, in severe injury, that there are present diffuse though minute areas of haemorrhage and thus a generalized oedema and congestion of the brain is the result.

That this is not the only pathological change in this group of cases is obvious, and pointed attention has been drawn to this fact by various writers. The oedema and the resultant congestion must take time to develop, at least twelve

hours, but the alteration of mental condition is noticeable from the period of concussion and hence there must be neural damage or disturbance of cerebral function from the direct effect of trauma alone.

Traumatic stupor.—This forms the last group of cases and presents the greatest difficulty in determining the actual damage to the intracranial contents. The cases that do not show any improvement and in whom the unconsciousness is prolonged from the stage of concussion with gradual onset of bulbar paralysis and with death occurring within few hours of injury are due to damage of extensive nature, laceration of the brain or rupture of big vessels, and very little can be done for them.

But by far the largest group of cases show an interval between the period of concussion and the secondary onset of unconsciousness. During this interval, the period of which again varies from a few hours to days or even weeks, the patients show signs of cerebral irritability.

The underlying pathology of this condition of secondary unconsciousness is supposed to be due to clot compression.

The rise of pressure, owing to haemorrhage, is essentially local at first and the area thus compressed becomes anaemic and there is loss of function or paralysis. As the pressure still rises it is transmitted to the opposite side and produces congestion and cerebral irritation of the opposite hemisphere first, and later on bilateral cerebral anaemia and paralysis. With the continuous rise of intracranial pressure supratentorial pressure presses down the mid-brain through the tentorial notch and thus strangulated, it brings forth the series of bulbar symptoms, first irritative, later paralytic.

Though this is the usual picture in traumatic stupor this is not the whole truth. That clot compression can and does produce secondary unconsciousness is of little doubt but that cerebral laceration without massive haematoma can also produce stupor, though disputed, is also a fact.

An example :—

Case 1.—Male, 20 years, knocked down by a car and was admitted on 24th January, 1939; unconscious; bleeding from the nose; pupils equal and dilated reacting to light; no paralysis; no subconjunctival haemorrhage. Lumbar puncture—clear fluid.

On 26th unchanged mentally; talks incoherently; disorientation of time and place. No paralysis. Gradually symptoms cleared up and he was discharged on 25th February.

Here the syndrome is typical of laceration of the under surface of the frontal lobe and there was never anything suggestive of clot compression.

The drawing of the brain (figure 2) is another example of cerebral laceration with mental disturbance, ending fatally but absence of any clot compression.

Anatomical varieties of intracranial haemorrhage.—By far the largest group of cases of

traumatic stupor are due to haemorrhage and this may be sub-dural or extra-dural.

(1) *Sub-dural haematoma.*—This type is far more common than the extra-dural, and in the majority of cases, is due to moderate haemorrhage, so that the pressure symptoms are delayed by days or weeks. The patient shows signs of prolonged cerebral excitability and signs of localized compression-paralysis sets in. Progress of symptoms from irritation to paralysis is the chief character of intracranial haemorrhage and must be looked for.

In the majority of cases it is possible to localize the seat of haemorrhage clinically and a few cases may be cited.

Case 2.—Male, 28 years, was admitted on 14th March, 1938. History of being struck by an iron rod on the right parietal region on 9th March. He was unconscious for three days then recovered incompletely.

On admission.—Patient was conscious but did not talk. He attempted to answer simple questions. When given food he took it regularly, never showed any irritability. There is paresis of the left side. X-ray showed a linear fracture over the right parietal eminence. He was improving but suddenly worsened and was operated upon on 20th March. There was huge sub-dural and a moderate extra-dural haematoma in the region. Recovery was uneventful.

Arachnoidal haemorrhage.—This diffuses in the spaces and there is absence of any localizing signs. Lumbar puncture shows blood intimately mixed with the cerebro-spinal fluid.

Intra-cerebral haemorrhage.—This is still rare. Compression symptoms usually take about a week before becoming apparent. But if it occurs in the silent area, vague symptoms are difficult to analyse and if the patient comes after a long time it is often confused with cerebral tumour.

(2) *Extra-dural hematoma.*—If the bleeding is from the middle meningeal artery there is practically no lucid interval. Patient shows incomplete signs of recovery from concussion, often becomes violent and then passes into unconsciousness again with the appearance of paralytic symptoms.

If the bleeding is moderate, especially venous, the lucid interval is prolonged a few hours then the compression signs appear. As regards classical compression symptoms, slow bounding pulse, Cheyne-Stokes' respiration and raised blood pressure, these are due to pressure on the bulb and are very late signs; one should endeavour to diagnose before they appear. I consider pupillary changes with hemiplegia are quite diagnostic of clot compression and alteration of mental condition is of the greatest help.

Case 3.—Male, 30 years, admitted on 22nd February, 1938. History of fall from a height of about 80 feet. On admission, bleeding from both ears. Fractures of four ribs on the right side. Patient deeply comatose and remained so till death. No reflexes elicited. Pupils equal but dilated and sluggish. Ultimately died in the forenoon of 23rd February.

Post-mortem report.—Huge haematoma on left fronto-parietal area. There is rupture of middle meningeal artery near its exit and at the site of fracture. Interesting points in this case are, absence of lucid interval,

no localizing signs and pulse throughout varied between 110 to 120 per minute.

Depressed fracture.—It results, as already mentioned, from localized deformation of the skull. Cases with local contusion, which may follow such fracture over the motor area of the cortex, may come later on with symptoms of Jacksonian epilepsy.

Case 4.—Male, 30 years. History of being struck by rod, on the parietal region. He was unconscious only for about half an hour and was up and about next day. Twelve days after the incident he had a convulsive seizure in left limbs. Since then having fits now and then and lately accompanied by loss of consciousness.

Operation.—There was an old scar filling a trephine hole and dura was adherent to the skull. There was a depressed fragment present over the motor area; pia mater is also adherent to scalp. No blood cyst found. Silver foil was interposed on either side of the skull, after proper mobilization and decompression. He developed temporary 6th nerve palsy. Discharged on 5th February with complete recovery.

Thus after covering in rather a sketchy way the important symptom changes and the related pathological condition, some observations may now be made about the management of such cases.

Treatment

The majority of cases of head injury, as met with in civil practice, if treated skilfully, recover without any ill effect. But it requires great attention and constant watch, together with competent nursing.

Leaving aside details, for the sake of brevity, an attempt will be made to bring forth only the salient points in such management.

The chief aim in all head injury cases is to counteract the bad effect of raised intracranial pressure and if not caused by clot compression one may succeed by conservative treatment alone; even in clot compression, the basic idea is the same—reduction of the compression effect by surgical means. Of course any accompanying complication will require special attention.

Concussion.—Treatment should be expectant as the exact sequelæ are not known. It is directed to combating shock and caution is necessary in administering stimulants.

Rest in bed for three weeks (both physical and mental) is a necessary safeguard against post-traumatic epilepsy, in all cases of severe, though uncomplicated, concussion. Strenuous exercises should not be allowed before three months and any return of symptoms—headache or mental changes—require immediate return to bed and careful watch for complications.

Traumatic delirium.—Here we are dealing with more-or-less diffuse bruising and œdema of the brain and our aim is to ensure rest to the patient and to lower excessive rise of intracranial pressure, and watch for developing signs of complications.

It is better to nurse the patient in a dark isolated room. To diminish the excitability,

sedatives are essential and bromides and chloral hydrate are usually sufficient. Luminal can safely be used when necessary. The doses required are often large, at the same time it is useless to dope the patient while the real indication is a decompression. If oral administration is difficult rectal medication is to be resorted to.

Lowering of the intracranial pressure is obtained as follows:—

Magnesium sulphate enema: This is a very useful method in the treatment of head injury. It reduces the excess pressure without any ill effect and can conveniently be repeated, thus, having a more-or-less continuous effect of decongestion. In an adult, about 6 ounces of 50 per cent solution is injected into the rectum under low pressure and after half an hour it is washed out with a plain water enema.

Intravenous saline: It is one of the most powerful means of reducing the intracranial pressure. With its first introduction, enthusiasm ran high but moderation came with experience and now it is held a valuable adjunct but with limited field of usefulness. Though there are a large number of adherents to using it in all stages, I do not think it is based on known physio-pathological findings. In large doses it reduces the pressure rather too rapidly and too much and it is always followed by quick return to the previous level or even higher. It is also futile, and even dangerous, in the early stage of head injury. When used, 15 per cent of 25 to 50 c.cm. of a 15 per cent solution is injected into the vein, where the C.S.F. pressure is recorded near the 300 mark. Fifty c.cm. of 50 per cent glucose may also be injected to lower the intracranial pressure.

Lumbar puncture.—As a diagnostic method it is to be done early. But for reduction of pressure it is not necessary to repeat it before 36 hours. The practice of doing it daily as a routine should be discarded. Caution is necessary when doing it in the presence of very high pressure, as too rapid reduction may cause impaction of the bulb and mid-brain in the canal below. As a safeguard it is imperative to use a manometer.

Persistent delirium, in the absence of clot compression, should be treated by decompression.

Treatment of compression: When clot compression is suspected the only treatment is decompression and removal of the clot.

If the mortality rate is to be improved upon one must be prepared to operate on cases of suspected clot compression. The passive attitude that is being taken in compression cases is largely responsible for the high fatality at present. Though decompression in such cases gives a better chance of recovery the patient may die of the effect of neural damage already undergone.

Operation is also indicated in compound and depressed fracture. Difficulty arises in cases

where underlying an apparent innocent scalp wound a linear crack is detected some time later by x-ray. Two cases have thus been lost following late septic meningitis. It is difficult to take the view to operate as a routine in all cases of linear fracture, particularly on the inner table accompanied by scalp injury, though on principle one should.

Convalescence.—In short it may be said that when the patient has become conscious and remains continuously so he passes into the stage convalescence.

To prevent post-traumatic neurosis, the patient is to be warned of early commencement of activity. All mental strain is to be avoided for a long time and also acts that raise intracranial pressure. Sedatives such as luminal should be continued for a long time.

Some observations on one hundred consecutive cases of head injuries

Age factor.—Only three cases out of twenty proving fatal were below 5 years of age. This is perhaps explained by the fact that there is more accommodating power in a child's calvarium than in case of an adult. Furthermore

List showing deaths in relation to time interval following admission

LEPTOSPIRAL JAUNDICE IN ASSAM

By B. M. DAS GUPTA

(From the Department of Protozoology, School of Tropical Medicine, Calcutta)

CONSIDERABLE interest has been aroused by the recent discovery of infectious jaundice in Calcutta (Das Gupta and Chopra, 1937), and since then, material (chiefly blood sera) from cases of jaundice occurring in different parts of India, viz., Bihar, Bikaner, Simla and Deccan, have been received by the writer for examination for evidence of leptospiral infection. The

TABLE I
Agglutination tests

Strains of <i>Leptospira</i>	TITRE OF AGGLUTINATION			
	20	40	80	160
Strain Chopra, Calcutta (classical <i>Leptospira icterohaemorrhagiae</i>).	+	+	+	+
<i>L. canicola</i>	+	+
Mg. Tin Tin	±	—
Andamans A	—	—
Andamans B	—	—

clinical features in most of these cases were not, however, suggestive of infectious jaundice and

(Continued from previous column)
extensive injuries are by nature commoner in adults.

Fracture of the skull : Out of about eighty-five cases clinically taken to be severe injuries only twenty showed fracture of the skull.

Lumbar puncture.—As a diagnostic procedure undoubtedly an important test but as a routine done in the ward it is of less significance (due probably to faulty technique) as a large number of reports show blood-mixed fluid.

It will be noted in the above list that 50 per cent of the deaths occurred within 24 hours of injury and another 25 per cent within 60 hours, that is 75 per cent died within three days of the injury. These deaths are always due to extensive injury to the intracranial contents and are obviously beyond treatment.

The cases of sub-dural haematoma might have been saved by early operation.

Three cases developed septic meningitis after 10 and 20 days. The third one is interesting in that he developed primary meningococcal meningitis with an uncomplicated head injury.

I take the opportunity of expressing my indebtedness to Dr. D. C. Chakravarty, for giving me all facilities in treating the above cases.

laboratory examination also failed to prove that leptospira was the causal factor. However, quite recently Mr. Watson of the Deamoolie Tea Estate, Assam, sent us a specimen of serum from a patient who was suspected to have been suffering from Weil's disease. The medical officer stated that eight cases of jaundice had come under his observation from June 1940 to July 1941, four having proved fatal. Agglutination tests and protection experiments were carried out with the serum.

TABLE II

Strains	TITRE OF AGGLUTINATION			
	100	1,000	10,000	100,000
<i>L. icterohaemorrhagiae</i>	..	+	+	+
<i>L. canicola</i>	..	+	-	-

It is evident from the foregoing tables that the serum is strongly positive, agglutinating the classical *L. icterohaemorrhagiae* in dilutions up to at least 1 in 10,000 and it also gives some para-specific reaction with *L. canicola* and Mg. Tin Tin. The latter strain was isolated by me from a case in the Andamans and found to be identical with a Java bat strain, 90 C.

Protection experiment

0.4 c.cm. of the serum under investigation was injected intraperitoneally into a young guinea-pig and six hours later the animal was inoculated by the same route with 2 c.cm. of virulent culture of the classical *L. icterohaemorrhagiae*. As a control, another guinea-pig of approximately the same weight, which had received 0.4 c.cm. of normal human serum, was similarly inoculated with the culture. The guinea-pig inoculated with the patient's serum was completely protected, while the control animal developed severe haemorrhagic jaundice and died. Post-mortem examination showed characteristic lesions and leptospiræ were present in large numbers in the liver and kidney emulsions. It would thus appear that the patient's serum contains sufficient protective antibodies and is homologous with the classical *L. icterohaemorrhagiae*.

As far as we have been able to ascertain, this appears to be the first authentic case of infectious jaundice yet reported in Assam.

Our thanks are due to Mr. Watson and Dr. Pal of the Deamoolie Tea Estate for sending us the material on which this note is based.

A NOTE ON THE OCCURRENCE OF LEPTOSPIROSIS IN BOMBAY

By M. N. LAHIRI
(From the Haffkine Institute, Bombay)

EPIDEMIC and sporadic cases of fever followed by jaundice suggestive of leptospirosis have been reported by workers from time to time in the city of Bombay, but so far none of these was supported by positive bacteriological findings. It has been emphasized that although diagnosis of leptospirosis can be made partly on clinical grounds, it cannot be regarded as completely reliable unless confirmed by laboratory examination. It is, therefore, not unlikely that for the lack of investigation by laboratory methods many cases might have passed unrecognized.

A survey of the literature shows that as early as 1907 Tucker described an outbreak of jaundice in one of the congested areas of Byculla; of the ten cases recorded in the paper nine proved fatal. No bacteriological studies were carried out. Parmanand (1922) studied seven cases of jaundice that came under his observation. The description of the symptoms no doubt conform to that of leptospirosis, but as in no case was the causal organism isolated by culture, the true nature of the disease remained undetermined. Liston (1922) received material from a fatal case in Santa Cruz; no spirochaetes were seen by him, but he did find in liver histological evidence of acute yellow atrophy.

Turkhud (1928) also claims to have seen a small epidemic of jaundice in Bombay due to leptospirosis, but the diagnosis was based entirely on clinical grounds.

More recently, Manohar (1940) studied a few cases of jaundice and also examined autopsy materials. No systematic bacteriological examinations were carried out and the causal organism was not isolated from any of them. Diagnosis was based partly on animal inoculation. Moreover, it is rather difficult to agree with the findings of the author in one case where diagnosis was arrived at by detection of leptospiræ in a sample of stool. Thus, it would appear that the laboratory confirmation is still lacking and it was considered worth while to undertake the bacteriological studies in such cases.

The following is a report of a case of jaundice with fever in which leptospira was isolated and the patient's serum gave evidence of high agglutination titre.

The patient was admitted in the Goculdas Tejpal Hospital and was brought to my notice by Dr. N. J. Modi, Honorary Physician. The patient was seen on the 11th day of illness suffering from fever, jaundice, headache and intense prostration. The history suggested acute onset with rigors and pain all over the body which made it practically impossible for him to move about in the bed. The examination of urine showed the presence of albumin, casts (both epithelial and granular), leucocytes and a few red blood cells besides bile salts and bile pigments.

The clinical picture was very suggestive of leptospirosis, hence special attention was centred on the laboratory examination of the materials from the case.

Laboratory findings

A blood sample was first collected and was examined microscopically, by cultural method and by inoculation into a guinea-pig.

Direct examination of blood.—Examination of the blood by dark-ground illumination and also of films stained by Fontana's method were carried out, but no leptospiræ could be detected.

Culture.—Two tubes of Vervoort's medium were inoculated with 0.5 and 1.0 c.cm. of the blood, respectively. There was no evidence of any growth in both the tubes which remained sterile for over a month when they were discarded.

Animal inoculation.—A young guinea-pig was injected intraperitoneally with 2 c.cm. of the patient's blood. The peritoneal fluid was systematically examined, but no leptospiræ could be detected. The animal remained alive and well during the observation period of six weeks.

Serological examination of blood.—Agglutination-lysis test:—The serum from a part of the specimen of blood which was cultured reacted to a titre of 1 : 160 against a classical strain of *L. icterohæmorrhagia*. The examination of blood samples collected subsequently showed a marked rise of titre and it may be mentioned that the one collected on the 34th day of illness gave a titre of 1 : 1,000,000, not only against the classical strain but also against a Bombay strain (Lahiri, 1941) of rat leptospira isolated here.

Urine.—The mid-stream samples of urine were collected beginning from the 13th day of illness to the 46th day. In all, twenty-three samples were examined. The centrifuged deposit did not show leptospiræ in any sample, either by dark-ground illumination or in stained films. Five c.cm. from each sample were inoculated systematically into guinea-pigs. The guinea-pig which received the urine collected on the 36th day of illness succumbed to the infection and at autopsy showed typical signs. The culture of the heart's blood of this animal gave a pure growth of leptospiræ.

Protective experiments.—Two guinea-pigs approximately of the same weight were taken. One was injected with 0.25 c.cm. of the serum from the specimen of blood collected on the 34th day of illness and the other was inoculated with the same amount of normal human serum to act as a control. Half an hour later both were inoculated with 2 c.cm. of a virulent culture of classical leptospira. The one which received the patient's serum remained alive, whereas the other died of leptospiral infection, confirmed by autopsy and cultural examination. The protective value was similarly tested against the patient's own strain isolated from his urine with the same result. In this case, 1.5 c.cm. of an emulsion of liver of a guinea-pig infected with

the patient's strain was used as the infective dose.

Comment

Taylor and Goyle (1931) recorded the value of blood culture as a method of diagnosis, if done between the 3rd to 6th day of illness; cultures made after the 7th day were invariably negative. Das Gupta and Chopra (1937) obtained positive blood culture from a case as late as the 9th day of illness. Although the chance of isolation of leptospiræ from the blood in the present case was not at all likely on the 11th day of illness, yet it was done on the ground that the patient was not sure about the exact date of the onset of the illness. Evidently the culture was made at the time when the infective period of the blood had already passed. As regards urine, out of twenty-three samples only one proved infective. This low infection rate may be ascribed to two factors, namely, the acid reaction of the urine and the presence of bile in it. Both these factors are not only inimical to the vitality of leptospiræ, but are also apt to destroy morphology so that their recognition becomes rather difficult. The possibility of the isolation of the organism from the urine of cases where blood culture is of no value is worth trial, although the method is a laborious one and entails the use of a large number of animals.

Summary

A case of leptospirosis is reported from whom the causative organism was isolated. The serological tests of this case are also recorded.

Acknowledgments

My thanks are due to Dr. F. N. A. Moos, superintendent of the G. T. Hospital, Bombay, for providing every facility, to Dr. N. J. Modi, physician, and to Dr. H. S. Patel, pathologist of the hospital, for their help in many ways. I am also indebted to Dr. B. M. Das Gupta, professor of protozoology, School of Tropical Medicine, Calcutta, for confirming the results of the serological findings.

A Mirror of Hospital Practice

EPHEDRINE POISONING IN A HUMAN SUBJECT

By M. N. DE, M.B. (Cal.), M.R.C.P. (Lond.)

*Professor of Medicine, Medical College, Calcutta, and
First Physician, Medical College Hospitals
(From the Department of Medicine, Medical College,
Calcutta)*

ALTHOUGH unpleasant toxic effects of ephedrine are sometimes met with in susceptible individuals after therapeutic administration of the drug, actual poisoning by a large amount is not usually seen. All its pharmacological effects including those of lethal doses have been thoroughly studied in animals only. The following short communication will therefore, it is hoped, be read with interest.

A young boy of about 14 years had an attack of difficulty in breathing which was diagnosed as bronchial asthma. A prescription containing the usual anti-spasmodic drugs was given to him. Information was received afterwards on the phone that the spasms had become rather severe and the mother of the boy wanted something to be done for relief. At this, a telephonic instruction was given to his father, who was a medical man, to add $\frac{1}{2}$ grain of ephedrine hydrochloride to each dose of the mixture. The doctor absent-mindedly wrote 2 grains of ephedrine hydrochloride on the top of the prescription. This obviously signified 2 grains of the drug in each dose of the mixture. The prescription was taken to the nearest chemist's shop where it was served as written. The compounder did not note that an overdose of ephedrine had been prescribed; nor did he ask the prescribing doctor anything about it. The prescription having been served was taken to the patient who was given a dose of it at 1 p.m. The boy felt very ill within half an hour. This was reported to the father in his office who thinking it might be a severe attack of bronchial spasm instructed the mother over the phone to give a second dose of the medicine at 2.30 p.m. This however made the patient feel worse and he vomited probably a major portion of this dose. In this way he must have taken more than 2 grains of ephedrine within one and a half hours.

The symptoms, which appeared within half an hour, were of a very distressing nature. He felt sick, had vertigo and severe pain in the area of the heart with intense throbbing in the chest. One peculiar feature was that these sensations came on in successive bouts and he could tell his mother when he would get the throbbing. After they started, they increased gradually till they reached the fastigium, after which they slowly waned. After this another paroxysm would come. The palpitation and precordial pain appeared so violently and spasmodically that at the height of the attack the boy had to sit up and press hard with both hands on the cardiac area as if, as described by the patient in his own language, to prevent his heart from being forced out. This series of spasmodic attacks lasted for nearly two hours. He vomited frequently and could not retain even fluid. There was also considerable retching. He perspired profusely all over the body, his extremities were cold and he seemed to be in a state of collapse. He was very restless all the time. An exceedingly painful symptom was frequent desire to pass urine which he could not do owing to severe strangury. No blood was passed per urethram. Pulse was very rapid and feeble.

All these severe symptoms lasted for nearly two hours. When the patient was seen again at 4 p.m. the

same day he was just recovering and some of the symptoms were still present though with lesser intensity. It took him nearly the whole night to get over these symptoms and he felt relieved the next morning.

His asthma, however, disappeared completely.

SUCCESSFUL ADMINISTRATION OF SULPHANILAMIDE TO AN INFANT*

By BRIJ LAL BATRA, L.S.M.F. (Pb.)

(Sir Biji War Memorial Hospital for Women, Bilaspur State, Simla Hills)

A HEALTHY female child was born at the above hospital on 25th May last.

On the 20th day after birth the temperature rose from normal to 98.8°F. and it continued to rise steadily for the next four days until it reached 104°F. During this period the child was given an alkaline mixture, and glucose water and on the last two days, when the temperature was above 103°F., cold packs were applied, but there was no improvement.

The mother then drew my attention to an inflammatory condition of the vulva which was found to extend backwards around the anus and downwards on the inner sides of both thighs.

Half a tablet of prontosil rubrum (Bayer) was divided into four parts and given the same evening at two-hourly intervals. Boric fomentation every four hours and painting with 5 per cent mercurochrome was the local treatment. On the following day the axillary temperature was 100°F. No more prontosil rubrum was available so one tablet of prontosil album was divided into six equal parts and given every three hours. The same evening the temperature was 98°F. The fomentation was continued for one day more by which time all signs of inflammation had disappeared. The temperature remained below normal for the remaining eight days that the child remained in hospital.

Comment

This case is of interest because of the successful administration of prontosil to such a young child, with apparently no serious by-effects.

Acknowledgment.—I am thankful to Dr. S. N. Seal, chief medical officer, for his guidance, and to Dr. S. Brara, for her help in the treatment of the case.

A CASE OF TWIN PREGNANCY—ONE UTERINE AND THE OTHER EXTRA-UTERINE

By A. G. PEREIRA, L.M.&S.

District Medical Officer, Coimbatore

A FEMALE, aged 21 years, was admitted into the Government Hospital, Tellicherry, on 7th February, 1941, with fever following abortion. An honorary assistant surgeon of the hospital had attended on her at her home and he extracted a foetus of about 4 months 13 days previously, and the next day he saw the placenta, which was expelled. He gave the history that previous to the onset of abortion she had pain and tenderness on the right side of the abdomen over the appendicular region and there was also rigidity with high temperature and he prescribed

* Rearranged by Editor.

sulphonamide. The abortion took place the next day.

On admission into the hospital there was pain and tenderness in the right iliac region. There was also rigidity on the right side of abdomen. Temperature 102°F., pulse 122 per minute. She was put in Fowler's position. Urea sulphaside solution was injected and urea sulphaside tablets no. II were given orally (*t.d.s.*). The temperature came down to 100°F. on the 6th day and the pain on the right side decreased and she was on the way to recovery.

On 16th February the temperature rose again and a swelling began to appear in the lower part of the abdomen just to left of middle line. This steadily increased in size and extended a little above the umbilicus. The patient now began to show signs of distress—leucocytosis present. On 20th laparotomy was decided on. Under local anaesthesia the abdomen was opened by a left paramedian incision. The tumour was adherent to the peritoneum and, on opening it, foul-smelling dirty blood-coloured fluid with small streaks of pus escaped. There were dense adhesions all round but the hand could easily reach the right iliac fossa to the region of the appendix. It was thought inadvisable to put a drainage tube on the right side as there were dense adhesions and coils of intestine between the hand and the abdominal wall. Therefore a long tube was introduced up to the region of the appendix. Another tube was introduced in the direction of the umbilicus and the abdomen closed.

She had a stormy convalescence. Profuse bloody discharge with flakes of slough were coming through the tubes and the dressing had to be changed morning and evening.

On 16th March a mass looking like omentum was protruding through the wound. It was ligatured and excised. On 18th another mass was seen projecting. It was also ligatured and excised. The excised portion contained 2 small bones—radius and ulna. The next day the projecting mass was slowly dragged out of the wound and excised. It contained a humerus and scapula. On 21st a mass was projecting. It was slowly dragged out and consisted of a macerated foetus about 4 months old.

Profuse discharge continued for a few days more. Now she has only a small sinus and it is healing quite satisfactorily and the patient is in good condition.

A CASE OF TETANUS TREATED WITH SERUM AND MAGNESIUM SULPHATE

By N. C. PAUL, I.M.F.

Assistant Medical Officer, Karimpore Tea Estate

ON the 22nd of March 1941, a tea garden coolie, aged about 16 years, attended the dispensary in the morning complaining of pain and difficulty in moving his neck. The symptoms were so slight that I took it to be a case of torticollis and prescribed accordingly. The next morning I was called to attend the boy in the lines.

Examination.—

1. The patient was conscious.
2. Complete lock-jaw but could drink water with difficulty between spasms.
3. The patient was unable to turn himself on his side, the whole body was in a rigid condition and there were tonic spasms almost every minute, the body assuming the position of opisthotonus during contractions.
4. His temperature was 100°F. Bowels not moved and no micturition during the last 18 hours. The patient had no sleep during the night.

While examining him I found a small neglected ulcer on the dorsum of his left foot, which I was told was from a bamboo prick he received about a month ago, for which he applied tincture of iodine.

He was at once put in a dark room, the ulcer was cauterized with carbolic acid and regularly treated with antiseptic dressings and the following treatment was adopted:—

23rd March.—Morning—6,000 international units of tetanus antitoxic serum was given intramuscularly. 12 a.m.—Two c.c.m. of 25 per cent magnesium sulphate solution intravenously and at 6 p.m.—6,000 international units of tetanus antitoxic serum—intravenously.

24th.—No improvement was noticed. Morning—6,000 units of tetanus antitoxic serum intravenously. 12 a.m.—Five c.c.m. of 25 per cent magnesium sulphate solution intravenously and at 6 p.m.—6,000 units of tetanus antitoxic serum was given intravenously.

25th.—No definite improvement, except slightly longer intervals between spasms. 6,000 units of tetanus antitoxic serum was given intramuscularly in the morning, and 10 c.c.m. of 25 per cent magnesium sulphate solution intravenously in the evening.

26th.—Definite improvement was noticed. Ten c.c.m. and 5 c.c.m. magnesium sulphate solution was given morning and evening intravenously.

27th.—A more definite improvement was noticed. Ten c.c.m. of magnesium sulphate solution was given morning and evening intravenously.

28th.—Five c.c.m. of magnesium sulphate solution was given morning and evening intravenously.

29th, 30th and 31st March.—No magnesium sulphate was given and the contractions began to appear after longer intervals ($\frac{1}{2}$ to 1 hour or more) and not so severe as before. The general outlook of the patient was good though he could not open his mouth.

1st and 2nd April.—Five c.c.m. of 25 per cent magnesium sulphate solution was given intravenously morning and evening.

3rd.—The patient could now sleep for a long time though there were some occasional contractions of a very slight nature. He could drink liquids and felt more comfortable, he also could open his mouth a little.

4th.—A purgative containing calomel followed by magnesium sulphate was given.

In addition to the above treatment, the patient was given a mixture containing potassium, sodium and ammonium bromide and chloral hydrate gr. $\frac{1}{2}$ each four times daily and an occasional dose of mist. alba. The ulcer of the foot was dressed with ensol lotion. Plenty of drinks containing soda water, glucose with vitamin D and milk were given during the attack and from the 5th April rice and milk diet was given to start with, gradually increasing to his normal diet.

Points of interest in the case are:—

1. Severe tetanic convolution developed from a neglected superficial ulcer on the foot from the prick of a bamboo stick after one month.
2. A relatively small dose of tetanus antitoxic serum was used yet the patient recovered. Total serum used 30,000 international units.
3. The effect of 25 per cent magnesium sulphate solution was very encouraging; the dose of 10 c.c.m. was more effective than the smaller doses of 1 c.c.m. to 5 c.c.m. The intravenous route of the injection was adopted owing to the severity of the case. Total magnesium sulphate solution used—82 c.c.m.

I am grateful to Mr. C. T. Cramphorn for his permission to report this case and to Dr. N. N. Ghose for his advice in managing it.

Indian Medical Gazette

NOVEMBER

THE BIOCHEMICAL STANDARDIZATION LABORATORY

It is eleven years since the Drugs Inquiry Committee revealed a highly unsatisfactory state of affairs to be in existence in the conduct of the drug trade in India. They found that adulteration was rife, that many mixtures did not contain the amount of the various drugs they were stated to contain, and that the drugs themselves were often far below the standard quality required by the British or United States Pharmacopoeias, which are the standards generally accepted in India. A beginning was made in 1937 to remedy the bad conditions brought to light by the report of this committee, by the establishment of a Biochemical Standardization Laboratory whose function is to test and check the various products on sale in India for the treatment of disease.

The first report issued from this laboratory has recently been received*. It covers the first three years' operations, and the amount of work in testing drugs has been considerable, especially in view of the limited staff and laboratory accommodation that has been made available.

Formerly, when drugs were confined almost exclusively to plant products or simple inorganic chemical compounds, testing their purity and pharmacological activity was a relatively simple matter and therefore did not require a very large establishment nor a particularly highly qualified staff, and the present laboratory accommodation and staff would probably have been sufficient to do the greater part of the testing then necessary. Now, it is a very different matter because, in addition to the above kinds of drugs, several other distinct groups of important remedies are being used in great quantities. For example, there are gland extracts, highly complicated organic compounds, specific sera and vaccines, and the vitamins. No single expert nor any single laboratory can hope to cope successfully with the standardization of all the compounds and products included in the above groups, because they differ so widely in their composition and processes of manufacture that very many entirely different methods have to be employed in their assay.

To give one example—an important method of drug testing, and one that is now widely employed and is the only satisfactory method for many products, is biological assay, that is the testing of products by their action on

animals. For the accurate reading of results by this method perfectly healthy and as far as possible identical animals regarding age, weight, colouring, etc., are needed. To have an adequate supply of such identical animals always available necessitates the maintenance of hundreds or thousands of the species in use, and even for small animals such as mice very extensive animal-house accommodation is required. Therefore, on the grounds of the limited space available and the difficulty of maintaining healthy laboratory-bred animals in the Calcutta climate, it is doubtful if the present laboratory will be adequate when it has reached the full working capacity that will be needed to cope with the tremendous amount of work that will have to be carried out, if it is to prove an efficient instrument in the control of all the drugs and other products used in India in the treatment of disease.

While we welcome this report and congratulate its director, Colonel Sir R. N. Chopra, and his staff on the amount and the quality of the work they have performed with the facilities at their disposal, we wish to take this opportunity of emphasizing the fact that this laboratory in its present form and situation can only be regarded as the small beginning of what must in time be developed into an extensive organization.

It may be said that owing to the enormous expenditure that the country has to meet in upholding its share in the Empire war effort money is not available for the necessary expansion of this drug standardization laboratory. However great the national expenditure may at present be in other directions, we feel that the necessary funds should be found somehow, because the international situation makes the rapid expansion of the laboratory urgent, as the war has suddenly placed upon it a very much augmented volume of work, which in peace time might have been assumed more gradually.

The overseas supplies of nearly all drugs are very much reduced and in many instances completely discontinued. The result is that locally manufactured drugs and biological products have suddenly become of much greater relative importance. Many of the countries of Europe and America from which we obtained by far the greater quantity of remedies before the war already had legislation in force to ensure the purity and strength of their pharmaceutical products; so that drugs emanating from well-known manufacturing houses in these countries could largely be taken on trust, thus local assay was not of particular importance in most cases. This sudden stoppage of overseas supplies has led to a rapid expansion of local drug manufacture, and it is still far from fulfilling the demand. Many of the firms engaged in India on this type of industry are sound concerns with good laboratory accommodation and efficient staffs, and they turn out materials

* See abstract on p. 699 of this issue.

that are up to standard, but unfortunately there are many others with inadequate laboratory equipment and staff who may be trying honestly to do their best but are incapable of carrying out correctly the highly technical operations needed in making modern drugs, and there is a third class of manufacturers who are deliberately placing on the market remedies of inferior quality in the hope of making large profits out of our present emergency.

There are two aspects to this situation; there is the point of view of the health of the people, for it is to the drug standardization organization that we must look for ensuring that safe, pure and potent drugs are placed on the market, and the commercial aspect. The present situation has provided pharmaceutical manufacturers in India with a great opportunity which they will be unable to exploit to the full unless the standard of drug manufacture is maintained at its proper level by legislation backed

by a drug standardization organization suitable to the requirements. Otherwise the opportunists, the third class of manufacturers mentioned above, whilst making their own quick profits will ruin the name of the Indian drug industry. Imported drugs always cost more, but hitherto they have been readily purchased because people believed, rightly or wrongly, that on the whole drugs manufactured in India were of inferior quality. Now in many instances they can only buy locally manufactured drugs and on the opinions they form while the present situation lasts will depend their attitude towards Indian manufactured drugs in the future and whether they return once more to drugs of foreign origin. Strive how they will, individual manufacturers cannot save the situation unless they receive the support of the Government. Now not after the war is the time, therefore, to expand the drugs standardization organizations in India.

(From the School of Tropical Medicine, Calcutta)

BLOOD GROUPING AND BLOOD TRANSFUSION

Historical.—After Harvey's discovery of the circulation of the blood, Sir Christopher Wren in 1650 injected opium, beer, etc., into the veins of dogs, using quills as cannulae, but the first transfusion of blood was given by Richard Lower in 1665; he transfused blood from one animal to another of the same species, using dogs mostly as his experimental animals. The credit, however, for performing the first transfusion in man is usually given to Denys de Montpellier, physician to Louis XIV.

After this, transfusion was indiscriminately used as a curative agent in all diseases and in many cases animals were used as donors. So many deaths followed this indiscriminate use of transfusion that the operation was banned by the Royal Society in England and by the Académie de Médecine in France, and was condemned by the Pope as immoral. Blood transfusion then fell into disuse as a therapeutic measure for about 150 years, being revived in 1818 by James Blundell, an obstetrician in Guy's Hospital. For the first time, he gave transfusion through a syringe in cases of post-partum haemorrhage and claimed immediate success. He was of the opinion that transfusion by the new technique was 'a very feasible operation' which 'after undergoing the usual ordeal of neglect, opposition and ridicule will hereafter

be admitted into general practice'. By this method, whole blood was used for transfusion until 1835 when Bischoff first introduced defibrinated blood for this purpose and showed that it was safer, as it obviated the dangers of coagulation. However, the transfusion of both whole and of the defibrinated blood still resulted in death very frequently, and it was not until early in the present century that transfusion of blood was firmly established as a dependable therapeutic agent. In 1900, Landsteiner, an Austrian biochemist, made the crucial discovery of the presence of iso-agglutinins and iso-agglutinogens in the blood. On the basis of Landsteiner's discovery, Jansky, a Czechoslovakian, and Moss, an American, independently showed (1907-08) that the blood of the human race belonged to one of four groups—I, II, III and IV with this difference however that Jansky's groups I and IV corresponded, respectively, to groups IV and I of Moss; groups II and III being identical in the two cases. To do away with the confusion caused by the two different nomenclatures, recently an international committee of the Health Organization of the League of Nations introduced a simplified and rational nomenclature for the four main blood groups which they called AB, A, B, and O. The international nomenclature of the blood groups and those of Jansky and Moss are shown in the table below.

International nomenclature	Moss nomenclature	Jansky nomenclature
AB	I	IV
A.	II	II
B	III	III
O	IV	I

Hæmagglutination and blood groups.—The transfusion of blood requires the use of compatible blood, that is, blood in which the corpuscles of the donor are not agglutinated, or haemolysed, by the plasma of the recipient (the patient), and the corpuscles of the recipient are not agglutinated, or haemolysed, by the plasma of the donor.

The phenomenon of hæmagglutination is due to the fact that there are in the blood of man iso-hæmagglutinogens in the red corpuscles and iso-hæmagglutinins in the plasma; there are two main iso-hæmagglutinogens, A and B, that occur in the red cells and two corresponding agglutinins α and β in the plasma. It is possible to divide mankind into four main groups according to the agglutinins and agglutinogens that are found in their plasma and red cells, respectively. Agglutinogens are present in the red cells of an infant from birth but specific agglutinins only make their appearance after some time. Both increase in titre up to the age of puberty, after which the titre of the agglutinogens remains stationary but that of the agglutinins gradually diminishes and is very low in old age. Both the agglutinogen and agglutinin remain constant qualitatively throughout life. These four groups are as follows :—

Group (International nomenclature)	Agglutinogens in red cells	Agglutinins in plasma (or serum)
AB	A and B	none
A	A	β
B	B	α
O	none	α and β

It is thus the agglutinogens in a person's red cells that give the name to his group, though by simple deduction it is possible to ascertain his group from the agglutinins in his plasma (or serum). When A agglutinogen (in the red cells) comes in contact with α agglutinin (in the plasma) agglutination takes place: similarly agglutination takes place when B agglutinogen comes in contact with β agglutinin.

The arrangement of agglutinogens and agglutinins is always such that in any single individual auto-hæmagglutination will not take place, but the fact that in the human race there are four different groups of individuals precludes the indiscriminate mixing of blood of different individuals *in vivo*. Provided bloods are of the same group they can usually be mixed with safety; for example, group AB blood can be given to an AB individual, because neither the donor nor the recipient has α or β agglutinins in his plasma to act with the A and B agglutinogens in the red cells and cause agglutination, but AB blood cannot be given—to an A individual, because he will have β agglutinins in his plasma which will act with the B agglutinogen in the donor's red cells and agglutinate them, to a B individual, because of

the α agglutinins, or to an O individual, because he has both α and β agglutinins.

On the other hand, in an O blood there are no agglutinogens, so that, such a blood can be given with safety to any person of his own group, or as far as the donor's red cells are concerned any other group, and for this reason such an individual is sometimes called a 'universal donor'. However, in the plasma of the universal donor there are agglutinins, both α and β , and these are capable of acting on the appropriate agglutinogens in the recipient's red cells; agglutinins are always weaker than the agglutinogens, so that, in practice, if the blood is given slowly, the agglutinins in the donor's plasma become diluted with the recipient's plasma, and no agglutination of the recipient's red cells takes place, unless, as sometimes happens, the agglutinins are present in exceptionally high concentration (high titre); a person who has agglutinin present in high titre is known as a 'dangerous universal donor' and his blood should only be given to an individual of his own group.

Now let us consider the position from the point of view of the recipient; A, B, and O persons have in their plasma β , α , and both α and β agglutinins, respectively, and can therefore receive blood only from persons of their own groups, that is, persons who have not the corresponding agglutinogens in their red cells, but an AB person has no agglutinins in his plasma, so that he can receive red cells of any group, and consequently an AB person is known as a 'universal recipient'; however, his red cells contain both A and B agglutinogens and therefore, if plasma from an A, a B or an O person which happens to contain a high concentration of agglutinins is given, his red cells may be agglutinated.

For these reasons it is always essential that direct matching should be done before the blood of a universal donor is given to anyone except a person of his own group, or the blood of anyone except a person of his own group is given to a universal recipient. Further, as there are a number of sub-groups in the main blood groups—especially in groups A and AB, and as an extra check against mistakes, even when blood is given to a person of the same group, it is advisable, except in cases of great urgency, to do a direct matching, that is a matching of the donor's plasma with the recipient's red cells and *vice versa*.

A. GROUPING

Collection of blood for grouping.—Grouping of blood can be done with a drop of blood obtained by pricking a finger or the ear lobe, but it is best done with washed red cells and the result checked by the cross identification of the agglutinins in the serum.

Collect about 3 c.cm. of blood aseptically in a dry syringe, put 2 c.cm. in a dry labelled test-tube, and 1 c.cm. in another

labelled tube containing 3 to 4 c.cm. of citrated saline (1.5 per cent sodium citrate in normal saline). Write the name and full description of the individual on the labels of the tubes.

Wash the red cells in the citrated saline tube three times with normal saline*. Finally, make a 5-per-cent cell suspension in normal saline. The cells are now ready for use.

The blood in the other tube is also centrifuged, and the clear serum is then transferred to another labelled tube on which the name and description of the patient is written again—this is an important detail neglect of which is liable to lead to serious mistakes, and it must be emphasized that such mistakes may be fatal. The name should at the same time be entered into a register and a serial number given which should also be written on the label.

Apparatus and material required—

- (i) Known high-titre α and β sera†.
- (ii) Known A and B cells—washed but not diluted‡.
- (iii) Glass slides 3 inch \times 1 inch.
- (iv) Glass pencil.
- (v) Capillary pipettes with rubber teats.
- (vi) Small solid glass rods with a diameter of not more than $\frac{1}{4}$ inch and with the ends rounded off.
- (vii) Black-and-white tile (figure 1).
- (viii) Hand lens.

* The washing of the red cells is done in the following way:—Centrifuge the blood in the citrated saline tube until the supernatant fluid is clear; carefully pipette off the supernatant fluid, add an equal volume of normal saline, centrifuge again, and again discard the supernatant fluid; repeat the process a third time.

† When doing grouping of blood for the first time, known high-titre α and β sera should be obtained from any reliable institution where blood grouping is done as a routine. Serum, collected aseptically and kept in rubber-capped vials in a refrigerator, will keep for 6 months or more, provided the serum is removed aseptically with a sterilized syringe. For subsequent use high-titre α and β sera should be collected from time to time to replenish the stock from the subjects whose bloods are grouped. In places where blood grouping is done only occasionally, the groups of the personnel of the laboratory, hospital or dispensary should be ascertained, so that in an emergency grouping of an unknown sample of blood can be carried out with α and β sera collected from among them, even if the agglutinins are not present in high titre.

A high-titre serum is one which will agglutinate the appropriate red cells in a dilution of at least 1 in 10.

In some countries, dried high-titre grouping sera, α and β , are now available; such sera are supplied in powder form and are reconstituted by the addition of saline. The advantage of these is that they are easy to send any distance, they keep almost indefinitely, and they can be reconstituted to form a hyper-concentrated solution.

‡ Known A and B cells must always be collected freshly from persons known to belong to A and B groups, for even when collected aseptically and kept in a refrigerator, the cells haemolyse in a few days and are not suitable for use. There is also a danger in using stored cells as haemagglutination has been found to occur when stored cells come in contact with bacteria, especially of the corynebacterium group, which may be present in the glassware used in performing the test (Thomsen's haemagglutination phenomenon).

(ix) Moist chamber (figure 2). This can be prepared by placing a piece of filter paper at the bottom of a petri-dish and keeping it wet with water. Two glass rods of equal calibre are placed across the diameter of the petri-dish about 1 inch apart with a piece of glass rod of a smaller calibre inserted in between the two long glass rods to keep them apart. It is then kept covered.

(x) The unknown washed 5 per cent red cell suspension in normal saline.

(xi) The unknown serum.

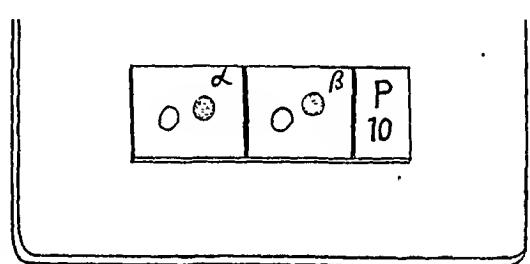

Fig. 1.

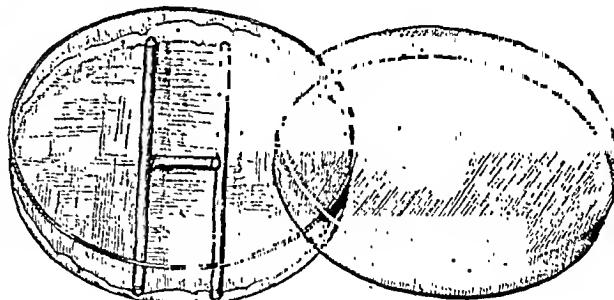

Fig. 2.

Procedure.—To ascertain the group of an unknown sample of blood, mix the unknown red cells separately with each known high-titre serum which contain α and β agglutinins, respectively, wait for a few minutes, and then examine for the presence or absence of agglutination, which will indicate the group of the unknown cell as shown below.

Example	1	2	3	4
α serum (from group B) + unknown cells.	+	+	0	0
β serum (from group A) + unknown cells.	+	0	+	0
Group to which unknown blood belongs	AB	A	B	O

+ denotes agglutination.

0 denotes no agglutination.

Technique.—Place a clean glass slide lengthwise on the white portion of the tile in front of you. With a glass pencil put a mark across the slide half an inch from the right end of the slide, and with another mark divide the remaining portion of the slide into two equal portions. Write the letter α on the upper right-hand corner of the extreme left portion, the letter β on the upper right-hand corner of the middle portion, and the number of the unknown sample of blood on the extreme right-hand portion of the slide (see figure 1).

Place a drop of α serum on the slide in the area marked α and a drop of β serum in the area marked β .

Rotate the tube containing the unknown cells between the palms of your hands to get a uniform suspension of the cells. Withdraw a little cell suspension with a pipette and put a small drop of it by the side of, but not in contact with, the α serum, and another drop by the side of the β serum. Mix each combination well with the glass rod using one end for each

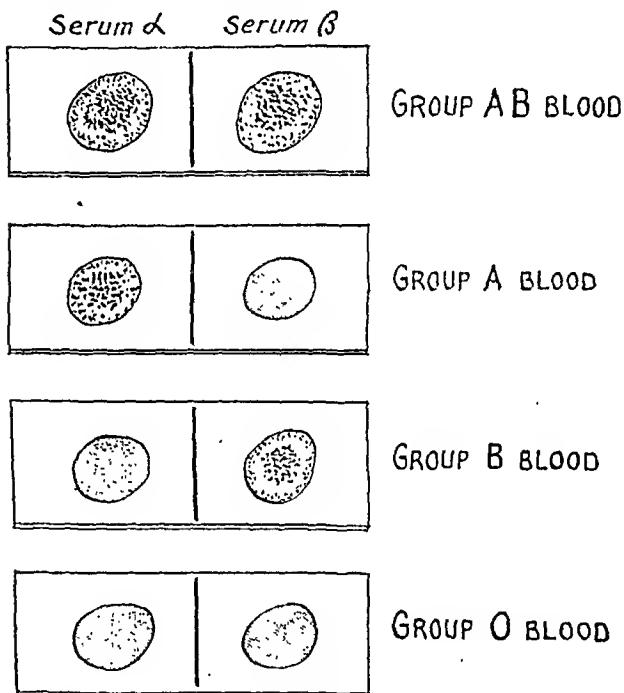

Fig. 3.

and then tilt the slide backwards and forwards to get an intimate mixture of the cells and the serum. Place the slides on the glass rods of the petri-dish over the moist filter paper and keep them covered (see figure 2).

Examine for the presence of agglutination after 10 minutes. In most cases clear-cut results are obtained but if there is any doubt about the presence of agglutination examine with a hand lens or under a microscope; this will enable one to distinguish it from the *pseudo-agglutination* that is occasionally seen in certain pathological states. In haemagglutination real clumping of the cells occurs, whereas there is

(Concluded at foot of next column)

Medical News

TRAINING OF FIRST-AID PARTIES FOR A.R.P. GOVERNMENT GRANT TO ST. JOHN AMBULANCE ASSOCIATION

To assist the St. John Ambulance Association in training first-aid personnel for the air-raid precautions services, the Government of India have given the Association a grant-in-aid of Rs. 10,000.

The Association is already training staff for first-aid posts and parties, and it is hoped that it will provide a sufficient number of trained personnel, either members of the St. John Ambulance Brigade Overseas, or those holding the first-aid certificates granted by the Association, for all the first-aid posts and parties which will be needed under the air-raid precautions organization.

(Continued from previous column)

only rouleaux formation of the cells in pseudo-agglutination. If there is still any doubt, shake the preparation gently by tilting the slide backwards and forwards, when clumping due to haemagglutination becomes marked but that due to rouleaux formation will often tend to disappear. If there is still any doubt, the unknown cells in the tube must be centrifuged and the test repeated with a more diluted cell suspension, when clear-cut results will be obtained (see figure 3).

For corroboration, a further test with the unknown serum may be made. The unknown serum is mixed with known A and B undiluted washed cells, when one of the following combinations of reaction will occur, indicating the group of the unknown serum.

Example	1	2	3	4
Cells of group A + unknown serum	O	O	+	+
Cells of group B + unknown serum	O	+	O	+
Group to which the unknown belongs	AB	A	B	O

Very rarely undiluted serum will exhibit a peculiar inhibitory property and agglutination will not occur, but agglutination becomes quite evident when the serum is diluted, this is known as the *prozone phenomenon*.

B. DIRECT MATCHING BEFORE TRANSFUSION

This should be done not only the first time but on each occasion that a donor gives blood to a particular recipient, because instances have occurred when bloods that were compatible at the time of the first transfusion have on a subsequent occasion shown a degree of heterogeneity and some agglutination has resulted.

Technique.—One drop of 5-per-cent washed cell suspension of the donor is placed by the side of one drop of the serum of the recipient in one section of the slide, and, in the other, one drop of serum of the donor by the side of one drop of 5-per-cent washed cell suspension of the recipient. Each pair is mixed as in the original grouping procedure, and in due course the two mixtures are examined for agglutination. If in neither case there is any agglutination, this confirms the fact that the bloods are compatible.

(Transfusion technique will be given in the next issue.)

The provincial St. John Ambulance Organizations are arranging special classes in towns at which A.R.P. measures are being adopted, in order to produce the full quota of trained men to meet the requirements of the A.R.P. organization. An officer has also been appointed at the Association's headquarters to assist provincial centres with training schemes and to act as liaison officer between these centres and headquarters.

A number of officers of the St. John Ambulance Brigade are to be trained at the air-raid precautions school in Calcutta, to qualify them to train other personnel.

THE PHARMACEUTICAL JOURNAL (1841-1941)*

A CENTURY of useful existence for an organization is a fitting event to commemorate and the idea of issuing a special number of the *Pharmaceutical Journal*, the official organ of the Pharmaceutical Society of Great Britain, on the occasion of its centenary, is a very welcome one and should be appreciated in all quarters. A cursory glance through the pages indicates that the editorial board has spared no pains in making the issue an attractive one. Replete with advertisements, illustrations of historical interest, and sketches of pharmaceutical instruments and apparatus, the volume immediately attracts the attention of the reader. To those associated with pharmaceutical education, trade and industry, the pages offer very valuable and interesting information on the events associated with the evolution and growth of a century of organized British pharmacy. It is a copy worth while possessing for one's personal library.

Starting with an article on the 'Origins of the Pharmaceutical Society' which, by the way, forms a very good setting for the narrative which follows, a series of illustrated articles are presented bearing mainly on the historical aspects of pharmaceutical legislation, retail pharmacy and shop routine during the last 100 years, apprenticeship in the early days, hospital pharmacy in the centennial period, developments in pharmaceutical apparatus, and the growth of the trade in proprietary medicines since the days of the establishment of the society in 1841. Written by eminent pharmacists, the articles are extremely interesting and informative.

As pharmacy is a handmaiden to medicine, and has depended much on the progress of the medical sciences, the broad lines along which medical science has progressed from empiricism and scepticism to rational conception of diseases based on bacterial theory of causation and their treatment by means of chemical and immunological measures, are also briefly outlined. Under the caption 'Honoured Names in Pharmacy' a biographical account, with photographs wherever available, is presented of some of the founders and pioneers of the Pharmaceutical Society of Great Britain. This is followed by a short descriptive note of nearly 43 British pharmaceutical manufacturers who have carried on trade in drugs and medicinal chemicals for over 100 years. Many of these firms are well known in the world markets for ethical trading in drugs of all descriptions.

The reviewer is particularly happy to have been afforded the privilege of writing a note on this special edition of the *Pharmaceutical Journal*. As one who spent some months as a visiting worker in the pharmacological laboratories of the society, he came personally in contact with the varied activities of the society towards the organization of British pharmacy on a sound and nation-wide basis. Starting with a membership of about 800 in 1841, it has now nearly 25,000 members on its rolls, each of whom is now equipped by training and examination to offer professional service of a high standard to the medical profession and the public. Not many voluntary organizations in the world have such an inspiring account to put forward and the present authorities of the Pharma-

ceutical Society deserve the congratulations of all interested in pharmacy in India. The centennial edition of the journal which puts on record all the brilliant past achievements of the society, thereby serving to act not only as a constant source of inspiration for all pharmacists of the present generation but also for generations to come.

B. MUKERJI

CENSUS OF ESSENTIAL DRUGS: NEW GOVERNMENT ORDER

WITH a view to maintaining a check on the import, manufacture and sale of essential drugs, a new order has been promulgated by the Central Government under the Defence of India Rules. The order is called the Essential Drugs (Census) Order, 1941, and is to come into force at once.

In accordance with this order, any person engaged in the business of manufacturing, importing or selling such drugs, whether wholesale or retail, is required to submit to the authority specified for his area, so as to reach that authority not later than the 27th day of each month, a return showing the quantity of any essential drug in his possession or under his control within British India on the 20th day of such month. No return, however, is required to be submitted if the total quantity of any essential drug in the possession or under the control of any person is less than that specified in the order.

Every manufacturer, importer or dealer in drugs, whether wholesale or retail, is required to keep a record of the purchase or sale of any quantity of an essential drug made by him, whether such quantity is less than that specified or not. No record of such transactions, however, need be kept by a retailer if the total quantity of an essential drug in his possession or under his control is less than that specified.

The correctness of any return submitted or record kept in pursuance of this order is subject to verification by any person authorized by the central or the provincial government for this purpose. The person so authorized will have the right to enter and inspect the premises of any manufacturer, importer or dealer and to inspect and take copies of any records, books or accounts kept in connection with such business.

The following are the authorities specified for receiving the returns in the various areas:

Madras, the Central Provinces and Berar, and Coorg—the deputy assistant director-general (medical stores), Madras.

Bombay Presidency, Sind and Ajmer-Merwara—the deputy assistant director-general (medical stores), Bombay.

Bengal Presidency, Bihar, Orissa and Assam—the deputy assistant director-general (medical stores), Calcutta.

United Provinces, the Punjab, North-West Frontier Province and Baluchistan—the deputy assistant director-general (medical stores), Lahore.

WAR STIMULUS TO MANUFACTURERS

TWO HUNDRED AND NINETY-TWO drugs and many items of other medical supplies formerly imported are now being manufactured by Indian drug manufacturers or Government medical depot factories. All these drugs have been transferred to the indigenous list.

Twenty-eight drugs are being produced in sufficient quantities for export. Orders have been placed for substantial amounts of the following drugs: amyl nitrite, atropine sulphate, boric acid, nikethamide, peptone, tetanus antitoxin, sodium tauroglycocholate and trichloracetic acid.

Every drug for which the basic materials are available in India is now manufactured in India while many drugs are being manufactured from imported raw materials.

The surgical instrument industry has been fully mobilized and it is now possible to manufacture in India approximately 75 per cent of the army and civil

*Published by the Pharmaceutical Society of Great Britain, 17, Bloomsbury Square, London.

Nov., 1941]

requirements. The majority of the rubber articles used in hospitals are now manufactured in India.

The manufacture of sera required in the treatment of tetanus, diphtheria, anthrax, epidemic jaundice, etc., is developing and a promising beginning has been made, which should lead to India producing a large percentage of her requirements of sera, as she already does of vaccines.

An efficient substitute for cod-liver oil is now made on an extensive scale in India from the livers of sharks caught in Indian waters. The Government Medical Stores Department alone has purchased over 8,000 gallons of this oil. One of the leading woollen mills in India has agreed to supply a certain quantity of adeps lanæ and has, for this purpose, erected special plant for the recovery of wool-grease.

Another firm which manufactures chemicals is increasing its output of anaesthetic ether to 10,000 lb. per month. A Bengal firm is in process of erecting a large new pharmacy for the manufacture of galenicals and some special preparations. This firm is one of the world's largest manufacturers of strichnine and also specializes in the preparation of paris green for anti-malarial work.

Blood transfusion is largely used in modern medicine to combat shock through loss of blood. Such blood is difficult to obtain in quantity for the treatment of the wounded in the field and other methods are being carefully considered. One of the most successful and promising of these methods is the use of dried blood plasma. Blood to which sodium citrate has been added to prevent coagulation is allowed to settle and the clear liquid drained off. This liquid is dried *in vacuo* to a granular powder and packed aseptically in containers. Before use it is made into a solution with sterile water and given to the patient in the same manner as a blood transfusion.

The production of emetine hydrochloride required for the treatment of amœbic dysentery is closely associated with the growth of ipecacuanha which grows wild in the forests of South America. It has also been proved to grow well in Mungpoo, Bengal, and the question of encouraging its cultivation in India is under consideration.

The manufacture of acriflavine, an important disinfectant particularly in war time, in India from locally produced materials is under investigation.

Troops in the field deprived of fresh vegetables or fruit develop scurvy. To prevent this disease, tablets of vitamin C are made up and India's most concentrated vitamin C is 'amla'. Amla berries are collected in the Nilgiris under the supervision of the director, Nutrition Laboratories, Coonoor, dried and made into tablets of suitable size.

Chloroform manufactured by a Bengal firm has been tested and found satisfactory. Sodium citrate is now being manufactured in small quantities by a firm in the Punjab from lemons grown locally.

Acids and other reagents of analytical purity are being extensively manufactured in India. Certain stains used for bacteriological work such as Congo red, eosin, methyl violet, etc., have been prepared from imported commercial dyes and are being purchased for the Medical Stores Department.

Distillation of essential oils has increased since the outbreak of the war and one firm has specialized in the manufacture of essential oils from indigenous raw materials such as lavender oil, lemon oil, etc.

Rubber goods, such as waterproof sheeting, hot-water bottles, air cushions of good quality, are now obtainable in India. Glass of many varieties and sufficiently pure chemically to be used as ampoules for biological products and in various designs for laboratory work is manufactured. There are two or three important glass manufacturers in Calcutta who make thermometers and glass-stoppered bottles. All kinds and sizes of bottles are being made, including stoppered bottles, by several firms in different parts of the country. Improvement has been found in the resilience of samples of rubber tubing manufactured by a Calcutta firm. A firm which produces waterproof sheeting for

the first-field dressings and for hospital use, hot-water bottles, rubber corks and ice bags is erecting two extra mills for work for the Medical Stores Department.

A new and up-to-date factory for the manufacture of earthenware articles has been established and the Medical Stores Department have obtained large quantities of earthenware articles for hospital equipment from this source.

One of the biggest enamel works in India is being called upon to manufacture enamelware for the use of the Medical Stores Department.

Arrangements have been made by the Director-General, Indian Medical Service, for the production by private firms in India of 150,000 packets of 3 yards absorbent gauze. These packets were formerly made exclusively in Medical Store Depot factories.

Initial experiments made in sterilizing and ampouling locally-made catgut for surgical purposes at a government institute, have been reported as satisfactory. It has therefore been decided to commence production on a small scale of plain sterilized surgical catgut of all sizes.

ASSAM MEDICAL COUNCIL

An Ordinary General Meeting of the Assam Medical Council was held on Monday the 12th May, 1941, in the office of the Inspector-General of Civil Hospitals, Assam, Shillong.

Among the subjects considered in detail by the council was the question of Government subsidy and it was decided that in view of the deficit budgets of the council Government should be approached again for the grant of a subsidy.

The Assam Medical Register was then scrutinized and after discussion it was resolved that the Assam Medical Register be amended by erasing from it the names of the practitioners known to be dead and of those practitioners whose whereabouts are unknown.

The council then considered the question of appointing a Standing Committee under Rule 28(1) of the Medical Council Rules, and resolved that a Standing Committee be constituted under Rule 28(1) of the Assam Medical Council Rules consisting of the President and two other members selected by the President from the members of the Assam Medical Council who are resident in Shillong at the time.

Among other matters discussed was the question of appointing a medical man as registrar of the council, raised by Dr. G. S. Das. On considering all the aspects of the proposition it was decided that a non-medical man with office experience and knowledge of administrative procedure was preferable for performing the registrar's duties.

The council then proceeded to consider a motion put forward by Dr. G. S. Das for revision of the procedure of the election so that the voting papers could reach the electors one month before the date of the election. On the understanding given by the President that steps will in future be taken to see how the procedure of the election can be speeded up, the motion was withdrawn by the proposer.

On a motion moved by Dr. G. S. Das it was unanimously resolved that the Government be requested to consult the Assam Medical Council when considering any re-organization of medical education or establishment of any new medical institution in the province.

Dr. G. S. Das then moved that in view of the recommendation of the Indian Medical Council the Assam Government be strongly moved to take immediate steps to raise the Berry-White Medical School to a college standard.

Dr. B. Bhattacharyya suggested an amendment which was disallowed by the President on the ground that the amendment was so worded that it could not be taken as an amendment but was altogether a different resolution.

Dr. M. S. Dutta proposed an amendment to the motion and suggested that for the words 'to raise the Berry-White Medical School to a college standard' the words 'to raise the medical schools to a college

'standard' be substituted. This was also disallowed by the President on the grounds that it contemplated a hypothetical proposition and the council should confine itself to conditions as they existed.

The motion was then put to the vote and was carried by a majority, two members voting against, and the rest voting for, it. The members voting against it gave a notice of submitting a minute of dissent.

Dr. G. S. Das moved the following motion:—

That the Inspector-General of Civil Hospitals, Assam, be requested to issue a circular to all medical officers serving under him asking them to refrain from granting testimonials to manufacturing concerns.

The motion was withdrawn by the mover when the President referred to the provision in the Code of Medical Ethics II-I(f) which debars all medical officers from granting testimonials to manufacturing concerns.

THE 18TH ALL-INDIA MEDICAL CONFERENCE

THE 18th All-India Medical Conference is to be held at Hyderabad Deccan in the last week of December 1941—the dates provisionally fixed are the 26th, 27th and 28th of December 1941.

There will be three sections—(1) medicine, (2) surgery, and (3) midwifery and gynaecology.

There will also be an exhibition in two sections:—(1) scientific and (2) medical and surgical appliances, pharmaceutical preparations, etc. Visits to places of interest and socials are also being arranged.

Members of the medical profession are invited to contribute to the success of the conference by taking part in its deliberations.

INDIAN MEDICAL COUNCIL

In exercise of the power conferred by clause (a) of sub-section (1) of section (3) of the Indian Medical Council Act, 1933, the Central Government is pleased to nominate the following persons as members of the Medical Council of India, with effect from 29th September, 1941:—

1. Colonel W. C. Spackman, M.B., B.S. (Lond.), M.R.C.S. (Eng.), L.R.C.P. (Lond.), F.R.C.S. (Edin.), F.R.C.O.G. (Lond.), I.M.S., Inspector-General of Civil Hospitals, Bihar (from Bihar).

2. Lieutenant-Colonel J. P. Huban, O.B.E., M.B., B.Ch. (N. U. I.), I.M.S., Inspector-General of Civil Hospitals and Prisons, North-West Frontier Province (from North-West Frontier Province).

3. Colonel A. C. Macrae, M.B., Ch.B. (Aberd.), D.M.R.E. (Camb.), I.M.S., vice Brevet-Colonel A. MacD. Dick, C.B.E., M.B., Ch.B. (Edin.), L.R.C.P. (Lond.), F.R.C.S., I.M.S., vacated. 30th July, 1941.

In exercise of the power conferred by clause (a) of sub-section (1) of section (3) of the Indian Medical Council Act, 1933 (XXVII of 1933), the Central Government is pleased to nominate Colonel W. C. Paton, M.C., M.A., M.B., Ch.B. (Edin.), F.R.C.S. (Edin.), I.M.S., Surgeon-General with the Government of Bengal, to be a member of the Medical Council of India, from Bengal, with effect from the 29th August, 1941, vice Major-General P. S. Mills, I.M.S., resigned.

ADDENDA

CARDIAZOL—All the cardiazol preparations (penta-methylenetetrazol), formerly manufactured in Germany, have now been manufactured in England for a very long time, by Knoll Limited of London. The name

'Cardiazol' is still used in England, but in India, the name has been changed to 'Cartazol'.

DORYL—This was formerly manufactured by E. Merck, of Darmstadt, but also for a very long time has been manufactured in England by Savory and Moore, Limited, of London. It is obtainable under the name 'Moryl'.

Both these British preparations are available in this country.

THE FACULTY OF TROPICAL MEDICINE AND HYGIENE, BENGAL

THE following students are declared to have passed the L.T.M. Examination, Session 1941.

Passed with Distinction

1. Jai Dev Raj Kohli, L.S.M.F., private practitioner.

Passed

(Arranged in alphabetical order)

2. Dilip Kuniar Banerjee, L.M.F., private practitioner.
3. Kalyan Kumar Banerjee, L.M.F., private practitioner.
4. Sailendra Mohan Bhattacharjee, L.M.F., assistant medical officer, Jainti Tea Estate, Jalpaiguri.
5. Sailendra Mohan Chakrabarty, L.M.F., private practitioner.
6. Tarak Nath Chakraburty, L.M.F., private practitioner.
7. Jitendra Kumar Chakravorty, L.M.F., temporary doctor on epidemic duty, Public Health Department, Bengal.
8. Nirmal Kumar Chaudhuri, L.M.F., private practitioner.
9. Vishvambhar Harishankar Dave, L.M.F., private practitioner.
10. Shombhu Nath Dey, L.M.F., private practitioner.
11. Usha Ranjan Dey, L.M.P., assistant medical officer, Mokalbari Tea Estate, Assam.
12. Sudhindra Kumar Dhar, L.M.F., private practitioner.
13. Satyabrata Dutt, L.M.F., private practitioner.
14. Tanjore Sundaram Ekambaram, L.M.P., sub-assistant surgeon, Government of Mysore.
15. Krishna Narayan Ghose, L.M.F., private practitioner.
16. Jatindra Nath Ghosh, L.M.F., private practitioner.
17. Promode Chandra Ghosh, L.M.F., private practitioner.
18. Santi Priya Ghosh, L.M.F., private practitioner.
19. Tejendra Nath Guha Ray, L.M.F., garden doctor, Mathura Tea Estate, Jalpaiguri.
20. Amulya Charan Haolader, L.M.F., private practitioner.
21. Harbans Singh, L.S.M.F., private practitioner.
22. Krishen Sarup, L.S.M.F., private practitioner.
23. Govindas Gangadas Lad, L.M.P., assistant medical officer, Central Provinces Government.
24. Jagdish Chandra Mahyer, L.M.F., private practitioner.
25. Abani Mohan Nandy, L.M.F., house surgeon, S. K. Hospital, Mymensingh.
26. Balknshna Wasudeo Parasnis, L.C.P.S., private practitioner.
27. Balbantrai Hirachand Parekh, L.C.P.S., private practitioner.
28. Kantilal Haribhai Patel, L.C.P.S., private practitioner.
29. Ratilal Chhaganbhai Patel, L.C.P.S., private practitioner.
30. Vithalbhai Jhaverbhai Patel, L.C.P.S., private practitioner.
31. Ram Singh, L.S.M.F., private practitioner.
32. Kadaba Yajman Ramaswamy, L.M.P., private practitioner.
33. Dharam Vir Saigal, L.S.M.F., private practitioner.
34. Taruneswar Sarma, L.M.P., private practitioner.
35. Birendra Nath Sircar, L.M.F., private practitioner.

Public Health Section

RURAL MALARIA

Of the many factors that have contributed towards the decline in the health of the people of rural India, malaria is probably the most important. Despite the brilliant discoveries regarding the mode of transmission, and the treatment and control of the disease, malaria continues to cause an enormous amount of ill health and to collect a heavy toll of human lives every year. It has been estimated that as many as 200 million people suffer from malaria in this country and that 2 million people die as a direct or indirect result of this disease. The economic loss to the country attributable to the disease has been estimated by several eminent authorities as being well over 50 crores of rupees per annum. It is therefore justifiably considered to be the most important of India's public-health problems.

The public-health departments in all the provinces of India are devoting much of their time, money, and energy to lessening the morbidity and mortality caused by malaria. The various weapons available for fighting this scourge are being tried and the achievement, though marked, is not as satisfactory as it might be. Many reasons have been given to explain why malaria still continues to be a major problem. To discuss these is not the purpose of this article; suffice it to say that among them all one reason stands out which is easy to remedy. This is the apathy of the villager to any problems affecting his own health.

The average villager lacks the enthusiasm for social improvement and is seldom willing to co-operate with his fellow villagers for a common cause. This is particularly unfortunate because malaria is one of those diseases which the villager can do a very great deal towards controlling through a communal effort.

The Public Health Commissioner in his report for 1938 says :—

'The necessity for securing the interest and co-operation of the people in measures designed for their own welfare demands that they should be encouraged to participate in the execution of such measures. It was the custom in India for villagers to carry out certain duties without any remuneration. Free labour was their contribution for communal works. If this custom could be revived, or introduced where it does not exist, the amenities of village life could be vastly improved; for, the villager himself is unable to pay for hired labour and it is hardly likely that the Government can fully provide either the men or the finance for such works.'

This indicates that the real salvation of the rural population of India lies not in sitting quiet and praying to the *Sircar* to provide this, that, and the other amenities, but in girding up their loins and striving to improve themselves. The lethargy and indifference must be shaken

SOME SOCIAL OBSTACLES TO MALARIA CONTROL*

By PAUL F. RUSSELL

Introduction

THERE was a time when the question, 'Why malaria?' was answered simply by saying,

*This paper is one of a series arising from Malaria Investigations, a research project under the auspices and with the support of the International Health Division of the Rockefeller Foundation co-operating with the Health Department of Madras Presidency and the Pasteur Institute of Southern India in Coonoor.

(Continued from previous column)

off; the ignorance and superstition must be dispelled; a strong desire to live like their brethren in other countries must be born; and the requisite enthusiasm and energy to help themselves must be built up. Social workers must be found in every village with a genuine love for the people and an undying desire for service and sacrifice. They must educate and unify the people, awaken their dormant sanitary conscience, and make them contribute in terms of community labour if not in money, and effect through the medium of self-help societies whatever improvements are possible for ridding the villages of malaria.

If that is the position to-day, the question naturally arises as to how this change in the outlook of the villager is to be brought about. In this vital matter of rural health every official and every educated individual in the country should play his or her part, but a very special responsibility devolves on the public health departments who are the legal custodians of the health of the people. They can do much in the way of organizing the village self-help societies, providing them with practicable technical measures, and giving frequent technical supervision over the carrying out of these measures.

Malaria is only one of the many ills from which the poor Indian villager suffers, but it is by far the worst in sapping his vitality insidiously until his physique is damaged beyond repair. With the political awakening of the people of India and the introduction of responsible self-government in the provinces, it is encouraging to note that in some places genuine attempts are being made to revive in the villager his old love for his village and to obtain his willing co-operation and help in all measures directed towards the improvement of his environment in general and the eradication of malaria in particular. Let us hope that the villager will respond to the call and contribute his share towards the achievement of the common goal.

'Bad air!' Then, following Ross, at the turn of the century, came the aphorism, 'No mosquitoes, no malaria!' This satisfying but deceptive slogan was soon paralleled by the equally accurate and misleading, 'No gametocytes, no malaria!' Such men as Koch saw in widespread distribution of cinchona derivatives, a relatively quick and sure method of eradicating this disease. Then there was progress through the stage of 'No *Anopheles*, no malaria!' to modern species sanitation on the basis of 'No vectors, no malaria!' There have been devised potent weapons, such as screening, larvicultural oils, Paris green, pyrethrum sprays, drainage, and water-manipulation. The blunderbuss has been stream-lined. But malaria persists, of all diseases of mankind to-day, the most effective destroyer of health, happiness, and prosperity.

This paradox seems understandable only when one steps out of the laboratory to examine social aspects of malariology. Why is malaria control still a relatively feeble effort? Is it lack of laboratory and field knowledge, of tools, of means? Or is the social organization unable to apply effectively the money, potential labour, control weapons, and research findings? Is it not time for scientists, whatever their specialty, to ponder what Bernal (1939) calls *the social function of science*?

The purpose of this paper, however, is not to enter into an abstract consideration of the social implications of malariology but rather to consider, as practically as possible, one phase of the subject, namely, *social obstacles to malaria control*.

Why malaria?

The question 'Why malaria?' seems to be answered to a considerable extent by the fact that in many parts of the malarious world to-day there are five fundamental lacunæ which must be filled before one may reasonably expect much further reduction in prevalence of the disease. These social causes for the maintenance of malaria appear to be as follows:—

Some social reasons for perpetuation of malaria as a public-health problem

1. Absence of a sufficient weight of public opinion which has been enlightened regarding (a) economic and public-health importance of malaria; (b) available measures of malaria prophylaxis and control; (c) social responsibility for prevention of malaria.

2. Lack of sound administrative principles, especially as regards (a) co-ordination of, and effective distinction between, hygiene and preventive care, on the one hand, and preventive medicine and medical-surgical care, on the other; (b) methods of obtaining effective co-operation between such governmental departments as public works, agriculture and public health; (c) necessity for continuity of effort when dealing with malaria.

3. Lack of adequate training of health officers in practical malaria control methods and lack of sufficient numbers of specialist personnel, such as malariologists, malaria entomologists, engineers, and agronomists.

4. Lack of official cognizance of economic considerations as to (a) what malaria actually costs a community; (b) what benefits the control of malaria would confer on a community; (c) what constitutes a proper budget item for malaria control.

5. Inadequate knowledge of methods for applying practically, that is effectively and economically, the results of research in malariology.

These points may be considered in more detail.

I. Absence of a sufficient weight of public opinion which has been enlightened regarding (a) economic and public-health importance of malaria; (b) available measures of malaria prophylaxis and control; (c) social responsibility for prevention of malaria.

Many a man's whole concept of disease prophylaxis may be summed up in the words, 'God bless my heart, liver, and lungs'. Malaria control to average laymen, and indeed, to lay administrators, is simply the pouring of oil or of quinine pills from bottles. Schools teaching history but not hygiene, training colleges too busy with pedagogy to consider public health are common anachronisms. One sees a textbook on political science held against the bulge of a malarial spleen and one hears of social achievements of an ancient civilization from lips blanched by malarial anaemia. Advertisements of quack doctors and patent medicines constitute 'home study in health education' for multitudes. Yet, without sufficient health-knowledge among laymen, personal and community hygiene is impossible, necessary appropriations for public health measures are not voted, salutary laws are not made or obeyed, sanitary progress is delayed. In the absence of totalitarian methods, an educated community opinion about public health is essential to the conquest of such preventable diseases as malaria.

Two types of general health education are required (see Hydrick, 1937). In the first place, there is *Student Training* in principles and practice of personal and community hygiene. This teaching must permeate the curricula of all schools from lowest grades through technical colleges and universities, and must be intensely practical. Secondly, there is *Health Propaganda* designed chiefly for adults and most successful if they have had previous instruction as students. This propaganda must be accurate, simple and, above all, *practical*. The combined effect of student training and health propaganda should be to develop an intelligent and articulate desire for such changes in habits and environment as are necessary to prevent disease; and a willingness to pay, in effort or money, for

these changes. How long would a community remain malarious if a majority of its population had a practical understanding of what malaria cost them, of why it existed, of what measures were available to control it? Health education must impart significant information, must arouse both interest and desire, and must lead to effective practical action.

Schools, colleges, and universities must expound not only general principles of malaria control, to develop a basic appreciation of local conditions and problems, but they should also attempt to create in students, (a) sound economic ideas regarding the impact of malaria on a community; (b) a scientific rather than folklore understanding of malaria prophylaxis; (c) social concepts of the responsibilities of good citizenship as regards disease prevention in general and malaria control in particular.

Students must learn that the protection and conservation of life is a major social function. Education must be much more closely related to the actualities of everyday life. Simple reiteration of the fact that malaria is a mosquito-borne disease does not meet modern requirements.

By way of example, consider India. Sinton (1936), than whom no one is better qualified to comment, states that in this country malaria in ordinary years directly kills at least one million persons a year and indirectly is almost certainly responsible for another one million deaths. There are at least one hundred million cases of malaria each year in India. Further, Sinton states that financial losses from malaria to the individual and the family in India annually amount to not less than eighty million pounds sterling. This financial loss is apart from effects of the disease upon all aspects of the labour problem. Sinton concludes that malaria gives rise to the greatest economic problem with which India is faced. Quoting 'the problem of existence in very many parts of India is the problem of malaria. There is no aspect of life in this country which is not affected, either directly or indirectly, by this disease. It constitutes one of the most important causes of economic misfortune, engendering poverty, diminishing the quantity and the quality of the food supply, lowering the physical and intellectual standard of the nation, and hampering increased prosperity and economic progress in every way'.

Malaria is usually not a dramatic affliction like cholera, plague, or smallpox. It is an insidious, anaemia-producing, ambition-destroying enemy. The average individual in India, if he ever thinks of it at all, views malaria with resignation, without the faintest realization of how it has retarded the development of his country. He has not the slightest conception of the fact that, over and over again, it has been conclusively demonstrated that malaria prophylaxis is not only feasible but is economically profitable in many areas. Finally, as a rule,

he has not the remotest feeling of social responsibility for the control of this disease. There is little urge to contribute either money or labour, in fact even co-operation is often unobtainable. One rarely finds, anywhere in India, an educated, articulate, and effective public opinion regarding malaria and its prevention. Absence of this primary mainspring for effective control programmes constitutes one of the chief reasons why malaria continues to ravage the countryside, practically unchecked.

II. Lack of sound administrative principles, especially as regards, (a) co-ordination of, and effective distinction between, hygiene and preventive care, on the one hand, and preventive medicine and medical-surgical care, on the other; (b) methods of obtaining effective co-operation between such governmental departments as public works, agriculture and public health; (c) necessity for continuity of effort when dealing with malaria.

(a) There is no doubt logically that basic principles of prevention must permeate all private and official practice of medicine,—and to a much greater extent than before. In this sense there can be no separation between prevention and cure in medicine.

But, important as it is that all medical work should be imbued with modern ideas of disease prevention and maintenance of public health, it appears to some observers that in practice there must be an administrative separation at the periphery between (a) hygiene and preventive care on the one hand and (b) preventive medicine and medical-surgical care on the other.

Following, in general, Hydrick's (1938) definitions, *Hygiene* means protective care of the body, largely a personal matter, stimulated by adequate instruction from parents, teachers and health workers. As regards malaria, hygiene includes such personal precautions as the use of screening and bed-nets. *Preventive care* is the social utilization of scientific knowledge to prevent disease and to maintain health through organized community effort. It attempts by technical, chemical, naturalistic, or other methods, to prevent unhygienic factors and the causative agents of disease from coming in contact with the body. It is chiefly a communal, rather than a personal, matter. Preventive care may be divided into, (a) technical preventive procedures and (b) epidemiology. In the cases of malaria, technical preventive procedures range all the way from spray-killing adult mosquitoes to extensive drainage schemes, which eliminate mosquito breeding. Epidemiology, in a broad sense, includes such matters as investigation of endemic and epidemic malaria; development of statistical and registration services; isolation and quarantine; use of proper laws and regulations.

Preventive medicine is a medical rather than a hygienic social service, for it deals with medication by vaccines, sera, and drugs. It is

preventive in the sense that by mass treatments it tends to reduce suffering and death, and, in some cases, to prevent the spread of disease. *Preventive medicine* includes such procedures as the mass treatment of malarious peoples. Another branch of medical service is that of community *medical-surgical care*, which includes the treatment of individuals in public hospitals and dispensaries, or at home, by public medical officers.

There is no doubt that malaria control in some localities has been hindered by a confused combining of preventive care and preventive medicine in what should be a strictly hygienic agency. Over and over again during the past 40 years, it has been demonstrated that malaria cannot be controlled in practice by mass distribution of such therapeutic drugs as have been available. No fact in malariology has had more convincing proof than this. Malaria cannot be prevented by a system of dispensaries or dispensing agents, however well organized. No one questions the value of malaria treatment or the need for a much wider use of anti-malaria drugs. But there is no evidence that this phase of malariology constitutes control. It is *medical* and not hygienic service. There is need for administrative reform which will provide adequate treatment for the malarious sick but will prevent those whose primary concern should be *preventive care* from devoting their energies to the field of preventive medicine.

As regards details of an effective administrative set-up for malaria control, there will be wide variation since local conditions differ greatly from country to country. As a matter of fact, considerable research is required to determine what constitutes the best type of organization for this specialty. Some administrators prefer to have all malaria control done by regular health officers as a part of their routine duties, others prefer to have a special division of malaria control. It is not possible to say which is the better plan until there have been sound studies in this problem of administration. At any rate, as will be noted under section III below, specially trained officers are essential.

The Inter-governmental Conference of Far Eastern Countries on Rural Hygiene (1937), convened by the Health Organization of the League of Nations, made the following suggestions as regards administrative policy in malaria control : 'The Conference, secondly, recommends that since malaria is a focal disease in any country—absent in some rural areas, lightly prevalent in others, and moderately or heavily endemic elsewhere—the structure of, and programme for, rural health organization, including health units and health centres, should not be stereotyped, but flexible. In those areas where malaria is the outstanding social and health problem, the resources of the health administration, especially augmented where necessary,

should be directed chiefly towards malaria control, even if this should entail the restriction of other public health activities, until malaria is no longer of major importance. As a rule, the physical debility and mental apathy of malaria-stricken people will not permit them to respond to a general public-health programme, so that it is a logical procedure first to deal with malaria. On the other hand, where malaria is of minor importance, it may be dealt with adequately as a part of an ordinary health programme'.

'Thirdly, the Conference would like to emphasize the value of practical demonstrations of malaria control as a means of arousing the interest of lay (and even health) administrators. The lack of a good example of malaria control, well documented as regards statistics and costs, often explains official apathy and failure to appropriate funds for control programme. The Conference recommends that, in countries where malaria control programme is poorly developed or is being projected for the first time, sufficient funds be allocated for at least five years, to carry out a model project. This should include, not only the controlled area, but also an equally carefully-studied area nearby, in which no control is carried out, so that a contrast may be available. Such a demonstration control project with its contrast area has very great propaganda value, much more than a score of surveys barren of practical results'.

Sound administrative principles in democratic countries require an appreciation of the twin virtues of self-government and self-support. There must be standards of objective and of technique in malaria control, with a practical degree of uniformity of procedure. Projects should be feasible and beneficial, based on ample legal support, and having strict regard for public economy.

One cannot, as a rule, logically plan elaborate and expensive control programmes for rural communities any more than one can give such areas piped water supplies or complex sewage disposal systems. Yet country districts need not be burdened with malaria any more than with bowel diseases. Cheap methods for providing safe water and sanitary disposal of body wastes are available. They are not so perfect as one has a right to expect in municipalities but they meet the needs. So too, in dealing with malaria, there must be a recognition of the difference between urban and rural control. In the latter, one must rely usually on cheaper and less perfect measures, although there are places where extensive rural drainage projects to combat malaria are both feasible and economically sound. When such projects are designed to make better cultivation of crops possible, the results may greatly enhance the economic welfare of a community.

Generally, for cities one can recommend cash-purchase of malaria control, whereas country towns should be encouraged to rely on self-help to a greater extent. For populous

municipalities time frequently has considerable economic importance. Malaria control can often be obtained rather quickly by paying for speed. In the rural tropics, time has far less importance than money. Cheapness, not speed, is essential. Further, as noted below, persistence, not perfection, should be the motto. Central Governments can put up supervision and sometimes materials if a local community will provide labour. Participation by individual citizens is far more important in rural malaria control than in urban programmes.

(b) There has been a notorious lack of co-operation, as regards malaria, between departments of public works, agriculture and public health. By way of illustration irrigation malaria may be cited (see Russell, 1938). This has been subject to investigation by health officers for almost a hundred years but is probably a greater nuisance now than ever before. Waste irrigation water is an agreeable sight only to an entomologist who collects mosquitoes. To the irrigation engineer it represents spoilage of a valuable commodity, to the agronomist it offers another reason for high rates and water-logged soil, and to the health officer it is frequently known as a source of malaria-carrying mosquitoes. Yet, in spite of this and numerous other aspects of irrigation clearly calling for co-operation, even to-day projects are being planned and opened which are certain to distribute malaria as well as water, because of a fatal lack of co-ordination between the three departments of public works, agriculture, and public health. There is urgent need for more frequent, more active, and more practical co-operation between malarialogists and irrigation engineers, before, while, and after an irrigation project is undertaken in any area potentially or actually malarious.

An appalling amount of malaria is generated by human beings, who should know better, in such situations as (i) defective and untidy irrigation systems; (ii) engineer-sponsored borrow pits, embankments, and faulty culverts; (iii) town and village ditches; (iv) excavated depressions, and ill-kept tanks; (v) uncontrolled jungle clearance; (vi) improper siting, housing, and labour control during dam, canal, hydroelectric, bridge, road and railway construction, and (vii) in forest cuttings. Most of this 'official' man-made malaria could be avoided by intelligent co-operation between various government departments and the health administration.

The Intergovernmental Conference, referred to in a preceding section, reported as follows : 'In the fourth place, the Conference emphasizes the vital need for administrative co-operation between the health and other government departments, such as agriculture, education, finance, forestry, irrigation, and public works. Further, the Conference recommends that, in the development of rural malaria control, the aid of such local bodies as co-operative societies,

health leagues, and rural improvement centres should be enlisted and utilized to the fullest possible extent'.

Again quoting from this report, 'the Conference recommends, first, that every effort be made by lay administrators to secure close co-operation between their engineers and health officers, secondly, that appropriate legislation be enacted to prevent the creation of malarigenic nuisances by engineering departments or contractors under their supervision; thirdly, that, in the budget of every constructional project in malarious places there be an item for malaria control; and, fourthly, that engineers be instructed in the fundamental principles of anti-malaria sanitation before assuming executive responsibilities in the tropics. In the opinion of the Conference, this end would be best achieved by special pre- and post-graduate courses of instruction and by suitable pamphlets for subsequent guidance'.

In this connection, it is of interest to note that at the Eastern Bureau of the Health Organization of the League of Nations in Singapore and also at the Malaria Institute of India in Delhi, malaria courses for engineers have recently been organized. These have been well attended and have been enthusiastically supported by engineers.

(c) When dealing with malaria there is a vital need for continuity of effort. All too often malaria control consists of spasmodic 'campaigns', the net result of which may be almost or completely nil. It has not been sufficiently understood that there is as much need for continuing malaria control from year to year as there is for carrying out other public services without interruption. One does not expect that having repaired the roads this year they will require no further maintenance. So, too, the control of malaria, unless endemicity is very weak, is a never-ending procedure, like the sterilizing of water. Certain substantial works will lessen the amount of recurring effort required but will not obviate the need for an annual item in the budget. Good and thorough as was malaria control in the Panama Canal Zone during the construction period, yet year by year the work still goes on, as incessantly as maintenance of the canal itself.

It sometimes happens, as in Bombay, that when control measures have brought malaria mortality and morbidity rates down to low figures, lay officials will say, 'why a malaria appropriation when we have no malaria?' They fail to realize that it would be equally illogical to say, 'why, since our drinking water was chlorinated last year with good results, should we vote any further money for its sterilization?'

In any area where malaria is more than faintly endemic the chances of securing really permanent control from an 'extra' budget item, granted for a year or two, are slight. Officials must accept the fact that there will have to be routine

annual items for malaria control in the budget during this and perhaps several generations.

Co-operative lay organizations for malaria control have rarely been capable of the necessary *sustained effort*, chiefly because of (i) the lacuna listed under section I above; (ii) lack of adequate technical supervision; and (iii) failure of *sustained official encouragement and support*.

Persistence is far more important than either speed or perfection in malaria control. A modest programme *continuously applied*, year after year, is less dramatic but very much more effective, and more economical, than an occasional period of feverish endeavour followed by inactivity. This sound administrative principle has been demonstrated repeatedly but is still not grasped by the average administrator.

III. Lack of adequate training of health officers in practical malaria control methods and lack of sufficient numbers of specialist personnel, such as malarialogists, malaria entomologists, engineers, and agronomists.

The day of the amateur lay or official malarialogist has passed. The average general health officer or sanitary inspector is not qualified to carry out malaria control measures until he has had specialized training in this highly technical field. Effective malaria control, on any but the smallest backyard scale, requires specially qualified personnel, who may or may not constitute a separate division in the Health Department.

The Inter-governmental Conference, mentioned above, reported as follows : 'The Conference, in the first place, considers that the technical assistance of staff specially trained in malaria work is absolutely essential if an administrator is to deal successfully with malaria control. This consideration follows the general lines suggested by the League of Nations Malaria Commission as far back as 1924. Any malarious country which to-day has no health personnel skilled in malaria technique must be regarded as an anachronism. But the Conference believes that responsibility for malaria control should rest squarely on the minister or other officer in charge of the health policy of a country and not on the technical expert'.

It would appear that Governments, such as Presidencies and States, within whose territory malaria constitutes a public health problem, logically could include among their officers the following :—

1. A health officer specially trained in methods of malaria control, or better still, a professional malarialogist, who should also have had general public-health training.

2. A sanitary engineer specially trained in methods of malaria control, or better still, a professional malaria engineer, who should also have knowledge of general sanitary procedure and of agricultural engineering. If it is not feasible to employ either a general sanitary or a malaria engineer, there should at least be health inspectors or overseers available who have a sound

knowledge of running levels and constructing drains. When dealing with irrigation malaria, skilled technical advice is essential. Every Public Works Department or Irrigation Department in malarious areas should see to it that at least one of their regular staff has had special training in malaria control.

3. A medical entomologist is essential to a Department of Public Health not only in connection with malaria problems but to assist in planning the control of other insect-borne disease.

4. A malaria agronomist, whose time and skilled attention could be devoted to ways of avoiding that all-too-prevalent, man-made malaria directly due to agricultural methods or lack of them. If such a specialist is not available, efforts should be made (a) to impress those health officers dealing with malaria with the importance of anti-malaria drainage in reference to agriculture; (b) to obtain some realization on the part of farm demonstrators of the close association between agronomy and malaria and the agricultural benefits to be derived from rural malaria control.

Such a staff, augmented by a sufficient number of trained field inspectors and laboratory assistants, would seem to constitute a minimum requirement, especially at the beginning of a malaria control programme. Certainly, size of malaria staff should have positive correlation with magnitude of malaria problem. This staff can make surveys, recommendations, and demonstrations of malaria control. It may have either advisory or executive functions or both, depending on the administrative plan found most practical for a given area.

One reason why there are a hundred million cases of malaria yearly in India is the fact that the numbers of personnel specially trained for malaria control are so few.

IV. Lack of official cognizance of economic considerations as to (a) what malaria actually costs a community; (b) what benefits the control of malaria would confer on a community; (c) what constitutes a proper budget item for malaria control.

All too often it is stated officially that no money is available for malaria control. Not until public officials become convinced that malaria control is a good investment will they budget adequate amounts of money to accomplish it. Many more malario-economic surveys are required to convince lay administrators of the fact that malaria as a rule, even in rural areas, costs a community more actual cash-money, year by year, than would be required for its control.

For example, in a recent survey of a strictly rural South Indian village (Russell and Menon, 1941) it was found that the *per capita* annual payments for the treatment of malarial fevers by quacks, priests, and doctors were Rs. 2-8-0. Losses due to money paid out and to cash wages not received because of malaria amounted to

Rs. 3-14-0 *per capita* per annum. In this village malaria can certainly be controlled by spray-killing adult anophelines for less than Rs. 0-8-0 *per capita* per annum (Russell and Knipe, 1941). There are few villages in India on a much lower economic level than this one, where the total *per capita* annual income was only Rs. 35-3-0. Yet, viewed simply as a matter of rupees and annas, malaria control here would be a good investment.

However, the people in this village are undoubtedly too poor themselves to make a cash investment in malaria control. They will have to endure their affliction until there exists official cognizance of the economic aspects of the situation and both an official and a local sense of social responsibility for malaria prevention. To call upon these people to put up money for malaria control is as ignorantly unreasonable as was Marie Antoinette's suggestion to the people of Paris : 'If you have no bread, why don't you eat eake?' But, as in most rural, tropical villages, there is a surfeit of unemployed labour which is potentially available.

Quoting Hoffman (1928), statistician of the Prudential Life Insurance Company, 'the cause of malaria eradication rests upon sound economic as well as self-evident humane considerations, leaving no escape from the final conclusion that the entire subject most urgently demands the qualified and intelligent co-ordination of all existing governmental agencies and related health-conserving activities, on the one hand, and a broad-minded public policy, on the other, with special reference, however, to the expenditures on behalf of local anti-malarial measures on the part of the general public. For economic reasons alone the effort would be worth while, since the economic results of effective anti-malarial measures are a foregone conclusion'.

What would constitute a proper budget item for malaria control in one area might be out of proportion in another. Governments must budget in accordance with the size of their problems, realizing that it is doubtful if they can make a better investment than that in malaria control.

There are many examples that prove that, for constructional projects in malarious places, an item in the budget for malaria control of less than 3 per cent of the total cost of the project will be found to be an excellent investment.

V. Inadequate knowledge of methods for applying practically, that is effectively and economically, the results of research in malariology.

Undoubtedly, more research is required to devise cheaper measures of malaria prevention in rural areas, where, as a rule, *per capita* costs of available methods are two or more times the probable maximum *per capita* funds which could be raised locally for malaria control. For example, in South India, malaria control in rural areas probably cannot be done by any method known to be effective for much less than five to eight annas *per capita* per annum, including the

cost of paid labour, while it is a consensus of opinion that two annas *per capita* per annum would be a maximum amount which could be obtained from local or government funds for malaria prophylaxis. Even this amount would be difficult to find, no matter how much one stressed the fact that malaria itself was costing several times this sum. Not until rural malaria can be controlled more cheaply, will rapid progress be made, and here is a promising field for research, especially in naturalistic and agricultural measures of mosquito control, such as shading, pollution, and intermittent irrigation (the 'turn system').

But more research is by no means the complete answer. For example, the abundance of potential labour, which might be contributed on a co-operative basis, and the availability of potent weapons have been mentioned. One might also point out that it has certainly not been lack of funds or equipment that has delayed the control of malaria in the southern United States. The difficulty there as elsewhere is explained by the four lacunæ already mentioned, together with the absence of suitable methods for applying promptly and effectively the results of research in malariology, long available to public-health administrations. Governments, as a rule, are not only slow to budget money for malaria research but are loath to try out newer methods as they come from laboratory or field research units. There is need for more use of 'testing grounds', more willingness to budget money for demonstration projects and trial programmes.

Discussion

Bernal (1939, p. 383) reflects upon the function of science in relation to society. His remarks, appertaining to science in general, seem applicable directly to malariology. Quoting : 'How can all mankind best be maintained at a level of bodily efficiency and well-being, and how can we, once that minimum has been reached, secure the greatest possibilities for social and intellectual development? These are the crucial problems of our time. To solve them requires, in the first place, a wide extension of the field of science. No amount of physical or biological knowledge will suffice. The obstacles to the solution of the problem are not any longer mainly physical or biological obstacles; they are social obstacles. To cope with social obstacles it is first necessary to understand society. But society cannot be understood scientifically without at the same time changing it. The academic social sciences of the present day are useless for such a purpose; they need expansion and transformation. The science of society must grow up in contact with the social forces which are moulding it'.

This quotation should not be used to suggest that malaria is a sociological rather than a sanitary problem in any but the widest sense. For instance, there is no sound evidence that

famine and malnutrition are direct etiological factors in malaria, in fact such experiments as have been done indicate that a well-nourished individual is fully as susceptible to plasmodia as one who is mal-nourished. Passmore and Sommerville, 1940). Witness how readily well-nourished, physically superb troops go down with malaria when unprotected from the vector mosquito. The presence of famine conditions may cause malarious individuals to attempt to work before they are fit, increasing the relapse rate, or they may tend to drive families into other areas which are thus seeded with gametocyte carriers. But basically, what Hackett (1937, p. 15) calls the American Thesis, that malaria is a simple function of anopheline vector density, has never been upset and must be kept in mind. Any measure that directly attacks the plasmodium, or that tends to destroy the anopheline vector, to lower its density, or to keep it from man, may have prophylactic value. Without one or more of these characters, a method cannot be classed as malaria control. 'Good housing', for example, has no malaria control value unless it includes screening and proper siting with reference to malaria vectors. The provision of proper food and shelter is, of course, an important social health service but there is no proof that one can control malaria by increasing the food supply or supplying better-ventilated homes.

True it is that malaria sometimes maintains its greatest prevalence in areas of lowest economic status. This may be due, for example, to poorer drainage of cheaper lands. The evidence goes to prove not that poverty is responsible for malaria but that malaria frequently maintains poverty. It is a very difficult task to raise anaemic, malaria-beaten individuals to a plane of greater agricultural or industrial activity by any amount of political afflatus or social service. But it is surprisingly easy to stimulate a community which has been lifted up from the sloughs of chronic paludism by anti-mosquito measures.

It seems clear that as regards the immediate technique of malaria control one must not fail to make direct attacks on the plasmodium and especially on the insect vector. Attempts to control malaria by supplying routine social service or more opportunity for industrial and agricultural activity are apt to be futile.

However, in a wide sense it is quite true, as Bernal suggests, that the obstacles in the way of malaria control to-day are no longer mainly technical or biological, they are chiefly *social*. It would be useful if cheaper methods of malaria control were available for rural areas and one would certainly not suggest that no further research in technical or biological phases of malariology is required. But it is true that the basic aetiology of malaria has been known for over 40 years and that there are mechanical, chemical, and naturalistic weapons available to combat the disease. Science has perfected these

weapons so that they are readily available, remarkably effective, and reasonably economical.

Why then does malaria kill, directly or indirectly, over two millions of persons a year in India? Why to-day, throughout the tropics and sub-tropics, does malaria, to a greater extent than any other single factor, tend to lower and to keep down the level of bodily efficiency and well-being?

The answer seems to lie primarily in such *social obstacles* as have been discussed above. These are (1) a fundamental absence of educated and effective public opinion; (2) a far too limited use of sound administrative principles in public health; (3) a lack of sufficient numbers of specially trained personnel; (4) a failure among officials to take cognizance of economic considerations involved in malaria and malaria control; (5) an inadequate knowledge of methods for applying in a practical way the results of research.

Quoting again from Bernal (1939, pp. 385-6), 'the task of the future is to make the work of the scientist more conscious, more organized, and more effective; to create a proper appreciation of that work by the mass of the people and to link both together in a common effort to realize, in practice, the possibilities that science offers'.

What to do?

It is one thing to recognize social lacunæ that, even more than technical or biological ignorance, seem to be delaying the advance of malaria control. But it is quite another and more difficult matter for a director of health to devise a practical way to begin to close these chasms which are so huge that the handfuls of material available for filling seem scarcely worth using. Would that 'to do', were as easy as to know how to do'!

But, having attempted to outline the problem one may perhaps be permitted to mention some initial steps, some practical moves which would appear to be possible, in India for example, without much delay. In preceding paragraphs some of these and other points have already been mentioned.

To begin with, it is obvious that the need for enlightened public opinion can never be met until student training and health education have been developed to a vastly greater degree. A first practical step in each province or state would be to persuade the director of education to co-operate in setting up a suitable committee to prepare syllabuses for health education in the schools, from primary grades upwards. Until there are suitable courses and textbooks prepared by local authorities specially for local use there will not be much progress. Such a committee should consist of an experienced administrator in education, an outstanding teacher, and a capable health officer. It should not only outline courses but should also enlist properly qualified authors to prepare original textbooks

of hygiene and public health based on local conditions. Student training in public health has long been a feature of the Philippine Bureau of Education, in Manila, which would no doubt be pleased to send specimens of their excellent syllabuses and textbooks. A beginning has already been made along these lines in Madras, where a committee is studying this need for suitable outlines and school books in hygiene and public health.

Then, too, it is essential that much more emphasis be given in teacher-training schools and colleges to special instruction in the teaching of principles of hygiene and public health. If directors of public health will investigate, they will find that their subject is scarcely touched in teacher-training institutions. If courses are given, the instruction is generally perfunctory and has little or no practical value. An obvious first step for a director of health would be to obtain a copy of the syllabus used in teacher-training institutions in his province, to find out how inadequately the subject of public health is treated, and then to confer with the director of education and attempt to impress upon him the vital need for adequate practical student and teacher training in basic principles of, and social responsibilities for, hygiene and public health with special reference to malaria.

Health education for adults has been attempted in several provinces with indifferent success, largely because of a failure to realize that skilled, not amateur, direction is required. This specialty has been developed to a considerable degree in England, America, and Java. A first step in each province would be to send a suitable officer abroad for specialized training in this important field.

As regards administration, certainly a director of health should pause to study carefully his own system and locality to see if the needs as regards malaria control are being met. Perhaps on reflection, strategic changes could be devised which would effect notable results.

To secure adequate co-operation with departments of public works and agriculture no doubt directors of health will have to go more than half way. Having prepared facts and figures it might be possible, for example, to have conferences with directors of these two departments which would result in correcting or avoiding such serious blights as malaria due to irrigation. But the director of health must first have his basic data, photographs, and practical suggestions well in hand. Conferences, especially if held at a place where lack of co-operation has created malaria, will be found much more effective than correspondence. Perhaps a permanent *malaria prevention committee* could be formed, to consist of one responsible official, each from the departments of agriculture, public works, and public health, meeting once a month. Directors of health might also call to the attention of directors of public works the annual course in malaria for engineers, given

at the Malaria Institute of India in Delhi. This course is not designed to train malaria engineers but to instruct public works officials in some basic principles of avoiding malaria.

Skilled personnel is essential in malaria control. The chief institution in India for specialized training in malariology is the Malaria Institute of India in Delhi where there is an annual course which is open to selected health officers from the provinces and states. Full use of this facility, of course, should be taken, as well as of the courses at the All-India Institute of Hygiene and Public Health in Calcutta.

In any state or province where malaria is a problem it would also be useful to employ a malaria engineer. It is probably best to select a young graduate in engineering and to give him the necessary specialized training. Unfortunately, such specialized training in malaria engineering is not fully adequate in India but should be supplemented by study tours in Malaya and the United States. If it is not feasible to employ a malaria engineer perhaps a sanitary engineer with special training in malaria control can be added to the staff. As noted above, there should at least be inspectors or overseers qualified to run levels and construct drains.

As to medical entomologists, here again specialized training is essential. Well-qualified graduates in entomology are available in India and they can obtain locally the knowledge in regard to malaria that is required.

The idea of employing malaria agronomists is a new one but such specialists seem as logical a need as malaria engineers in a country like India, where at least three-fourths of malaria is rural and where it is so closely associated with agricultural procedures. Well-qualified agricultural graduates are available in India and can be trained locally in the principles of malariology. Every effort should be made to impress the department of agriculture with the importance of malaria control to the farmer.

One important and common defect in administrative procedure, as regards personnel, arises from the practice of service rotation. It frequently happens that by the time an officer has become well versed in the technique of malaria control the wheel turns and he is replaced by an untrained man. This precludes the possibility of technical competency. Such inefficiency might be avoided by an administrative change which would ensure that a man remaining in his malaria post would continue to make normal advances in seniority on the service lists.

An easily-made first step as regards developing official cognizance of economic considerations of malaria could be taken if a director of health would order some malario-economic surveys in well-chosen villages and towns. Such survey should be made by a health officer, living in each town during the survey and becoming

well known and trusted by the inhabitants. Information should be obtained painstakingly as to vital statistics, spleen and parasite rates, value of houses, income, taxes, debts and interest on debts, payments to doctors, quacks, and priests for treatment of malarial fevers and days and wages lost because of malarial fevers. It will usually be possible to demonstrate that malaria control in such villages would be a good investment. Only by carefully collected and presented facts and figures can hard-headed revenue officials be persuaded to budget adequately for malaria control.

As to malaria research, probably this is done best by specially-trained personnel. Many excellent and basic malaria studies have been reported by such institutions as the Pasteur Institutes of Assam and Coonoor, the Haffkine Institute of Bombay, King Institute of Madras, the All-India Institute and the School of Tropical Medicine in Calcutta, and especially the Malaria Institute of India, in Delhi and Kasauli. But in every department of public health there are always a few officers who have a *penchant* for field research and they should be encouraged to do as much as possible in connection with their routine duties.

In applying the results of malaria research a director of health can take a first step by setting up a demonstration malaria control project in a typical area. Here methods can be tested and results displayed. It is important to choose at the same time a similar nearby area where no control is done but where simultaneous observations as to the incidence of malaria and of vector mosquitoes are carried out. This contrast area will serve to prove to lay officials that reduction of malaria in the controlled area has been due to the prophylactic measures and not to a cyclic decline. When the natural curve rises, as it always will sooner or later, the contrast may be convincing even to sceptics. The Malaria Institute of India has always been pleased to give technical assistance to provincial or state authorities setting up such demonstrations, in fact several are being aided at present.

So, it is apparent, there are certain practical initial moves which can be made to overcome the social obstacles to malaria control. One must not be discouraged by the magnitude of the problem or by the fact that decades will pass before there is appreciable national progress. Rather, one should be encouraged by the relative ease with which the above-mentioned first steps can be undertaken.

Quoting the late Sir Ronald Ross, malaria prophylaxis 'depends not so much on profuse expenditure as on the intelligence, enthusiasm, and energy of those who are responsible for sanitary affairs'.

Summary

This paper undertakes to point out that the main obstacles in the way of malaria control

(Concluded at foot of next column)

ANTI-MALARIAL OPERATIONS IN INDIA

By P. N. BOSE, M.B., D.T.M., D.P.H.

From the Department of Microbiology, All-India Institute of Hygiene and Public Health, Calcutta

UNDER a grant from the Rockefeller Foundation the writer recently went round India on a study tour to acquaint himself with the anti-malarial operations going on in the different provinces. In the course of his tour he visited certain parts of Assam, Madras, Ceylon, Mysore and Delhi, and saw the anti-malarial work

(Continued from previous column)

to-day are not so much technical or biological as they are social. They appear to consist of such lacunæ as (1) a fundamental absence of educated and effective public opinion; (2) too limited use of sound administrative principles in public health; (3) lack of sufficient numbers of specially-trained personnel; (4) failure among officials to recognize economic phases of malaria and malaria control; (5) inadequate knowledge of methods for applying practically the results of research.

In conclusion, the paper outlines certain initial steps which could be taken, in India for example, without much delay to eliminate these social reasons which appear to explain why malaria in the tropics and sub-tropics still takes first rank as a destroyer of prosperity, happiness, and health.

there. This article is a brief summary of the impressions he gained about some of the measures employed and the results achieved.

Assam

Gauhati.—Gauhati is a town in the District of Kamrup with a population of about 22,000 (1931 census). After several thousands of dissections of anopheline mosquitoes, it was found that *A. minimus* was the chief vector and it was breeding in the Bharalu river and in irrigation channels to the north-east of the town. The infection rate was 3.23 per cent. By adopting anti-larval measures against this species the incidence of malaria in Gauhati has been brought down, as shown in the table below. Applying paris green and oiling of the breeding places are the chief methods adopted.

TABLE I

	YEARS					
	1935	1936	1937	1938	1939	1940
Spleen rate ..	13.2	8.0	6.1	5.4	7.2	2.9
Parasite rate ..	7.4	11.5	6.6	2.6	1.8	1.2

Dishpur.—Dishpur, a village with a population of about 300, is on the way to Shillong from Gauhati. Here spray-killing of adult mosquitoes is done regularly. The adjacent village of Japrido is kept as control. Pyrocide 20 (1 part diluted with 19 parts of kerosene) is used for spraying. The figures given below show the decline in the infant index and in the spleen and parasite rates.

TABLE II
Infant indices—1940

	March	June	September
Dishpur ..	44.4%	20.0%	20.0%
Japrido ..	Not examined.	62.5%	50.0%

TABLE III
Spleen rates (2 to 10 years)—1940

	March	June	September
Dishpur ..	71.5%	45.0%	46.0%
Japrido ..	83.8%	84.0%	73.0%

Nongpoh.—Nongpoh is a small official colony on the way to Shillong. Here one method of controlling the breeding places of larvae is by the removal of aquatic vegetation growing in drains and channels. At one time Nongpoh

TABLE IV
Parasite rate (2 to 10 years)—1940

	March	June	September
Dishpur ..	32.1%	27.0%	23.6%
Japrido ..	51.3%	76.0%	40.6%

was a very bad place for malaria but by clearing the weeds from the breeding places and spraying with oil, larval breeding has been brought down considerably and the place is now quite healthy and free from malaria.

Shillong.—In Shillong, the last epidemic occurred in 1932. The Assam Medical Research Society found an infection rate of 13.9 per cent in *A. minimus* and 0.31 per cent in *A. maculatus*. Both the species were found to breed in two large streams, the Umkhroh and Umshirpi and their tributaries. *A. minimus* was also breeding in a fairly large stretch of paddy field near the polo ground. Control measures have been adopted since 1933 under the Joint Malaria Committee and the following table shows the reduction in malaria that has been effected. The chief measures adopted are application of oil and paris green to breeding places.

TABLE V

	1932	1934	1940
Spleen rate ..	13.6%	3.5%	1.5%
Parasite rate ..	12.1%	4.7%	..

Dhekiajuli T. E..—In Dhekiajuli tea estate in Jorehat, control of *A. minimus* has been going on for some years. The work is being carried out under the direction of Dr. Manson. Shading of the breeding places is the chief method adopted there. The following plants are being used very effectively for providing shade, as they grow abundantly:—(1) Dhuranta, (2) Tita-bakash, (3) Eupatorium (Naga), (4) Tarapat, and (5) Hibiscus. Any one of these shrubs may be used. They completely shade the drains and canals in a short time and act as effective checks on *A. minimus* breeding.

Madras

Pattukottai.—Pattukottai is a town in the Tanjore district of the Madras Presidency. It was formerly a dry tract of country with red, ferruginous soil and was not malarious. Since the introduction in 1933 of irrigation from the Grand Anicut Canal, which originates in the Cauvery river, about 50 miles from Pattukottai, the following changes have taken place:—

(1) Wet-weather streams are dry for a shorter period than previously.

(2) Old tanks contain water almost throughout the year.

(3) The subsoil water level has risen considerably, making the place water-logged throughout the whole year.

(4) Untidy irrigation without proper drainage has taken place.

The irrigation season extends from about 15th June to 15th February which also corresponds with the malaria season. The density of *A. culicifacies*, which is the carrier, is greatest between the months of June and September. Although twelve other species of anopheles have been collected and studied, *A. culicifacies* is the only species responsible for malaria. It is, however, not a very energetic carrier as the combined gut and gland infection index is only 0.12 per cent.

It is supposed that irrigation and rice-cultivation are responsible for malaria at Pattukottai. The question as to why malaria is prevalent at Pattukottai and not at Tirubedu which is close by, though rice-cultivation is being done at both the places, is being studied. In Tirubedu the infection rate is very low, 0.01 per cent, and the density of *A. culicifacies* is also small. From the observations so far made it appears that the density of *A. culicifacies* is great in Pattukottai owing to the increase in the number of breeding places. Malarial incidence is high owing to high density of *A. culicifacies* though the infection rate is as low as 0.12 per cent. This suggests that one should not only consider infection rate but also the density and longevity of mosquitoes and coincidence with the malarial season, to explain malariousness of a place.

The reasons why irrigation has increased malaria in Pattukottai taluk are :

(1) Excessive and injudicious supply of water in canals.

(2) The digging of borrowpits to make embankments for canals. (The borrowpits are always full of water owing to high subsoil water level and seepage water.)

(3) The provision of defective sluice-gates permitting water to run here and there.

(4) Badly maintained canal banks with scouring and allowing the water to flow here and there.

(5) Absence of effective maintenance of field channels.

(6) Complete absence of drainage.

In Pattukottai at any rate the engineers are responsible for the above defects and the remedy lies in their hands. Experiments are being conducted to find out the value of minor and major engineering measures in reducing malaria. The borrowpits and low-lying lands in the town are being filled up, and proper drainage of the town is being maintained through well-built drains. The Rockefeller Foundation has taken two villages, Enadi and Senjaykollai, outside Pattukottai town, for experimental purposes. All the borrowpits and low-lying lands have been filled up there. Proper drains have been built. Irrigation-channel banks have been properly stone-pitched and maintained. Distributing channels

which supply water to the field, have been fitted with water-tight 'Calco' sluice gates, and intermittent supply of water from the main channel has been introduced. The land gets 5 days of water-supply and 2 days rest, but the earth remains moist so that there is no danger to crops. This has proved the most effective measure so far and the incidence of malaria has been reduced in these two villages. In the main channel, where there is water throughout the year, paris green application with a new type of distributor, devised by Mr. Knipe, is the method used for killing *A. culicifacies* larvae; in the tanks *Gambusia* fish have been introduced in large numbers to destroy mosquito larvae. The dustless method of paris green application recommended by Barber has also been resorted to for tanks and ponds. This is a very convenient method as the diluent used is water and one has not to carry such a large volume of material as when the diluent is soft stone or soap-stone or road-dust. The man carries a stock mixture of paris green, kerosene and egg-albumin and mixes it with water from the breeding place, puts it in the sprayer and sprays. The stock solution has the following composition :—Paris green 100 c.cm., kerosene 200 c.cm. and egg-albumin 1 grm., 25 c.cm. of the mixture is mixed with 5,000 c.cm. of water and spread by means of a Hudson sprayer.

Another interesting study, that is being conducted in Pattukottai, is on the ecology of *A. culicifacies*. The following points have been noted :—

(1) The question as to whether *A. culicifacies* is zoophilic or anthropophilic has been investigated by catching mosquitoes from (i) different catching stations in the villages; and (ii) mosquito-traps with young calves as baits. By this it has been found that *A. culicifacies* is not strictly anthropophilic (*i.e.*, preferring human blood). This has been corroborated by the precipitin test. *A. culicifacies* may be found in both cattle-sheds and in human habitations.

(2) Irrigation channels are excellent breeding places for *A. culicifacies*.

(3) Newly dug pits near canals and paddy fields breed *A. culicifacies* larvae more profusely than old ones.

(4) Fallow rice-fields are good places for *A. culicifacies* breeding.

(5) When paddy grows about 1 foot high, breeding of *A. culicifacies* stops.

(6) Pits simulating paddy-fields with paddy growing in them do not breed *A. culicifacies*.

(7) When paddy plants are grown inside wide test-tubes and put in the pits with water, so that there is no communication of water inside the test-tube and outside it, *A. culicifacies* does not breed. Hence the conclusion drawn is that it is the obstruction by paddy plants after they have grown to a certain height, that prevents *A. culicifacies* breeding in the rice-fields.

(8) Effect of shading has some effect (but not to any great extent) on the egg-laying of *A. culicifacies*.

(9) Egg output by *A. culicifacies* is most marked during the first four hours at night, i.e., from 6 to 10 p.m.

Kasangadu.—Kasangadu is a village in Pattukottai taluk. In view of the encouraging results obtained from spray-killing of adult anophelines by Ross in 1936, De Meillon in 1936, and Covell, Mulligan and Afzidi in 1938, an experiment was undertaken in 1938 in this village on the value of spray-killing of adult mosquitoes in the control of malaria. The spray used was a mixture containing 19 parts of kerosene and 1 part of Pyrocide 20. The experiment was started in June and the results obtained by the end of the year showed that there was a distinct tendency for the spleen and parasite rates to drop in the sprayed village as shown in table VI.

TABLE VI

Month (1938)	KASANGADU		TUVARANGURICHCHI	
	Spleen rate	Parasite rate	Spleen rate	Parasite rate
April ..	41.1	39.8	41.3	37.0
November	24.0	11.5	61.0	52.0

The amount of money spent in the spraying experiment came to As. 1-11 per 1,000 c.ft. or As. 15.3 per capita per annum. Although the per capita cost of these measures is excessive and greater than that which a rural village can be expected to afford, the method was found to be quite efficacious in checking malaria and it should therefore receive attention, particularly in places where money is readily available, e.g., in military barracks, tea-garden bungalows, etc., and where anti-larval measures are extensive and expensive. To reduce the cost of spraying, attempts are being made to make the extract locally from the Nilgiri pyrethrum.

Gambusia has been found to be a good larvical fish at Pattukottai. *Gambusia* is being introduced in breeding places where application of oil or paris green is not possible. This fish is very hardy, can stand variation of temperature and handling, and breeds profusely in confined waters. Several nurseries have been constructed at Pattukottai and regular supplies of fish are being sent for use in tanks, wells, etc.

Ceylon

So far as malaria is concerned Ceylon may be divided into three regions—

(1) A dry zone including more than half of Ceylon—the whole of the north, east and part of the south-east. Average rainfall from March

to August, i.e., during pre-malaria and malaria seasons—10 to 20 inches. Spleen rate is very high—40 to 60 per cent or over. The area is full of forest and is very thinly populated owing to prevalence of malaria.

(2) A wet zone including less than a quarter of the whole area of Ceylon in the south-west. Average rainfall from March to August is 40 to 60 inches or at places more than 100 inches. Spleen rate is low—0 to 10 per cent—and so this area can be called the healthy area and is thickly populated.

(3) Intermediate zone—in between (1) and (2). Average rainfall during March to August is 20 to 40 inches. Spleen rate is 10 to 40 per cent and it is the most dangerous area.

A. culicifacies is the one species concerned in the transmission of malaria in Ceylon. It is essentially a dry zone species and is widely prevalent in the forest areas where malaria is hyperendemic. In the wet zone *A. culicifacies* is much less prevalent and has a patchy distribution. In the intermediate zone, the distribution of *A. culicifacies* varies from year to year and is unusually plentiful during a year of drought or scanty rain. The close association of rivers with the breeding of *A. culicifacies* has been established. Whenever there is a lot of rain during the period from March to August, the rivers are full and there is little breeding of *A. culicifacies*, but if the south-west monsoon fails then water collects in the river beds into pools, and *A. culicifacies* breeds in plenty. Colonel Gill has explained the occurrence of the malaria epidemic in Ceylon in 1934, as due to severe and prolonged drought during the preceding year and the year in question. He states that all fulminant epidemics that have hitherto been studied (e.g., the Punjab epidemic) have invariably been associated with excessive rainfall or with inundations resulting from the outflow of rivers, but here in Ceylon the picture is different; failure of rainfall has been responsible for the epidemic. In both cases the humidity is to blame. High humidity determines the onset of epidemics in the Punjab, while in Ceylon it is the lowered humidity due to prolonged drought that causes epidemics. As a result of the study of malaria, particularly the fulminant type of epidemic, attempts are being made in Ceylon to check malaria and to prevent future havoc. Systematic collection of *A. culicifacies* larvae and adults is being made under the direction of medical officers responsible for $1\frac{1}{2}$ miles radius around their jurisdiction as well as in their own areas. The samples are identified either by the local staff or by the central laboratory and the records are kept in a systematic manner in the medical entomologist's office. The latter sends out instructions to the local medical officers for adopting anti-mosquito measures as and when required. Two systems are followed: (1) oiling of pools or along the sides of rivers or other water collections is done regularly; and (2) on receipt of

instructions from the medical entomologist, emergency oiling is adopted. Circulars regarding instructions relating to emergency oiling of rivers and streams are sent to medical officers. This is done on the basis of findings on larval output; and when there are grounds to believe that conditions are getting worse, and that unless they are checked they may lead to severe and widespread out-breaks of malaria. This emergency oiling is not commenced after the monsoon rains without notification from the medical entomologist.

Chilow.—This is a town almost at the sea level. Malaria is endemic in the town. The methods of malaria control adopted at Chilow are:

- (1) Reduction of width of channels and drains by revetting and filling.
- (2) Filling of swampy areas and pools with coir dust.
- (3) Filling and draining of sides of ponds.
- (4) Paris green application (2 per cent with soapstone) to drinking water supplies.
- (5) Oiling with 'malariol' in other places.
- (6) Biological control of wells and *gala-wells* (used for irrigation) with *Gambusia*.
- (7) Construction of cemented permanent drains.

Deduru Oya Catchment area.—In Deduru Oya Catchment area in Chilow district, mosquito traps with human and animal baits were demonstrated. Big mosquito-curtains were placed in front of human houses and cattle-sheds to catch mosquitoes as they come out or go in to take their blood-meal. This method has been immensely helpful in the study of the bionomics of the vector species of the place. The collection time is usually from 6 to 8-30 p.m., and the number of adults caught gives an indication also of the extent of larval breeding going on at the time. It is in fact used as a check on the larval catches.

Kurunegala.—The town of Kurunegala with a population of about 10,500, is situated in the intermediate zone and was the most severely affected area in the 1934 epidemic. Here different naturalistic methods of control of anophleles larvæ are being tried.

- (1) Agitation of the water in the breeding places; particularly in hill streams.
- (2) Automatic flush syphon.
- (3) Hand-operating flush.
- (4) Stone packing.
- (5) Fascine drain.
- (6) Pollution of water by coconut husk.

The results of these have been quite encouraging, except the automatic flush syphon which very often gets out of order.

Mysore State

Bangalore City.—The area of Bangalore City is 15 square miles and the population is 2.5 lacs. It was malarious before 1927. Malaria control

work was started and in 1938 general mosquito-control was initiated. The two carrier mosquitoes are *A. stephensi*, breeding in wells, and *A. culicifacies*, breeding in tanks and borrow-pits. Wells used for drinking water are controlled by *Gambusia* and dirty wells by malariol. The latter is used for tanks and borrowpits. Minor engineering measures, such as filling-up of tanks, are also done. The following table shows the effect of control measures:—

TABLE VII

	Before 1927	After 1935
Spleen rate ..	25.0	0.22
Parasite rate ..	14.2	1.00

Hiriyur.—At Hiriyur the effectiveness of subsoil drains by means of stone-packing and of canalizing and training of a river were shown. Two per cent paris green mixed with charcoal dust is employed for dusting. But the work at Hiriyur is not satisfactory as after 12 years of continuous anti-malarial work the spleen-rate has been reduced only from 57 per cent to 35 per cent.

Mandiya.—Mandiya is a valley; its altitude is 2,191 feet above sea level, and it has a total rainfall in a year of 22.35 inches. Before 1932, cultivation depended upon rainfall, but in June 1932, irrigation was introduced, water being taken from the Irwin canal, and an epidemic of malaria started in August of the same year. *A. culicifacies* was found to be the carrier with 3.5 per cent infection-rate, and the spleen-rate shot up from 3.8 to 82 per cent in some places. Control work was started in 1935. Major engineering drainage is the chief problem. The subsoil water level has been raised considerably owing to irrigation, and the whole place, being a valley, has become swampy. Here is another example of malaria resulting from careless irrigation as seen at Pattukottai. Gradation and channeling of the whole valley are being undertaken by the engineering department. The special feature here is that the medical, engineering, agricultural and revenue departments are all working together in perfect harmony and the results that have been achieved are indeed praiseworthy. Though the place is still malarious, the spleen rate has markedly declined.

Nagenhalli.—Nagenhalli is on the way to Mysore and here malaria is due to rice cultivation. It is being controlled by paris green only. In 1929, the spleen rate was 90 per cent but by control of larval breeding by judicious use of paris green, it has come down to 25 per cent.

Delhi

Delhi was formerly highly malarious, but in recent years the incidence of the disease has

been greatly reduced by an intensive anti-malaria campaign, carried out throughout the urban area. The chief breeding places of the local malaria vector (*A. culicifacies*) are those provided by river flooding and by ill-regulated and excessive canal irrigation. A number of permanent engineering works have been executed, the main principle being the prevention of flooding from any source. Within the area thus protected, the ground is so dressed that local rain water is either drained off completely, or is directed into one or more tanks, or *lidos*, which are specially excavated for the purpose where necessary. Extensive filling operations have also been carried out in many parts of the urban area.

Other measures employed include the mosquito-proofing of cisterns and wells, the application of oil and paris green to breeding places and the stocking of ornamental waters with larvivorous fish (*Gambusia*). The problem of larval drift in the tail of the Western Jumna Canal and its distributaries is dealt with by the use of booms constructed of *sarkanda* grass. These trap the larvae, which are destroyed by means of oil-soaked *bhoosa* thrown on to the water immediately above the booms.

The spray-killing of adult mosquitoes with pyrethrum insecticide, among communities especially exposed to infection, is an important feature of the campaign.

Buzpur.—Buzpur in the Kumaun District in the U. P. has a foot-hill malaria problem. *A. minimus* is responsible for transmission of malaria in that place. The aboriginal tribes of the place are Buxas and Tahrus. They have been exposed to intensely malarious conditions for centuries and have developed a high degree of immunity. Thus they carry the infection but suffer little. They are a real source of danger

to visitors, as most of them are gametocyte-carriers. The imported population from the plains of the U. P. are not immune, and they suffer much more severely from the disease. The subject of immunity in malaria can be best studied here.

Conclusion

(i) Malaria is a great problem in India including Ceylon, and it is being tackled in all the important places.

(ii) The nature of the problem differs in different places.

(iii) Each place has its particular carrier-species of anopheles.

(iv) Bionomics of the vector species determines the nature of the anti-malarial measures to be adopted.

(v) In many places man is responsible for the introduction of malaria.

(vi) Naturalistic methods of control are more successful in some places than in others.

(vii) Permanent measures give better results and are more economical in the long run than temporary measures.

(viii) Spray-killing of adult mosquitoes is a measure of importance, particularly for military barracks, tea garden bungalows, etc.

Acknowledgment

The writer wishes to express his indebtedness to Dr. D. K. Viswanathan of the Assam Medical Research Society, Dr. Paul Russell of the Rockefeller Foundation at Pattukottai, D.M.S.S., Ceylon, the D.P.H., Mysore State, and Colonel Covell, the Director of the Malaria Institute of India, for giving him an opportunity to see their anti-malarial operations and for allowing him to quote their results. To Dr. K. V. Krishnan thanks are due for condensing the report into its present form.

Current Topics

Experiences with the Injection Treatment of Hernia.

By A. R. KOONTZ, A.M., M.D., F.A.C.S.

(Abstracted from the *Southern Medical Journal*, Vol. XXXIV, March 1941, p. 297)

I WISH to state at the outset that I am neither a protagonist nor an antagonist of this method. I undertook this work for the sole purpose of learning what value, if any, it held.

For many years I have given an elective course on hernia in the Johns Hopkins Medical School, and each year in the course, until the autumn of 1935, I have mentioned the injection treatment only to condemn it. The reasons I have always given students for not using the injection treatment have been as follows:—

- (1) The injection method does not cure the hernia.
- (2) Important structures may be injured by the injection.
- (3) The scar tissue caused by the injection makes operation more difficult when the patient does finally come to it.

However, by this time, so many favourable reports dealing with the injection method had appeared in the

literature that it seemed to me that I could no longer go on condemning it without having some first-hand information upon it.

I shall make no attempt in this paper to discuss the history of the injection treatment, the technique employed, or the relative merits of the various solutions that have been used. These matters have already been discussed at length by writers who have had far more experience with the method than I have.

In an effort to determine the relative merits of the various solutions that have been used for injection, I have used a considerable number of solutions, as follows: 'galtanol', 'neogaltanol', 'proliferol A', 'proliferol B', 'proliferol T-special', phenol-alcohol-oil of thuja solution, sylnasol, Mayer's solution, and phenol and glycerine solutions. I am not in a position at present to discuss the relative merits of these various solutions. Several of them have not been in use long enough to compare them with those used early in the series.

The number of cases in this series is small, totalling only 179. I hesitate to report this small series, and am impelled to do so only because I am constantly asked what my results with the injection treatment are,

and because I believe reliable workers in any new field should let the profession at large know what their results are, so that a proper evaluation of the new method may be made. If we waited until absolutely definite conclusions could be drawn with regard to the injection treatment of hernia, no reports would be made on the method for many years to come.

All but nine of the hernias injected in this series have been inguinal hernia. The series includes all varieties of inguinal hernias: direct and indirect, scrotal and non-scrotal, and recurrent. I have not considered femoral hernias as particularly suitable for the injection method. However, I may try the method on a limited number of cases at some later date. Umbilical and post-operative ventral hernias are not suitable for injection unless they are very small. If, however, they present a fascial defect only 1 or 2 cm. in diameter, the defect can readily be closed by the injection method.

The table shows the results obtained. I have made no attempt to show percentages of cures. The follow-ups have not been good enough, nor the length of time long enough, to make such figures at all worthwhile. The average number of injections and the average number of months that each patient was injected are rather high because in some of the older cases the hernias recurred and had to be re-injected. In some instances they recurred twice and were re-injected twice. Also, some cases were given strengthening injections as a precautionary measure months after the regular course of injections was stopped. The total number of injections and the total number of months treated (including the injection of recurrences) are included in each case. The number of short-period cures is rather impressive, while the number of long-time cures is not. This, of course, is partly due to the fact that the series is not an old one. The number of failures has not been large.

This man had a large scrotal hernia, and the injection treatment was begun on the patient's insistence, and after he had been strongly advised to have an operation instead. After having 38 injections the ring had been materially decreased in size, but the hernia was still not cured, and the hydrocele had developed. The patient then consented to operation, and at operation it was found that he had a sliding hernia. The bottle operation for hydrocele was done, the hernia was repaired with ox fascia, and the patient has remained well for the eighteen months since his operation. Sliding hernias have been considered contra-indications for the injection treatment, but it is well known that it is not always possible to make a diagnosis of a sliding hernia before operation. In this case, there was no difficulty in keeping the hernia reduced, apparently completely, although obviously not completely. This case shows, however, that if care is used in making the injections, placing them just under the aponeurosis of the external oblique and not too deeply, a sliding hernia may be injected without serious complication, but necessarily without cure of the hernia.

The most serious complication encountered was the formation of a deep abscess, following an excoriation of the skin due to the pressure of a rather severe truss. A gangrenous area of skin, 1.5 cm. in diameter, developed, and when this was removed the necrotic core was found to go down through the subcutaneous tissue to the aponeurosis of the external oblique. Some of the aponeurosis of the external oblique sloughed away, and the lesion required three months to heal. A lighter truss has been fitted on this patient and the injection treatment resumed.

In one umbilical hernia an abscess formed, which had to be incised, and in another one a small sinus developed, which healed promptly under proper treatment.

TABLE

Types	Number of cases	Average number of injections	Average number of months injected.	Number of cures less than 6 months.	Number of cures more than 6 months.	Number of cures more than 1 year.	Number of cures more than 2 years.	Failures	Incomplete or still under treatment.	Complications	
										Epididymitis	Deep abscess
Indirect inguinal (non-scrotal).	117	21	10	31	18	10	6	3	49	1	1
Indirect inguinal (scrotal).	20	31	14	5	..	2	1	4	8	1	1
Direct ..	15	26	13	1	1	1	..	1	11		
Recurrent ..	18	32	23	3	2	3	2	4	4		
Umbilical ..	4	6	2	2	1	..	1	Abscess ..	1
Ventral (post-operative).	5	6	7	2	1	2	Sinus ..	1

Complications.—There have been a fair number of cases in which a slight swelling of the cord followed injection, but in all cases this has subsided in a few days. There have been six cases in which the complication was more severe. In one case there was an epididymitis which subsided without any treatment except the wearing of a suspensory. In one case a small hydrocele developed, which completely disappeared in a few weeks without treatment of any sort. In another case a large hydrocele developed, which persisted.

In a few instances I have felt sure that the injections have gone into the peritoneal cavity. In these cases there has been generalized abdominal pain, and in some cases narcotics have been administered. In all cases the pain has subsided within a couple of hours, and there have been no untoward results.

I have operated upon several of the failures. While at operation a large quantity of scar tissue was found, the operation was not so difficult as the ordinary operation for recurrent hernia, as there was no distortion

Nov., 1941]

of the anatomy which is often found at operation for recurrent hernia.

DISCUSSION

It goes without saying that no hernia should be injected unless it can be kept constantly reduced with a suitable truss. At first I used the semi-rigid variety of truss, but during the last ten months I have been using elastic trusses. I believe that a rigid truss is apt to exert too much pressure and cause too much atrophy of the newly proliferated tissue. Elastic trusses are found capable of keeping hernias reduced, while not causing the marked atrophy that the rigid type causes. Some of the larger hernias are difficult to keep reduced, and in these cases any type of truss that will keep the hernia reduced should be used until the rings are so narrow that a lighter truss will prove efficacious. Trusses should be worn night and day during the first few weeks, after which they may be discarded at night. Naturally, the elastic type truss is much more comfortable to wear in bed than the semi-rigid variety. A great deal depends upon the co-operation of the patient. The truss should not be taken off until after the patient is lying down in bed, and should be put on before he gets out of bed, while he is still lying down. It should be put on if he gets up at night to go to the bathroom. The truss should be worn neither too tight nor too loose nor too high nor too low. The pad should rest just above the pubic bone, and the truss should encircle the body midway between the great trochanter and the crest of the ilium.

As with any new method, naturally, there is still much to learn about the injection treatment of hernia. It has been recommended by some writers that some of the solutions used be injected two or three times a week, while others are injected only once a week. I do not believe that the optimum time that should be allowed to lapse between injections has yet been worked out. Will injections given too closely together destroy new fibroblasts that have been caused to proliferate by previous injection? Will ground be lost by spacing the injections too far apart? So far as I know, sufficient experimental work has not yet been done to furnish the answers to these questions.

In this series patients from all age groups have been injected. Apparently the younger the patient the better the result. The number of children injected has been small, but the results have been uniformly good.

A group of patients in which the injection treatment seems to be especially indicated is the group of old patients with troublesome hernias, in which operation would be too hazardous.

Another type of hernia that is very favourable for the injection treatment is the recurrent inguinal hernia in which the defect through which the recurrence appears is small. I have one such patient who was operated upon three times on each side, and each time by an exceptionally competent surgeon. He came to me after the third recurrence, and the recurrence on each side was through a defect only about 1 cm. in diameter. Both of these were injected, and the patient has now been well for three years. Naturally, he is delighted with the result. I have another similar case, injected for hernias twice recurrent on each side, but this case has now been well for only a few months.

There is another type of patient in which I think the injection treatment is especially applicable. I refer to patients of the industrial class who, because of enlarged rings with slight impulses, are denied employment. I have a few patients of this class in whom I have been able to close the rings completely, who are free from impulses, and who have been accepted for employment in arduous tasks.

Patients who receive the injection treatment almost invariably say that they feel much better after they have had a few injections. The uncomfortable dragging down symptoms disappear.

CONCLUSIONS

(1) I believe that the injection method will have a permanent place in the treatment of hernia. Just how wide the scope of this place will be, it will take

years to determine. I further believe that the majority of the reports so far published have been too optimistic, and that the number of recurrences in ensuing years will reduce the high percentage of cures in the early reports.

(2) The chances are that the field for the injection treatment will be widened as methods and proliferating solutions improve.

(3) At the present time the injection treatment seems indicated in the following groups of patients:

(a) In old people with difficult hernias that cannot be satisfactorily retained by a truss. Many of these cases can be cured and kept cured if they continue to wear a light truss, while recurrences ensue in a great many of them if the truss is discarded.

(b) In those patients who will not, on account of fear or other reasons, consent to operation.

(c) In those patients who do not feel that they can afford to take time off for operation, either for financial or business reasons.

(d) In patients in the industrial class who have potential but not actual hernias, and who are refused employment because of this.

(4) The most favourable cases for injection from the point of view of cure are fairly early indirect inguinal hernias, very small umbilical and post-operative ventral hernias, and small recurrent inguinal hernias.

The National Loaf

(From the *Lancet*, Vol. I, 31st May, 1941, p. 698)

In its first memorandum on bread the accessory food factors committee of the Lister Institute and Medical Research Council advocated the use of wheat flour in which 80-85 per cent of the grain was extracted instead of the usual 70-75 per cent as a step to improve the health of the nation, and they also recommended that calcium should be added to bread. The Government adopted the second recommendation but not the first and announced their decision to fortify white flour with vitamin B₁ and calcium. A year has passed but the bakers have still not received from the millers flour containing either added vitamin B₁ or calcium and there seems no certainty when they will. Meanwhile the Government, without much enthusiasm, have adopted a loaf baked from 85 per cent extraction flour without added calcium as the national loaf and are encouraging us to eat it. But they have not explained the situation, and the public are inclined to suspect that some sort of war-time substitute is being offered them. Few people have grasped that the national loaf is probably the best bread, judged on its food value, that they have ever eaten, for it has been selected after a most careful scrutiny of the nutritive value of the different parts of the wheat grain. In milling white flour 70-75 per cent of the grain is used, leaving at least 25 per cent of the grain not normally used for human food. If we are going to eat 85 per cent of the grain we are going to eat another 10 parts out of the usually unconsumed 25 parts, but obviously we have a choice as to which 10 parts we choose, and it is on the choice of these 10 parts that great care has been lavished. In a second memo on bread from the M.R.C., the parts of the grain to be included in the 85 per cent extraction flour are defined in detail, and we are told the reasons for the choice.

These reasons were not all nutritional; the aesthetic one of providing the whitest possible loaf compatible with nutritive excellence was never lost sight of. 'The loaf is cream coloured and brings you the cream of the wheat' might be used as a slogan to express the ideal of the Ministry of Food's advisers in their wish to comply with what is believed to be the prevailing popular taste. The digestibility of the loaf also received attention, and a low content of fibre or so-called roughage, not more than half that of wholemeal, was fixed so that delicate digestive tracts should not be irritated. In 85 per cent flour, as defined in the memo, the purely nutritive advantages which are undisputed are the higher content of vitamin B₁,

of the vitamin-B₁ complex, of iron, and of protein of good quality. There is one admitted drawback; the browner the flour the more it contains of phytic acid and its derivatives, whose action is to precipitate and make unusable not only the scanty calcium in the bread itself but also that in the rest of the diet. There is little of these substances in white flour; in 85 per cent extraction flour there is a good deal more but only about half as much as in wholemeal. It was because of the extra phytic acid that the M.R.C. committee originally advocated the addition of calcium to the 85 per cent flour which they were recommending. Most dieticians agree that it would be a good thing to add calcium to white flour, since there is an insufficiency of calcium in small-income diets containing much bread, but the reason for adding it to higher extraction flours is much more cogent, and there can be no serious argument against it from the trade since the millers are already in the habit of 'improving' the baking properties of flour by adding acid calcium phosphate in about the same amount as it is now recommended to add calcium carbonate. In self-raising flour the amount of calcium salt habitually added is much greater.

When the M.R.C.'s new memo has been read, the reader is left wondering why the policy of fortifying white bread with vitamin B₁ should still be pursued by the Government. The arguments for adopting 85 per cent extraction flour with added calcium for universal consumption as soon as present stocks of white flour are exhausted seem overwhelming. Both the national (85 per cent) loaf and a fortified white one promise extra vitamins but the national loaf provides others besides B₁. Further, the supply of protein in our present diet is meagre, and the opportunity to introduce more protein of better quality by a simple change in our most widely used foodstuff should not be missed. Lastly, there is the need of shipping space. In the last war this imperative necessity drove the extraction of flour to 95 per cent; a general advance to 85 per cent now would afford an appreciable relief. Against the change can only be set popular prejudice (much of which will go when everyone has sampled the national loaf), the better keeping qualities of white flour, and an understandable reluctance to scrap the machinery which is now producing vitamin B₁ cheaply and on a large scale.

Reviews

THE BRITISH ENCYCLOPÆDIA OF MEDICAL PRACTICE INCLUDING MEDICINE, SURGERY, OBSTETRICS, GYNÆCOLOGY AND OTHER SPECIAL SUBJECTS—COMPLETE INDEX. 1941.
Edited by Sir Humphry Rolleston. Butterworth and Company (Publishers), Limited, Bell Yard, Temple Bar, London. Pp. 486. Price, Rs. 20. Obtainable from Butterworth and Company (India), Limited, Bombay

BRITAIN Delivers the Goods. There have been moments when we wondered whether we in India would ever see the index to Sir Humphry Rolleston's now world-famous encyclopaedia, but it has arrived.

It is a good index. It is a comprehensive but it is not a wasteful one. It gives the main references first clearly and then the subsidiary ones, so that the wood is not obscured by the trees. Finally, it doesn't overdo the 'see . . .', but whenever possible it gives you the main reference, volume and page. For example, Malta fever is described in the chapter entitled 'Undulant Fever', but if one looks up 'Malta fever', one does not find 'see undulant fever', but '12, 361'; whereas under 'undulant fever' the same main reference is given and nearly a column of sub-references. There is thus no duplication, but one is saved a second dive into the index. The point is stressed because the reviewer has so frequently been irritated by books in which this practice is not followed.

In conclusion, it can be said that it is an index worthy of the work which it serves. Incidentally, this volume almost fills another 'long-felt want', an English (as opposed to an American) medical dictionary.

We believe that it is still possible to obtain this invaluable encyclopaedia and we strongly recommend those who have not yet subscribed to try to obtain a copy: it will be many years before it is out of date and the publishers have a scheme of supplementary volumes for the addition of new matter.

STARLING'S PRINCIPLES OF HUMAN PHYSIOLOGY. Eighth Edition. Edited and Revised by C. Lovatt Evans, D.Sc., F.R.C.P., F.R.S., LL.D. (Birmingham). 1941. J. and A. Churchill Limited, London. Pp. x plus 1247, with 673 illustrations, 7 in colour. Price, 32s.

EVERY medical man who wishes to keep up to date should periodically buy a book on physiology and we know no more readable book on the subject than the one under review. Its extreme popularity and the world-wide demand for this book makes it possible for the publishers to give it to us at a very reasonable

price for a book of its size and quality, especially in war time.

Physiology is a very live subject and much has happened since the last edition, five years ago. The book has been very largely rewritten, some sections completely, and, though obsolete matter has been deleted, about 150 pages have been added; this fact will depress the young student and give food for thought to the older ones who worry about the future. (Why is it that it is the older ones who have less future to worry about that do most of the worrying?)

The section dealing with the central nervous system has been entirely rewritten and, as one would expect, the next most extensive revisions have been undertaken in the chapters on the endocrine organs and on nutrition in general with the vitamins in particular. Also there have been considerable changes in the chapter on renal function.

A very important feature of this book is the numerous references, both general and special; in this edition many new ones have been added.

This is of course the book of choice for both the student and the practitioner. It is a remarkable achievement on the part of the publishers that the only sign of the war on the format is that some of the forms in the centre of the book are of different paper from the rest. However, we doubt if one per cent of readers would notice this.

LECTURES ON WAR NEUROSES.—By T. A. Ross, M.D., F.R.C.P. 1941. Edward Arnold and Company, London. Pp. vii plus 116. Price, 6s.

As the author states in the preface, this little book represents a series of lectures given at one or two centres during 1940. Their object is to help battalion medical officers and general practitioners to deal with patients suffering mentally from war strain. Dr. Ross is a psychiatrist with a very long experience and he delivers his points clearly and simply. That he has a well-grounded understanding of the human mind is evidenced by his view that the introduction of the sphygmomanometer is a disaster from which mankind has not yet recovered. The book deals with acute and chronic war neuroses to which is appended a note on civilian war neuroses. It is not a little surprising to find that war neuroses among civilians have been much fewer than were expected. Dr. Ross thinks that army discipline through which the soldier is reduced to a state of childhood may partly account for the relative frequency of neuroses among soldiers as compared with civilians who have been bombed in cities and towns

Nov., 1941]

ABSTRACTS FROM REPORTS

Dr. Ross has some interesting advice to give on the treatment of hysterical conditions among soldiers, including hysterical deafness. He is emphatically opposed to the use of apparatus in cases of this sort. He maintains that it is essential that the patient should know he was cured, because he himself changed his mind about something.

O. B-H.

A TEXTBOOK ON THE NURSING AND DISEASES OF SICK CHILDREN FOR NURSES.—By Various authors. Edited by Alan Moncrieff, M.D., F.R.C.P. Third Edition. 1941. H. K. Lewis and Company, Limited, London. Pp. xiv plus 639, with 142 illustrations. Price, 21s.

HERE is a comprehensive volume dealing with various disorders of childhood written mostly from the nursing point of view. 'Complete revision has been carried out for this edition, which is almost fifty pages longer than its predecessor.' A new chapter on 'Children in the Tropics' written by Lieut.-Colonel E. H. Vere Hodge has been added.

The first part deals with the general principles of medical and surgical nursing, with special reference to the technique and apparatus of the procedures described. Anæsthesia, haemorrhage and shock, orthopaedic surgery, etc., have been described in separate chapters. The second part constitutes the bulk of the volume, and is devoted to various diseases of children, written in an elementary style. An appendix has been incorporated dealing with drugs, weights and measures, poisoning, recipes, physiotherapy, etc.

There are profuse illustrations with excellent drawings and photographs. The general production is of high standard.

The editor deserves congratulations for the manner in which he has welded the contributions of various writers, while preserving a continuity of style and general arrangement.

R. C.

ACROCEPHALY AND ACROCEPHALOSYNDACTYLY.—By David Ferriman, D.M. (Oxford), M.R.C.P. (Lond.). 1941. Oxford University Press, London, Humphrey Milford. Pp. x plus 119. Illustrated. Price, 10s. 6d. Obtainable from the Oxford University Press, Bombay and Calcutta

THIS monograph deals with a subject of medical curiosity that may interest a certain section of the profession.

Acrocephaly is said to result from an inherited defect of germ plasm giving rise to aplasia and incomplete differentiation of the skull so that the two sides fuse prematurely. When other bones are involved as well, the condition is called acrocephalosyndactyly.

The book is divided into two sections. The first part is a review of the subject with reference to history, aetiology, clinical and radiological signs, diagnosis, and treatment. Part two contains detailed records of eighteen cases with a few illustrations. Six families accounting for seventeen cases have been extensively investigated by the author. Consanguinity has not been found in any of these families. The book ends with a final discussion of some of the cases, followed by several tables of skull measurements.

R. C.

PROBLEMS OF NERVOUS ANATOMY.—By J. Boeke, LL.D. (Glas.). 1940. Oxford University Press, London, Humphrey Milford. Pp. vii plus 164. Illustrated. Price, 7s. 6d. Obtainable from Oxford University Press, Bombay and Calcutta

The purpose of this book is to give an account of some of the fundamental problems concerning the anatomy and physiology of the human nervous system.

The book has been divided into four chapters—(i) changes in the spinal and sympathetic innervation of the skin during degeneration and regeneration; (ii) the sympathetic ground-plexus in the glands, muscles, and connective tissues of the body; (iii) the problem of the 'interstitial cells' in the sympathetic

nervous system—their relation to neurones, and the innervation impulse as a humoral change in the tissues; (iv) on the present state of the neurone doctrine and of our knowledge of the synaptic junctions between nerve-cells and end-organs.

There is much personal research and conviction of the author embodied in this book, but the author has included the opinion of other workers on the subject when considering the various problems under discussion in the different chapters of the book.

The book will be of interest to the specialist in neurology and advanced students of neurophysiology.

Abstracts from Reports

REPORT ON WORKING OF BIOCHEMICAL STANDARDIZATION LABORATORY FOR 1937-1940 (31ST MARCH)

'FROM the number of enquiries received from all over India and from the interest evinced in this type of work from all quarters, including the medical and pharmaceutical professions and the lay public, there seems little doubt that the Biochemical Standardization Laboratory has filled a definite gap and removed a long-felt want in the medical and public health administration of the country,' says Colonel Sir R. N. Chopra, Director of the Biochemical Standardization Laboratory, in his first report covering the period 1937-40.

The appointment of the Drugs Enquiry Committee in 1930 was the first attempt in India to study and investigate the problems pertaining to drug standardization and drug control. As a result of the committee's report, which revealed a serious situation in regard to spurious drugs, the Government of India passed the Drugs Act, 1940, and also established the Biochemical Standardization Laboratory in Calcutta (in 1937) as a small nucleus to be expanded later as the Central Drug Control Laboratory.

The functions of the laboratory are to assay and test chemicals, drugs, biological products and organometallic compounds, on request by any person, including local governments and provincial laboratories, to standardize methods of analysis and tests with due regard to the climatic and other conditions prevailing in different parts of India, to undertake commercial testing of drugs for manufacturers and dealers on payment of prescribed fees, and to prepare and maintain stable standards of strength, purity and quality for drugs. The laboratory acts as a 'National' distributing centre for International (League of Nations) standards for biological products, galenicals, organic arsenicals and endocrine products, and as an expert referee in respect of disputed analyses.

The laboratory is also expected to do research on the pharmacological testing of drugs, guide, co-ordinate and correlate the work of the provincial government laboratories and also to serve as the training ground for public analysts in the methods of chemical, biochemical and biological assay. The laboratory consists of a 'Pharmacology and Bio-assay Subsection' and a 'Pharmaceutical Subsection'.

During the three years under report, the laboratory carried out a general survey of the quality of medicinal drugs in the Indian market, both imported and locally manufactured. Specimens of drugs from various parts of India were secured and more than 1,500 samples of drugs were carefully tested by pharmacological and chemical methods. In every case a report on the quality of the sample was forwarded to the party concerned.

Digitalis, in the form of a powder, infusion or tincture, is extensively used in India and is the mainstay of physicians in certain types of cardiac trouble. Of the 163 samples of digitalis preparations tested in the

laboratory, only 22 per cent were found to be within the prescribed standard; about 14 per cent were found to be either completely inert or weak in potency and the rest varied from 30 to 79 per cent in potency.

Researches on the stability of tincture digitalis and liquid extract of ergot in the tropics have shown that the maximum period during which these two preparations may be expected to retain full potency in the ordinary storage conditions prevailing in Calcutta is about 12 months, or probably even less, from the date of manufacture.

Forty-four samples of tincture of strophanthus were biologically assayed and about 15 samples agreed with the standard while the rest were either high or low in potency. In either case the position was found to be far from satisfactory. The stability of these preparations under storage was similar to that of digitalis. Not one of the samples of tincture of scilla examined in the laboratory was found to conform to the standard potency.

Of 56 samples of posterior pituitary extract, both of indigenous and foreign origin, 19 samples were found to be below the declared potency while the rest could be considered as satisfying the potency required of them.

Only 19 samples were found to be of standard therapeutic potency out of 36 samples of liquid adrenaline hydrochloride.

Two samples (both foreign) of insulin, the well-known remedy for diabetes, were found to be satisfactory. A small number of organic, arsenic and antimony preparations were tested, both chemically and biologically, and in a few cases the toxicity results exceeded the safety limits.

About 1,400 samples of drugs, medicinal chemicals described in the *British Pharmacopœia* or the *British Pharmaceutical Codex*, including patent and proprietary medicines, were examined chemically. About 50 per cent of these were found not to conform to the standards or not to comply with the specifications claimed by the manufacturers and senders. About 75 per cent of these samples were manufactured or bottled in India.

This comprehensive survey, undertaken systematically for the first time in India, has revealed that there can be no doubt about the seriousness of the situation regarding drug adulteration in this country. Perhaps a more alarming picture would have been presented if proper arrangements were available for checking of imports, policing of manufacturing houses, frequent inspection of retail dealers' stores, etc. With the enforcement of the Drugs Act, such investigation is now possible.

With the object of warning non-ethical and fraudulent manufacturers and distributors in India and also of creating a consciousness amongst the consuming public of the importance of the problem of drug adulteration from the public health point of view, the laboratory has carried out propaganda by the publication of informative articles and through press circulars.

Tables of specimens analysed in the laboratory, a list of pharmaceutical preparations which the laboratory undertakes to assay, and samples of laboratory protocols of bio-assays are given in the appendix to the report.

ANNUAL REPORT OF THE INSTITUTE FOR MEDICAL RESEARCH, FEDERATED MALAY STATES, KUALA LUMPUR, FOR THE YEAR 1939. BY A. NEAVE KINGSBURY, DIRECTOR

The trend of the activities of the institute has proceeded uninterruptedly throughout the year, although in certain directions the tempo has been slowed by the absence on furlough of two heads of divisions. The onset of war has had little effect either on the research programme or on the volume of routine examinations that form so large a part of the duties of some of the divisions.

It appeared prudent, however, to insist on all reasonable economy of stores and to encourage the further

utilization of local resources. There has been the fullest possible co-operation of all the medical and bacteriological division no. 1, no. 2, no. 3, no. 4, no. 5, no. 6, no. 7, no. 8, no. 9, no. 10, no. 11, no. 12, no. 13, no. 14, no. 15, no. 16, no. 17, no. 18, no. 19, no. 20, no. 21, no. 22, no. 23, no. 24, no. 25, no. 26, no. 27, no. 28, no. 29, no. 30, no. 31, no. 32, no. 33, no. 34, no. 35, no. 36, no. 37, no. 38, no. 39, CORRESPONDENCE

Nov., 1941]

'clinical carriers', in five of ten 'convalescent carriers', in five of seven 'chronic carriers' and in none of three 'contact carriers' were positive results obtained. Particulars are given of certain enteric 'carriers'. Two were women whose culinary activities were responsible for the spread of infection; in one case the surreptitious sale to a mess of cakes mixed under the most unhygienic conditions resulted in several typhoid cases.

From an analysis of nearly three hundred cases of dysentery, it is found that some twenty-five per cent were due to *B. flexneri*; ten per cent to *B. sonnei*; five per cent to *B. shiga*, while *B. alkaescens*, *B. dispar* and *B. schmitz* accounted for the remainder. Attention is invited to the increasing frequency with which organisms of the *Salmonella* group are isolated from cases of diarrhoea, obscure fever, local lesions and in young children, even of meningitis. An interesting note is also included on the various micro-organisms that from the laboratory records are known to have caused cerebro-spinal meningitis.

An extensive trial of the prophylactic (gametocidal) value of plasmoquine, with particular reference to *P. vivax* malaria has been completed. The drug was given bi-weekly in an adult dosage of 0.02 gm. to a population of some 650 under almost ideal experimental conditions. The breeding of anophelines was uncontrolled and endemic malaria, mainly benign tertian, was moderately severe. The effects were decidedly disappointing for infected wild-caught anophelines continued to be taken, while newly arrived labour previously largely free from infection, and children newly born on the estate acquired malaria. Infections also occurred among anophelines experimentally applied to *P. vivax* gametocyte carriers who were known to have regularly taken their plasmoquine.

The testing of various anti-malarial remedies has been continued; at the end of the year Totaquina, Type I, 'M. & B. 744' and quinine-phenazone awaited the completion of therapeutic trials. New methods for the rapid staining of thick films have been developed; by one technique in which brilliant cresyl blue is employed for staining, the examination of a thick film is possible within two minutes of the drawing of blood.

An investigation of malaria in the Ulu Jempol Valley is being undertaken preparatory to the introduction of 'naturalistic' methods for anopheline control.

In connection with the filariasis enquiry dissections were continued until October of mosquitoes trapped from Ayer Mati on the Perak River. *Mansonia longipalpis* was in great predominance and throughout was found to be infected with larvae of *Mf. malayi*. Three *M. indiana* and two *A. umbrosus* were also infected. Filariasis exists on Penang Island in areas that differ greatly in topography from the infected districts of Perak and Pahang. Trapping was instituted and *M. uniformis* proved to be the predominant species, one of which was found to contain immature filarial larvae. It may well be that here, species other than *M. longipalpis* transmit the infection. Breeding places of *M. annulatus* and *M. ochraceus* hitherto unknown, have been discovered. The larvae, associated with *M. longipalpis* and *M. uniformis*, were attached to the roots of grass and other vegetation in partially shaded peaty water contained in drains cut through a swamp.

On Estate 'T' the finding of *A. maculatus* following extensive clearing and planting was recorded last year. Among thirty-six specimens dissected in the period under review one gland infection has been noted. *A. umbrosus* and *A. novumbrosus* continue to be the important vectors and infected specimens were trapped in all months except January, February and August. *A. novumbrosus* disappeared from August onwards. On Estate 'N.G.' *A. barbirostris*, *A. maculatus* and *A. umbrosus* were all found to be carrying.

The investigation of rural malaria in the coastal area of Selangor has been continued. Interesting results are recorded of changes in fauna following bunding to exclude sea water. Of the brackish water breeders, *A. baezi* has vanished and *A. sundasicus* is disappearing, while their place is being taken by *A. separatus*.

In the Pathological Division the sera from monkeys previously inoculated with Japanese river fever and Sumatran mite fever, and that from the immunized horse have been found to have some immunizing value. *R. orientalis* has been successfully cultured in the yolk of developing eggs up to the fourth generation; guinea-pigs inoculated with yolk and with allantoin membrane from each generation reacted in the usual manner.

Experiments with a newly isolated strain of *Spirillum minus* have confirmed that this infection in rabbits may give rise to a positive Weil-Felix reaction, the titre with OXX (alch.) sometimes raising to over 1/300. It is interesting that after positive Weil-Felix results had followed the inoculation of *S. minus* into three rabbits and titres had fallen to normal, reinoculation with Japanese river fever virus caused no re-stimulation of agglutinins although characteristic ocular reactions developed. On the other hand, restimulation of agglutinins did occur in a rabbit when *S. minus* was inoculated after an interval following Japanese river fever infection.

The 'immobility' test has been utilized for the further investigation of experimental rat-bite and Japanese river fevers. Generally, sera having high Weil-Felix titres from human and rabbit Japanese river fever cases failed to immobilize *S. minus* although with two of six human sera, immobilization in very low dilutions did occur. This test was employed to assess the proportion of wild rats infected with *S. minus*. Eight of thirty-eight rats caught in Kuala Lumpur were thus shown probably to be infected; of three rats infected with *T. lewisi* the serum of one only yielded a positive result.

An investigation has been commenced to determine how long after manufacture, the virus of rabies can be demonstrated in anti-rabies vaccine. Following the intra-testicular injection of one c.c.m. of newly prepared vaccine, two of two rabbits became infected, and after the vaccine had been stored for fourteen days, one rabbit of two developed symptoms.

Correspondence

MALARIA SPECIFICS

SIR.—We are extremely glad to let you know that we have invented an ointment which cures malaria miraculously simply by applying on a finger of any hand. We are posting two phials [sic] of the same to you as sample complete with direction, etc. Will you please try the same and let us have your opinion and views?

We are sure you will kindly comply with this request of ours and thus encourage.

. . . & Co.

[Note.—We have received the above letter. What are we to encourage, quackery? We do not propose to do so. Needless to say the 'phails' were true to their name.—EDITOR, I. M. G.]

GLAUCOMA

SIR.—I have recently come across two cases of glaucoma who have said that on first getting up in the morning vision was fairly good, but that in a short while, an hour or so, it gradually faded and became practically nil. Is this a common experience, and if so what is supposed to be the explanation? I haven't heard of it before, nor read it.

G. F. ROWCROFT, M.R.C.S.,
L.R.C.P., COLONEL.

'CULMORE',
COONOOR,
9th September, 1941.

We have referred this letter to the officer in charge of the Eye Hospital, Calcutta, who has kindly made the following comment.—EDITOR, I. M. G.]

"This is possible, and the explanation can be that the tension of the eye goes up and that there is increasing oedema of the cornea. We see this especially in epidemic dropsey glaucoma and in sub-acute attacks of chronic primary glaucoma.

Patients often exaggerate their symptoms when they say that their vision is practically *nil*. However, I have seen such a case in my own consulting room—a patient when he came in was able to see; after an hour all was very dim from the oedema of the cornea. I brought down the tension with a drop of 1 per cent eserine and the vision returned."

INSULIN REQUIREMENTS IN INDIA

Sir,—We are very interested to read the letters in your September issue, on the subject of "Insulin Requirements in India."

This most important preparation has now had further restrictions placed upon its importation by the Government of India in their notification of the 23rd August.

Insulin is classified by the Customs Authorities as a "Chemical, Drug or Medicine, not otherwise specified" under Tariff No. 28, and is therefore included under Serial No. 13 of Part B of the Schedule, issued by the Government of India in their "Gazette of India Extraordinary", and also by the Import Trade Controllers in their respective Public Notices.

The basic period on which licences will be given out has been fixed as between the 1st April, 1940, and the 31st March, 1941, in respect of Serial No. 13. During this period, stocks of German and Danish insulin were still available, and, therefore, the importation of insulin from America was not so heavy as it is at the present time.

One has to face the fact that, in spite of all possible effort to help the export of products from Britain, that country unfortunately has grave problems of her own: in the first place, many manufacturing concerns have been thrown out of gear by the attention of the "Luftwaffe"; secondly, serious labour shortages have occurred owing to the calling-up of so many men for military duties; thirdly, a very large percentage of production to-day is needed for government and military purposes, and on top of all this comes the shipping question, which is still serious.

Even before the war, certain well-known brands of insulin manufactured in America were very popular in this market—and justly so, because of their reputation and the high standard of their products. To-day if insulin is to be obtained one must look more and more

to these American companies for help—yet, at this stage, the Government of India impose restrictions, and the quotas are to be based on a year which has little relation to present requirements!

With regard to the question of manufacture in India, this of course is a very desirable extension of the present rapidly-growing Indian pharmaceutical industry, but whatever can be done in this direction must be in the future, and there are several very pretty problems which will have to be solved. The present position is that there is a serious shortage of insulin in this country, and the position will rapidly get worse under the restrictions imposed by the Government of India.

We notice that Dr. J. P. Bose states:

"The manufacture and the standardization of insulin can be taken up by any of the big manufacturing concerns in India."

This may be so, but once again one comes down to the hard fact as to *when* such supplies would be available. Presuming that ample supplies of raw material are available in India, there is, firstly, the question of the necessary licence to manufacture.

Secondly, the all-important question of standardization and strict control on the finished product.

Thirdly, the supply and erection of the necessary complicated plant in the manufacture of insulin on a commercial scale—which is not, by any means, the same as making insulin for experimental purposes in a laboratory.

And, fourthly, the supply of the necessary neutral glass ampoules or phials and supplies of the special rubber caps and closures.

These are not problems that can be solved overnight, and the Indian pharmaceutical industry, even with the best will in the world, could not suddenly make available ample supplies of insulin.

We would therefore suggest that the medical profession in particular, and the medical, chemical and pharmaceutical associations in general, impress upon the Government of India the grave problem with which we are faced to-day, and request them to immediately withdraw the present restriction, not only on insulin, but on the importation of other urgently-needed and important biologicals and drugs of a like nature.

G. W. GOSLING,

Director,
Martin and Harris, Ltd.

BOMBAY,
25th September, 1941.

Service Notes

APPOINTMENTS AND TRANSFERS

THE VICEROY AND GOVERNOR-GENERAL has been pleased to make the following appointments on His Excellency's personal staff:—*To be Honorary Surgeons*

Colonel H. E. Shortt, C.I.E., vice Colonel T. C. Boyd, vacated. Dated 14th February, 1941.

Brevet-Colonel (local Brigadier) B. C. Ashton, vice Colonel H. J. M. Cursetjee, D.S.O., vacated. Dated 23rd February, 1941.

The services of Lieutenant-Colonel J. P. Huban, O.B.E., Additional Deputy Director-General, Indian Medical Service, are placed at the disposal of the Government of the North-West Frontier Province, with effect from the 19th August, 1941 (forenoon), for appointment as Inspector-General of Civil Hospitals and Prisons and Director of Public Health, North-West Frontier Province.

Lieutenant-Colonel S. L. Bhatia, M.C., is appointed Additional Deputy Director-General, Indian Medical Service, with effect from the 19th August, 1941

(forenoon), vice Lieutenant-Colonel J. P. Huban, appointed Inspector-General of Civil Hospitals, North-West Frontier Province.

Lieutenant-Colonel R. F. D. MacGregor, C.I.E., M.C., is appointed Additional Deputy Director-General, Indian Medical Service, with effect from 12th September, 1941.

On his reversion from Military duty Major C. J. Joyce assumed charge of the office of the Civil Surgeon, Amritsar, on the forenoon of the 18th April, 1941.

Major E. A. O'Connor, an Agency Surgeon, is employed to officiate as Chief Medical Officer, and Inspector-General of Prisons in Baluchistan in addition to his own duties as Civil Surgeon, Quetta-Sibi, with effect from the afternoon of the 5th July, 1941.

The services of the undermentioned I.M.S. Officers are placed at the disposal of the Government of India in the Defence Department with effect from the date noted against each:—

Major E. G. Montgomery. Dated 27th June, 1940 (afternoon).

Captain F. W. Allinson. Dated 6th September, 1940 (afternoon).

Captain J. W. D. Goodall. Dated 14th December, 1940 (forenoon).

Major F. H. A. L. Davidson. Dated 19th June, 1940 (afternoon).

Lieutenant-Colonel B. H. Singh, M.C. Dated 14th May, 1941 (afternoon).

Lieutenant-Colonel B. G. Mallya. Dated 15th May, 1941 (afternoon).

Captain P. I. Franks. Dated 16th May, 1941 (afternoon).

Major C. L. Pasricha. Dated 15th March, 1941 (afternoon).

Major R. Linton. Dated 11th June, 1941 (afternoon).

Lieutenant-Colonel J. C. De. Dated 9th July, 1941 (afternoon).

Captain W. H. Niblock. Dated 15th August, 1941 (afternoon).

LAND FORCES

(Emergency Commissions)

The undermentioned Captain (on probation) is confirmed in his rank, subject to His Majesty's approval:—

L. R. Flowers. Dated 17th February, 1941.

The undermentioned Lieutenants (on probation) are confirmed in their rank, subject to His Majesty's approval:—

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints gratis; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more, after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributors should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

ENDEMIC TYPHUS IN MYSORE

By ROBERT HEILIG, M.D.

Professor of Medicine, Medical College, Mysore
and

V. R. NAIDU, M.R.C.P. (Lond.), etc.

Professor of Pathology, Medical College, Mysore

HANS ZINSSER's book *Rats, Lice and History* has depicted impressively the important rôle of typhus in the cultural evolution of the human race. The epidemic form of the disease has even changed the history of nations. A certain uniformity in the symptomatology has been established in the louse-borne epidemic form as a contrast to the numerous endemic forms. The manifestation of the tsutsugamushi fever of Japan, the Mexican tabardillo fever, the spotted fevers of different localities are examples of such endemic varieties.

In spite of the divergent manifestations of endemic typhus, four signs are more or less constant, though certainly not all of them are to be found in every individual case: fever, rash, agglutinins to a proteus strain (Weil-Felix test) and the presence of Rickettsia bodies, demonstrable by animal inoculation. Three of these signs, for example, fever, rash and positive Weil-Felix reaction, or fever, rash and Neill-Mooser reaction, are sufficient to make a diagnosis proof against any doubt; even fever and a typical rash combined with other characteristic clinical features are a firmer ground for the diagnosis of typhus, than fever and Weil-Felix reaction without a rash, though recently such cases have been reported as definite typhus cases from Bombay (Patel, 1940) and from Bangalore, where only 12 out of 56 cases had a typical rash (Sharma, 1940).

Many interesting case reports have been added to the literature on typhus from India since the first publication of Megaw (1917) on the subject. In his later reports, he classified the Rickettsial diseases as louse-, tick-, mite-, and flea-borne depending upon the vectors. This has given an impetus to the investigation of the possible vector in localities where, off and on, a few endemic cases occur. Recently, we observed four clinically pathognomonic cases in the Krishnarajendra Hospital between November 1940 and February 1941 and the case reports with pathological investigations are submitted.

Case report

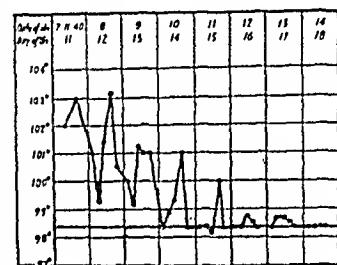

Case 1.—Hindu Brahmin, Jail Superintendent, Mysore City, age 37, admitted 7th November, 1940:—

Eleven days prior to admission, the patient, who had been in perfect health for many years, fell ill with severe headache and mild symptoms of a cold and fever: the temperature was nearly normal (99°–99.2°) every morning, and shot up every evening between 4 and 5 p.m. to 102°F.–103°F., accompanied by a

chilly feeling (never by a rigor), and increased headache; on the 9th day of the fever, the patient observed a pink rash on the forearms, hands and legs, which spread the next day (10th day) to the back and to a less extent on to the chest. The next day (the 11th day) on admission.

Case 1. Mr. S. I.

We found the rash very distinctly visible on the patient's fair skin, more or less regularly distributed on arms, legs, chest and abdomen and especially numerous on wrist, palms of the hands, feet and the back; the face was free. The efflorescences were discrete and nowhere confluent. The macular and maculo-papular rashes were pinkish and faded on pressure; while the ecchymotic ones were dark purple in colour and failed to fade on pressure. Apart from the rash the patient showed a well-marked conjunctivitis. No pathological signs were present in the heart, lungs, or in the nervous system; the tongue was moist and furred; the liver and spleen were not enlarged. The temperature on the day of admission reached 103°F., pulse rate 124, respiration 28 per minute. The patient complained of pronounced headache, poor appetite and slight constipation. On the following three days the rash did not change much, except for the spots on the wrists, feet and palms getting darker and browner with a copperish tinge. The following week the macular and maculo-papular non-petechial rashes began to fade gradually, while those ecchymotic ones on the hands, feet and on the back remained distinctly visible by deep pigmentation. The temperature which was swinging from 99.2° at 8 a.m. to 103°F. at 4 p.m. on the 12th day reached 101.2° on the 13th, 101° on the 14th, 100° on the 15th day and remained nearly normal, not exceeding 99°, on the 16th and 17th days, and became perfectly normal from the 18th day onwards. The pulse rate varied according to temperature, coming down to 84 on the 17th day. Convalescence was short and complete recovery soon followed.

Laboratory findings

Urine and stool examination.—Nothing abnormal.

Blood examination.—On the 13th day: leucocytes—12,800.

Differential picture: Polymorphonuclear—71 per cent. Lymphocytes—23 per cent. Monocytes—5 per cent. Eosinophils—1 per cent.

No malarial parasites.

Malarial-flocculation test (M.F.) negative.

Widal for typhoid, paratyphoid A and B: negative on the 12th and 16th day.

Weil-Felix: OX19, OXK, OX2 negative on the 14th day and 18th day.

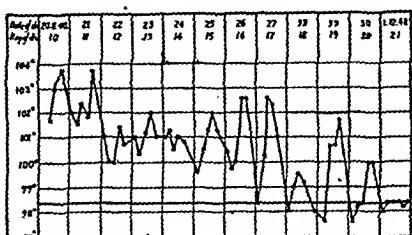

Wassermann	Kline
++	D E
	+++

A fortnight later all were negative.

Regarding the vector question, lice were improbable as the patient was a man of clean habits. Neither lice nor eggs were found on his clothes. Tick- and mite-bite was definitely denied and it was most improbable as he neither left the city nor had any close contact with cattle. But when we asked for possible contact with rats, he implored us to help him to get rid of them as he estimated the rat population of his house as several hundreds.

Case 2.—Hindu Brahmin, wife of a medical college student, age 21, was admitted on the 20th November, 1940, complaining of continuous fever for 10 days, varying daily between 100° or less in the morning and 103° to 104° in the afternoon; no rigor but severe

Case 2. Mrs. L.

headache and joint pains in all limbs. Two days prior to admission—on the 8th day of fever—a pink rash appeared on arms and thighs, spreading the next day to the hands, feet, back and much less to chest and lower abdomen; face and neck however remained free. Patient complained of loss of appetite and considerable constipation. Bowels moved only by enema. On admission, we found the slim but well-built lady without any pathological signs in the heart, lungs and abdomen. The tongue was moist and furred; liver and spleen not enlarged; very definite conjunctivitis; the painful joints showed no redness or swelling; the rash consisted of macular, maculo-papular and petechial spots of lentil-size and of pink to purplish colour, distributed as in case 1, everywhere very distinctly visible, leaving face and neck free; temperature on the 10th day at 5.30 p.m. was 104°F , pulse rate 124, and respiration 26. The further course showed remittent fever up to the 16th day, minimum near 99° and maximum between 102° and 104° ; intermittent fever continued from the 17th to the 20th day, the maximum on the 19th day being still 103° , on the 20th day 101° , from the 21st day, normal; the pulse rate corresponded with the temperature. The convalescence was rapid and uneventful. Pigmented spots remained clearly visible on the fair skin for several weeks, especially on forearms, wrists and palms of the hands and ankles; they were still faintly present on the ankles even 7 months later.

Laboratory findings

Urine examination.—A small amount of albumin and a few granular casts, both absent on the 20th day.

Stool examination.—Nothing abnormal.

Blood examination.—On the 11th day: Leucocytes—11,200 per c.mm.

Differential picture: Polymorphonuclears—67 per cent. Lymphocytes—28 per cent. Monocytes—4 per cent. Eosinophils—1 per cent.

On the 16th day: leucocytes—9,200.

Malarial parasites not found.

Malarial flocculation (M.F.) negative.

Wassermann reaction—negative.

D E
Kline ++ ++

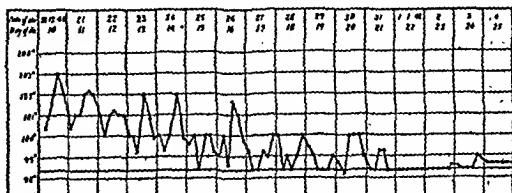

Lice could be excluded by the patient's social standard and by examination; tick- and mite-bite was definitely denied. But the young couple lived for several weeks, until about seven days before the fever started, in a village 14 miles from Mysore, swarming with rats.

Case 3.—Mohammedan, age about 45, wife of a grain merchant, living in Nanjangud, 15 miles from Mysore City, was admitted on 20th December, 1940:—

Ten days ago fever and bad headache started, the temperature coming down in the morning, rising without rigor but accompanied by a chilly feeling every

afternoon. The patient felt very weak, had no appetite, and was slightly constipated. Nine days after the fever began, a rash appeared, observed first on the face and simultaneously on arms, hands, legs and dorsum of the feet, the next day on abdomen, back and sacral region. On admission, the tall and strongly built

Case 3. Mrs. S. K. B.

patient complained of unbearable headache but no other pains, complete loss of appetite, repugnance for food, dryness in the mouth and thirst. The tongue was dry and covered with dark brown crusts; the eyes blood-shot; heart and lungs showed nothing abnormal; abdomen soft, not tender; liver not enlarged, spleen slightly enlarged. In spite of the dark skin of this patient a rash was so distinctly visible that it was quite impossible to overlook it; discrete maculo-papular and petechial efflorescences of deep purplish or copper-red colour and lentil to twice lentil-size covered the forehead, back and sacral region, abdomen, arms, hands, thighs, calves and dorsum of the feet in almost uniform distribution; on the chest only a few spots were present. Some of the slightly elevated papules disappeared on pressure, but most of the dark spots remained visible, due to their petechial character. Temperature was remittent between 100° and 103° up to the 14th day; intermittent, coming down by lysis from the 15th to the 21st day; and remained normal from the 22nd day; pulse rate 130 on the 11th day, 84 on the 22nd day. The patient's condition became restless and from the 13th to the 16th day she was almost comatose and could not be awakened from her 'typhoid' state. She passed urine and stool unconsciously. From the 17th day onwards with a temperature not exceeding 100° and a pulse rate below 100, she became clearer hourly and perfectly normal on the 20th day. She recovered from then on surprisingly quickly and left the hospital in good condition on the 20th day. At that time pigmented remains of the rash were distinctly visible all over the body with slight peeling on wrists and palms of the hands. When we saw the patient six weeks later, on the 3rd March, 1941, pigmented spots were still present on the palms and dorsum of the feet.

Laboratory findings

Urine examination.—Albumin in traces; a few red cells present.

DEC., 1941]

ENDEMIC TYPHUS IN MYSORE: HEILIG & NAIDU

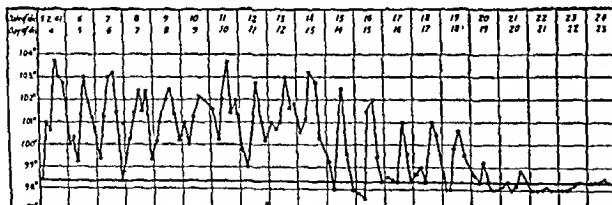

Malarial parasites not found.
 Malarial-flocculation (M.F.) positive.
 Widal: for typhoid and paratyphoid A and B: 13th day negative.
 Weil-Felix: for OX19, OXK, OX2 (17th, 21st and 9 weeks later): negative.
 Wassermann: 13th day \pm
 20th day \pm
 9 weeks later negative.
 Kline: 13th day D E
 \pm +
 20th day + +
 9 weeks later negative.
 Kahn: 20th day and 9 weeks later negative.

We tried also in this case to get some information about the vector. The patient and her family were clean and well-to-do people, and certainly not infested with lice. All our questions regarding the possibility of tick- or mite-bite or any sore, glandular swelling or groin pains as a result of it were denied. We were however assured by the patient and her relatives on questioning, that there were undeniably a large number of rats in her house. In order to investigate the truth, we sent one of our final year students to Nanjangud who spent a day with them. On return, he described that there was no separate godowns for storing their grain but the bags were stacked actually in the living room and the rats were rampant. It was surprising to learn from him that the rats lived as though they were part of the family and when the lady had returned from hospital to her home, she noticed a rat nest beneath her pillow.

Case 4.—Hindu-Vokaligar, a high school student, age 17, living in a village on the outskirts of Mysore City, admitted 5th February, 1941:

The only complaints of the well-built patient were continuous fever and severe headache for the preceding three days. There was no rigor, no cough nor other

Case 4. Mr. H. S. H.

pains. The only objective findings on admission (4th day) were conjunctivitis, a whitish fur covering the moist tongue, a slightly congested pharynx and a doubtfully palpable spleen. Temperature was deeply remittent, varying every morning between 99° and 100°F , every afternoon between 103° and 104° up to the 15th day, becoming gradually lower from the 16th and remaining normal from the 20th day on; pulse rate came down from 120 on the 6th to 82 on the 20th day. On the 10th day from the beginning of the fever a rash appeared on the forearms, the dorsum of hands and feet, spreading on the 11th day to the extensor surface of the legs and the palms of the hands, and on the 12th day over the whole back, developing also a few spots on the lower abdomen and very few on the chest. On the dark skin of the boy the brownish-purplish colour of the maculo-papular spots as seen in figure 1 and figure 2 were better visible than the subcuticular petechial spots which became more distinct on the following days. The appearance of the rash had

no influence on the temperature or on the general condition; the patient continued to complain of headache, weakness and lack of appetite, especially when the fever rose every afternoon. From the 15th to the 20th day the rash faded gradually on arms and legs leaving behind dark brown spots in great numbers on hands and feet clearly visible for at least 3 weeks after the temperature had subsided and complete recovery was achieved. Peeling was present during the fourth week.

Laboratory findings

Urine examination.—Nothing abnormal.
 Stool examination.—Pin-worm ova found.

Blood examination

Days of illness	Leucocytes per c.m.m.	Polymorphonuclear percentage	Lymphocytes percentage	Monocytes percentage	Eosinophils percentage

Kahn: 12th day negative.

22nd day negative.

Neill-Mooser's reaction

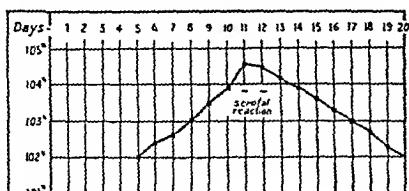

On the 11th day, a day after the rash appeared, 5 c.c.m. of the patient's blood was injected into two guinea-pigs intraperitoneally. On the 5th day the animals' temperature shot up and continued high for nearly 15 days, varying between 102° and 105°F . On the 9th and 10th day the two animals showed definite swelling and tenderness of the scrotum (Neill-Mooser's reaction). On the 12th day cardiac blood drawn from the guinea-pigs were re-injected intraperitoneally into other animals and reproduced the disease in the second group. Weil-Felix tests done by the blood drawn from these guinea-pigs on the 12th and 20th day were less than 1 in 40 for OX19, OX2 and OXK and can be considered to be negative.

A typical temperature chart and a picture taken during the height of the scrotal reaction are reproduced here (figure 3).

Two of the animals were killed on the 16th day of the infection and imprint preparations were made from the tunica vaginalis and stained with Castañeda's stain. Paraffin sections from

brain, spleen, liver, kidneys and muscles were also examined microscopically. The sections of brain, kidneys and muscles did not reveal anything pathognomonic. In the spleen and liver however there was evidence of proliferation of endothelial lining cells in the smaller vessels and the thickening of the vessel walls. Neither Rickettsial bodies in the endothelial cells nor adventitial reaction were present in these.

Temp Chart and Scrotal reaction Guinea-pig No 1

The imprint preparations showed large numbers of intra- and extra-cellular small coccoid Rickettsial bodies, measuring roughly 0.25μ to 1μ , taking up a lilac tint. Most of them were intra-cytoplasmic and none intranuclear. The extra-cellular ones were associated with ruptured and mangled cells. In some cells they were in several hundreds and in others only a few.

Again lice, ticks and mites were improbable as Rickettsia-conveying factors. The patient was perfectly clean, and his hair well kept; he denied having been bitten by ticks or mites, or having observed on his body any marks of such a bite described by us to him. We were told that plenty of rats lived in his house and to make sure about the local conditions, we went to his dwelling place, a village near Mysore, and found the living room of the family crammed with *ragi* and *dal* sacks. The adjoining bedroom of our patient was in open communication with the loft, which was swarming with rats.

Clinical picture summarized

Sudden onset with malaise, severe headache, occasional joint pains, chilly feeling, but no rigor. *Temperature* is high from the beginning, of remittent character, returning to normal by short lysis towards the end of the third week. *Pulse* and *respiration* rate are increased according to the temperature. *Conjunctivitis* appears very soon and is a prominent feature for the first two weeks or longer, giving the eyes a blood-shot appearance. *Tongue* moist, covered with a white fur in the milder, dry and coated with brown crusts in the severer cases. *Spleen* just palpable or not enlarged. The *mental condition* was clear in three and seriously obscured in one of our cases, who remained for several days in a typhoid state.

A maculo-papular rash appears by the end of the first or the beginning of the second week; its colour varies according to the intensity of the patient's pigmentation from pink to dark purplish or copper colour; the single efflorescences remain discrete, do not fuse together and many of them are petechial in character,

not fading on pressure. The rash is very distinctly visible and shows the richest development on wrists and palms of the hands, on the arms, the dorsum and soles of the feet and the legs, less on back and abdomen, the least on chest and face. A slight peeling occurs when the fever subsides. Brown pigmented spots, remainders of the rash, are visible—especially on hands and feet—for weeks or even months afterwards.

A moderate leucocytosis with a normal differential picture is a regular feature.

Weil-Felix test for OX19, OXK and OX2 was negative in these cases during the fever and the convalescence. Wassermann, Kahn and Kline reactions were sometimes positive at the height of the rash and became negative very soon in the convalescence.

Neill-Mooser reaction was positive in guinea-pigs injected with the blood of case 4.

Rickettsias have been found in the tunica vaginalis testis of the guinea-pigs that showed the Neill-Mooser reaction.

Vector: All patients lived in extremely close contact with rats.

Discussion

The diagnosis of endemic tropical typhus appears to be beyond doubt from the evidence reported, the clinical picture conforming with no other disease. In fact one of us (Heilig) reported cases 1, 2 and 3 and demonstrated case 4 as belonging to the group of 'endemic typhus', even before the confirmatory serological, animal inoculation or bacteriological findings, on pure clinical grounds alone*.

A few days later one of us (Naidu) succeeded in producing the typical Neill-Mooser's reaction and demonstrated the Rickettsias in the guinea-pigs injected with the blood of case 4. The last case resembled so closely the other three in the clinical signs that the same diagnosis may be considered as established for them as well.

Megaw's ingenious classification of all known Rickettsioses according to the different vectors and Fletcher's discovery of the two distinct forms of typhus in the Malay States conveyed to man by two different vectors, makes one generally realize the great importance of the vector question for solving the puzzling typhus problem. In the louse and the mite-borne typhus the clinical symptoms are diagnostic of the vectors, while in the case of rat-flea and tick-typhus it seems to be more difficult. In our cases the diagnosis of louse-typhus was excluded on epidemiological, clinical and social grounds. The reported cases came from towns far apart, with no familial incidence. The patients were free from lice and nits, and belonged to a social class used to cleanliness. The rash did not appear on the 4th, as in the louse-typhus, but between the 8th and the 10th

day, the fever lasting longer than the typical period of a fortnight even in the mildest of these cases. There was no circulatory disturbance and the convalescence progressed much more quickly than in louse-typhus.

The mite-typhus cases have the characteristic signs of mite-bite in common: infiltration or even ulceration at the point of the bite and more-or-less painful regional lymphadenitis. None of these signs were present in our cases and in fact no cases of mite-typhus have been yet reported from South India. Some have been reported from Punjab (Yacob, 1937) and Burma (Martin and Anderson, 1933). There is no reason to assume that mite-typhus was among our cases.

The survey of literature of Indian typhus shows that apart from Yacob's (1937) cases (Punjab), the only vector established beyond doubt in India or suspected with good reasons is the tick, as reported by Megaw (1917), Megaw, Shettle and Roy (1925), Ghose (1928), Pai (1931), Mukerji (1932), Blewitt (1934), Sachs (1934), Stott (1935) and Shortt and D'Silva (1936). Others, Norman and Rama-chandran (1925), Biggam (1932) in his excellent report of three cases observed in Bangalore and Macnamara (1935) could not trace the vector at all. Boyd (1935) analysed 110 cases reported from military stations in India in 1934, but in spite of the interesting results of his analysis he did not succeed in ascertaining the vector in more than a small minority of the reported cases. New ways of approaching the vector problem have been discussed by Napier (Editorial, 1936).

Our patients denied tick-bite definitely. No trace of tick-bite was seen on them and none of them had entered a jungle previous to the onset of the disease. Moreover, they differed clinically from those cases where tick-bite was ascertained as preceding the typhus; for these reasons we are unable to label the cases as 'tick-typhus'. There is however evidence strongly in favour of the rat-flea being the vector. The seasonal incidence (November to February), the non-epidemic character, the habitation in rat-infested houses, the presence of grain stores which harbour rats, are similar to the cases reported by Hone (1927), Fletcher and Lesslar (1925), in the Malay States, Maxcy (1926), in the south-east United States and many others from Syria, Greece, Roumania, France, North Africa, China, Indo-China, South America, etc. The final discovery of Rickettsias in the rat-flea trapped in typhus areas (Baltimore and Savannah) by Dyer *et al.* (1932), thus confirm and close the diagnostic and epidemiological ring.

The presence of inguino-scrotal reaction in guinea-pigs (Neill, 1917; Mooser, 1929), the demonstration of Rickettsia bodies in the tunica vaginalis, and the absence of any brain lesion, are features strongly in favour of rat-flea typhus. It may be mentioned here that Neill-Mooser's

reaction with demonstration of Rickettsia bodies after the injection of patient's blood has not been previously described in India so far as we know, even though Covell (1936) had produced Neill-Mooser's reaction in his experimental investigations in Simla, and Goyal (1941) found (apparently non-pathogenic) Rickettsia bodies in rats in Calcutta.

Our investigations of rats trapped in our patients' houses have not yielded any definite results up to the present time. We hope to be successful at the time of or just preceding the local seasonal maximum incidence of typhus.

We do not want to review here the huge literature on the Weil-Felix reaction. We mention as important for our question the investigations of Spencer and Maxcy (1930) and Felix and Rhodes (1931).

As the Weil-Felix reaction in our cases was negative for OX2, OXK and OX19, in spite of the fact that fresh antigen from Kasauli was used, we presume that a proteus-strain different from these three may be para-specific for this group. In this connection it is interesting to compare our cases with the groups classified by Boyd (*loc. cit.*). He used the agglutinated proteus-strain as the principle of classification. There is no doubt that our cases show resemblance with his OX2 group and the Ahmednagar-Poona type of the OX19 group in many respects. The late appearance of a very distinct rash, present in almost all Indian patients, its petechial character, its long duration and the remaining pigmented spots, its regular development on the limbs, on the palms of the hands and on the feet are clinical features, distinctly different from those in Boyd's OXK group and his other OX19 types (Bangalore group and mixed cases). These facts point towards an important relationship between his OX2-Ahmednagar-Poona cases and our observations. And in this combined group particularly the agglutinin titres are low and inconstant; co-agglutination far higher than in the other cases, so that Boyd assumes that neither OX2 nor OX19 are the main antigens of this group, but that the agglutination is only 'a group reaction to some other virus'.

There are many reports of a positive complement-fixation test (Wassermann reaction) in the epidemic louse-borne typhus; a similar feature is not uncommon in the Indian endemic typhus (Stott, Boyd and others). In all our cases either complement fixation, or flocculation, or both serological changes have been present, and they became negative early in the convalescence.

Summary

1. Four cases of endemic tropical typhus have been described.
2. The clinical picture of Mysore typhus is summarized.

TRICHOSTRONGYLUS INFECTION IN MAN

By P. A. MAPLESTONE, D.S.O., D.Sc., M.B., B.S., D.T.M.
(From the Helminthological Research Laboratory,
School of Tropical Medicine, Calcutta)

INFECTION of man with certain species of the genus *Trichostrongylus* has been recorded in several parts of the world, including India, since it was first found by Looss in Egypt in 1895. As a rule the infection is uncommon and only a few worms appear to be present at a time. As far as I am aware, the worms never give rise to objectionable symptoms, so the infection is looked upon as of little more than scientific interest, and on this account it has not attracted the attention of medical practitioners, even in places where experience indicates that it might be fairly often encountered. But there are other

(Continued from previous page)

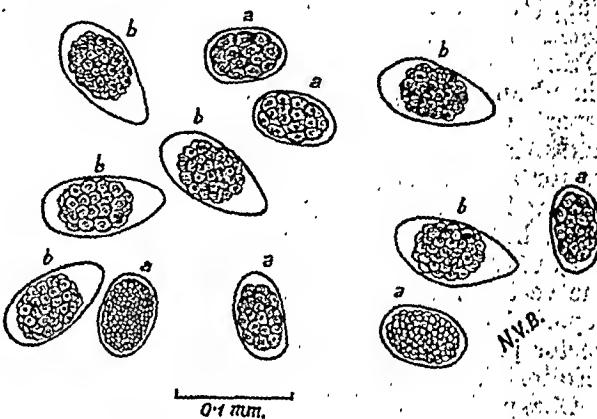

3. Positive Neill-Mooser reaction and presence of Rickettsia bodies are demonstrated.
4. The vector is most probably the rat-flea.
5. The reasons for the negative Weil-Felix reaction have been discussed.

aspects of the subject than the above which render it of some practical importance.

It is very difficult and usually impossible to get rid of this infection by any known anthelminthic, so it has been stated by more than one worker that failure to distinguish the egg of these worms from those of hookworms will lead to a false impression of the value of an anthelminthic used against the latter worms. This is undoubtedly a point worthy of consideration but in my opinion there is another and still more important aspect of the matter from the practical point of view, and one of which I have had a good deal of personal experience. In the past few years, I have had a number of patients referred to me as suffering from an 'incurable hookworm infection' because they were still passing eggs after several treatments with recognized efficient hookworm drugs. All of these patients have been found to be passing a few eggs of a species of *Trichostrongylus*, but no hookworm eggs. The fact is that because

Camera lucida drawing showing six hookworm eggs (a) and six trichostrongylus eggs (b).

their medical advisers failed to recognize the eggs these unfortunate people had been needlessly and ineffectively subjected to repeated treatments that are always objectionable and in the case of thymol, carbon tetrachloride and oil of chenopodium not without a certain degree of danger. The chance of this error arising has increased in the last few years because egg concentration methods are now much more widely employed than they were formerly in the diagnosis of intestinal helminthic infections, and these eggs, always few in number, are much more likely to be found now than when a plain faecal smear was used.

Distribution in India.—The worm appears to be widely prevalent in India and in some districts it is of fairly frequent occurrence, but the records are not generally known and are liable to be missed by the general reader because they nearly always appear in appendices or footnotes to survey reports dealing with commoner and more important intestinal helminths. The records given below show that the infection seems to have been found almost everywhere in India where large numbers of stools have been

TRICHOSTRONGYLUS INFECTION IN MAN:
P. A. MAPLESTONE

Photomicrograph showing three hookworm eggs and
three trichostrongylus eggs.

examined and the places are so far apart that it suggests that this infection is probably nearly, if not quite, as widely spread as hook-worm infection.

Boulenger (1920) found 1.2 per cent of Indian hospital patients in Mesopotamia in the 1914-1918 war to be passing trichostrongyle eggs. He pointed out that the number of times he examined the stools of each man was too few to render it probable that he had discovered all the infections, and he estimated that his figure was probably no more than half the actual rate. As concentration methods were not then in use it seems that even his estimate of about 2.4 per cent would be too low. In an extensive survey throughout India, Chandler (1926 and 1927), using Lane's centrifuge technique, found ten per cent or more positives in several tea gardens in the Bengal Dooars, and he estimated the general infection rate for Bengal as a whole to be about 1 per cent. In Chota Nagpur he found only two cases, and in North-Western India about 1 per cent were infected. In Bombay Presidency the infection was widespread with rates varying between 1 per cent at Poona and 9 per cent at Dharwar in the south, and in Madras Presidency the rate was 0.5 per cent. In Mysore, Sweet (1929) using a simple salt flotation method recorded 0.4 per cent among his total examinations of over eleven thousand stools.

Since 1930 the figures for helminthological examinations of all cases have been published in the annual reports of the Calcutta School of Tropical Medicine and in the eleven years concerned 15,578 stools have been examined in in-patients and out-patients, and 173 trichostrongyle infections have been found, that is 1.1 per cent. Maplestone (1930) in a series of periodical examinations in two tea gardens in the Bengal Dooars found an infection rate varying between 9.1 and 25 per cent, depending on the season when the examinations were made, and in a special examination of fifty Europeans in the practice of a doctor in the same district I found five (10 per cent) infected.

There are no published records of the occurrence of *Trichostrongylus* in Assam, but in records of stool examinations done there some years ago, for other purposes than recording worm infection rates, I found the eggs of this worm twenty times in about two thousand examinations. Seven cases came from Upper Assam and the other thirteen from Sylhet Valley. In all this work D.C.F. was used.

Helminthological considerations.—The family *Trichostrongylidae* Leiper 1912 is an extremely large group of nematodes having genera or groups of genera with particular morphological characteristics, which parasitize practically all animals (sens. lat.) and as a general rule display a considerable degree of host specificity. Up to the present, several species of the genus *Trichostrongylus* Looss 1905 have been found in man but, with one possible exception, these

worms appear to be natural parasites of other mammals and only to parasitize man occasionally, in other words they differ from most of the worms in this family in not showing much host specificity. The exception is *T. orientalis* Jimbo 1914 as he described this species after finding it at 20 out of 45 *post mortems*, previously having seen the eggs in many stools and differentiated them from hookworm eggs (Jimbo, 1914). Three other species have been found in man and none of them seem to have very definite host specificity because, according to Looss (1905), *T. colubriformis* (Giles, 1892) has been found in sheep, antelope, camel, monkey and man, *T. probulurus* (Railliet, 1896) in sheep, antelope, camel and man and *T. vitrinus* Looss 1905, in sheep, camel and man. Recently Maplestone and Bhaduri (1940) recorded *T. colubriformis* six times in 100 dogs in Calcutta a fact which, taken in conjunction with the wide range of hosts listed above for this species, suggests the possibility that a more important factor in determining its host is the opportunity afforded to the larvae of gaining entrance into any mammal rather than the type of mammal itself. There appear to be no records of identification of the species of *Trichostrongylus* living in man in India; all the reports given above refer to finding of eggs in the stools alone, but it is generally assumed that the species is *T. colubriformis*, which was first described by Giles in India. I am inclined to agree with this general opinion because the egg measurements correspond fairly closely to those given in most textbooks for the eggs of this species, and it is very common in this country in its normal host, the sheep.

Life history.—According to Koino (1925), who worked with *T. orientalis*, the eggs hatch in a similar manner to hookworm eggs and after the second moult produce a sheathed infective larva in three or four days, at a suitable temperature. In experiments on mice he traced the migration of the larvae and they seemed to follow the same route as hookworm larvae do; he obtained penetration and migration to the lungs both by the oral route and through the skin; so it seems probable that human beings acquire trichostrongyles in the same manner as they acquire hookworms.

Diagnosis.—The differential points between trichostrongyle eggs and hookworm eggs are that trichostrongyle eggs are larger and have one pole distinctly more pointed than the other, much more like birds' eggs in shape than hookworm eggs which present a regular oval, both poles being equally broadly rounded.

The accompanying photomicrograph and scale drawing have been made from a preparation artificially prepared by mixing trichostrongyle eggs and hookworm eggs obtained from the stools of two different patients by D.C.F. and placed in water immediately, before the salt solution had had time to alter their contours.

and

B. C. CHATTERJI, M.B., D.P.H., D.T.M.

(From the Calcutta School of Tropical Medicine)

Introductory

In the present study, an attempt has been made to evaluate the effect of sulphанилгуанидине in the treatment of cholera. This

(Continued from previous page)

It will be noticed that in the drawing all the trichostrongyle eggs clearly show that one pole of the egg is more pointed than the other, whereas in the photograph this character is not always so obvious. This is because in making a drawing it is possible to focus each egg separately and thus obtain an optical section of the shell passing through the most pointed part, but in taking a photograph some of the eggs are lying with their pointed ends either a little above or below the exact median horizontal plane so the end curve is somewhat broader and more nearly approximating to the contour of a hookworm egg, but even in these the difference in size is quite sufficient to render their identification easy.

Twenty hookworm eggs and twenty trichostrongyle eggs were measured in the same preparation as that from which the illustrations were made. The hookworm eggs varied between 66.2 and 57 μ in length and 42 by 38 μ in breadth with a mean of 62 by 40.8 μ and the trichostrongyle eggs varied between 96.5 and 80.2 μ in length by 55.3 and 42.4 μ in breadth, with a mean of 88.8 by 48.3 μ . These series of measurements may be taken as very fairly representative of the dimensions likely to be found in India for the eggs of these worms, but it is quite possible that the maximum and minimum figures may be occasionally exceeded. The differences both in shape and size of these eggs will be much more readily appreciated by a glance at the illustrations than by the written descriptions and measurements.

compound was kindly supplied to us last December through the courtesy of Professor E. K. John Marshall, Jr. and the Calco Chemical Co., and of E. R. Squibb and Sons, New York, through their representatives in India.

Sulphанилгуанидине, for the sake of brevity called sulphaguanidine, is a sulfonamide derivative and is distinguished from allied compounds by reason of its solubility in water and low absorbability from the ~~enteric tract~~ tract (Crossley, Northey and ~~et al.~~). This causes it to remain in the intestines and to exert strong antibacterial effects. It is, therefore, likely to be beneficial in enteric infections such as acute bacillary dysentery, enteric fever, cholera and similar conditions. Marshall *et al.* (1940) found that the concentration of the drug was higher in the intestine than in the blood. In this respect it resembles those sulfonamide derivatives which act as urinary antiseptics.

Toxicity and medicinal use.—Studying the toxicity of the drug Marshall and Litchfield (1939) found that sulphaguanidine was less toxic than sulphapyridine in dogs. According to van Dyke, Greep, Rake and McKee (1939) 2 per cent sulphathiazole in diet was toxic for mice and produced certain pathological changes in the kidneys. This did not occur in Marshall's experiments even with 4 per cent sulphaguanidine. The penetration and distribution of sulphaguanidine in the tissues appear to be very similar to that of sulphanilamide and sulphapyridine.

Clinically sulphaguanidine has been found efficacious in bacillary dysentery.

Clinical value in cholera.—On the strength of the above properties sulphaguanidine was tried in the cholera ward of the Campbell Hospital. These results have been summarized in the table.

It is evident from the table that the results in cholera treated with the smaller doses of sulphaguanidine combined with saline, showed very little superiority over cases treated with intravenous saline alone. Cases treated with bigger doses of sulphaguanidine combined with saline therapy gave definitely better results, and the case mortality was reduced to 3.21 per cent. It is also interesting to note that of the three series of cases, studied above, the series treated with larger doses of sulphaguanidine required 3.32 pints of saline per patient whereas the average requirements of saline for patients treated with smaller doses of sulphaguanidine or with saline alone were 4.8 and 4.27 pints respectively.

The effects of the larger doses of sulphaguanidine on the frequency of stools were also investigated. It was noted that cases having both sulphaguanidine and saline had 5.24 and 3.73 stools per head on an average on the first and second days of treatment against 7.81 and

4.09 stools per head for similar periods of treatment with saline alone.

The effect of the larger doses of sulphaguanidine and saline in the anuric stage of cholera demonstrated that out of 117 cases 99 passed urine within 24 hours, 12 passed urine within 48 hours, 4 passed urine within 72 hours, and 2 patients died after 48 hours. Among 94 control cases (treated with saline alone), 81 were admitted with suppression of urine, out of which 12 passed no urine within 24 hours and the rest passed urine within 24 hours. Out of these 12 patients 6 passed urine within 48 hours and 2 passed urine within 72 hours, 4

the stools become fewer than 5 in 24 hours, 0.05 gm. per kg. is given every 8 hours. It is proposed to try this dosage during the next cholera epidemic.

Summary and conclusions

1. In a series of 218 cholera cases, sulphaguanidine 1 gm. initial dose, followed by 0.5 gm. six-hourly for 72 hours, has been found effectively to reduce the mortality. The mortality in control saline-treated cases (94) was 6.38 per cent, whereas the mortality in sulphaguanidine-treated cases was only 3.21 per cent. Sulpha-

TABLE

The comparative value in cholera of different doses of sulphaguanidine combined with hypertonic saline on the one hand and saline therapy alone on the other hand

Type of cases	SULPHAGUANIDINE: INITIAL DOSE 0.5 GM. MAINTENANCE DOSE 0.25 GM. EVERY 6 HOURS FOR 72 HOURS				SULPHAGUANIDINE: INITIAL DOSE 1 GM. MAINTENANCE DOSE 0.5 GM. EVERY 6 HOURS FOR 72 HOURS				CONTROL CASES WITH I. V. SALINE PERfusion ONLY			
	Number treated	Number cured	Number dead	Mortality percentage	Number treated	Number cured	Number dead	Mortality percentage	Number treated	Number cured	Number dead	Mortality percentage
Culturally positive ..	26	25	1	3.84	54	52	2	3.70	67	61	6	8.97
Culturally negative ..	9	9	nil	0.00	42	42	nil	0.00	7	7	nil	0.00

died 72 hours after admission. It is thus obvious that larger doses of sulphaguanidine are definitely more effective than smaller doses.

It is realized that the doses of sulphaguanidine tried in both the series of cases were small compared to those that have been recommended subsequently for this drug. This was due to the fact that when the drug was received early in 1940, it was still in the experimental stage and proper dosage had not been worked out. Besides, in an acute infection such as cholera, we thought it would be advisable to try small doses to begin with in the interests of the patients.

Much larger doses of the drug have lately been recommended in the treatment of bacillary dysentery. The drug is administered according to a dosage of 0.1 gm. per kg. of body weight for the initial dose followed by 0.05 gm. per kg. every 4 hours as maintenance doses. When

guanidine is not toxic to human beings in these doses.

2. Sulphaguanidine-treated cases passed fewer stools per day and required less intravenous saline.

3. The percentage of deaths among culturally-positive cases, treated with large doses of sulphaguanidine, was 3.84, whereas among control culturally-positive cases of cholera, treated with saline transfusions only, this was 8.97.

A METHOD FOR ASCERTAINING THE OVERLAPPING OF THE PUBIS BY THE HEAD BY MEANS OF ABDOMINAL EXAMINATION ALONE*

By N. A. PURANDARE, M.D., F.C.P.S. (Bom.), F.R.C.O.G.
and

B. N. PURANDARE, M.D., F.R.C.S. (Edin.)

ANTENATAL supervision is now in general recognized as indispensable; and there is no civilized country, where it is not practised. One of the essential objects gained by it is the determination of the cephalo-pelvic relation soon enough to form beforehand a clear conception about the character and behaviour of the future labour. The cephalo-pelvic relation is made out by the engagement of the head. The latter can be determined by palpating the head at the brim, to know how far it has descended into the pelvis.

The other method for judging this relation is by ascertaining the height of the anterior shoulder above the top of the symphysis pubis. By palpation of the head at the pelvic brim, we can find out how much of the head is to be felt above the pelvic cavity, whether it is one-fourth, one-half or three-fourths, the rest of it at the same time being naturally in the cavity. When only one-fourth is felt above, the anterior shoulder is at the height of 2 inches from the pubis and the head has descended up to the ischial spines, and the greatest circumference of the head is in the pelvis. When half is made out above, the anterior shoulder is 3 inches from the pubis and the head has reached the mid-plane, and its greatest circumference is at the brim. When three-fourths of the head is distinguished above the brim, the anterior shoulder measures 4 inches from the top of the pubis and the head is just entering the pelvis, the greatest circumference being naturally above the brim. When not entering the brim, the whole head is free above it and can be readily moved from side to side. The anterior shoulder is then from $4\frac{1}{2}$ to 5 inches high. The head is, under the circumstances, also said to be floating. When in this condition, it is to be seen whether it can be made to enter the pelvis.

In a multipara who has had several successive pregnancies, whose uterine wall as well as abdominal wall might have lost its tone, and in whom the foetal head might not have been pressed down into the brim, the head thus situated might be made to engage the pelvis by exerting pressure on it by both hands and pushing it down towards the brim. Should it not enter, there is disproportion between the head and the pelvis; either the head may be larger or the pelvis smaller than the average. As a rule, except when the head is exceptionally large, as in hydrocephalus, the large size of the

head in itself very seldom offers hindrance to its descent into the pelvis. This can be proved by the fact that the head is not infrequently delivered in the persistent occipito-posterior position even though its occipito-frontal diameter, measuring $4\frac{1}{2}$ inches, is lying first across the pelvis and later in the antero-posterior diameter of the outlet. Usually in the normal occipito-anterior position, undergoing normal mechanism, the engaging diameter is sub-occipito-frontal, which is $3\frac{3}{4}$ inches and is therefore $\frac{1}{4}$ inch smaller, whereas with $4\frac{1}{2}$ inches of the occipito-frontal diameter, the circumference of the head filling up the birth-canal is comparatively very much larger; yet the delivery is not uncommonly effected normally.

This proves that moderate increase in size of the head does not much matter, whereas diminution in the size of the pelvis does raise a material obstacle. Besides diminution in size of the pelvis, other causes preventing the entrance of the head into the pelvis are placenta praevia, obliquity of the uterus, feebleness of the uterine wall due to successive pregnancies at short intervals, great thickness of the extraperitoneal fat and of the abdominal wall, and development of the placenta in connection with the anterior wall of the uterus; and also malpresentation of the child, such as face or brow presentation. Excepting these conditions, the head has more often than not entered the brim in due time.

When the head has not gone down the brim and also it cannot be pushed into it, there might be disproportion. With this the head would be felt overlapping the symphysis pubis. This overlapping may be slight, moderate or great.

To ascertain whether the head can be made to enter or not, and if not, how much it overlaps the pubis, the method which is most commonly used and gives the greatest help is the one advocated by Muller and Munro-Kerr. To carry out examination by this method, the patient is placed on her back in the ordinary gynaecological position. Two fingers are introduced into the vagina, while the thumb is made to rest on the top of the pubis. An assistant is then asked to make pressure on the fundus, when the fingers in the vagina will note whether the head descends into the cavity and to what extent. If it does not descend, the thumb above the pubis will perceive how much it overlaps the pubis. But in this method as the fingers are inserted in the vagina, there is every chance of conveying infection thiere. Secondly, an examiner with small hands often finds it difficult to reach the top of the pubis, especially when the index and the middle fingers are simultaneously in the vagina. To deal with these conditions successfully a method has been devised. It gives almost precise information. We have both been practising it for some time now and have found it useful. It is carried out as follows.

The patient is first placed on the examination table in the dorsal position, to ascertain that the

* Read at the Third Obstetric and Gynaecological Congress at Calcutta in April 1941.

head is floating. Then the patient is moved down so as to bring the buttocks over the edge of the table. The examiner now stands in front of the buttocks and with the fingers of his right hand locates the top of the symphysis pubis and rests them above it. The patient is then put in the exaggerated lithotomy position, the thighs being separated and completely flexed on the abdomen (figure 1). Should the head be felt to descend through the brim, the fingers will notice it, especially by feeling the surface of the head behind the vertical plane of the

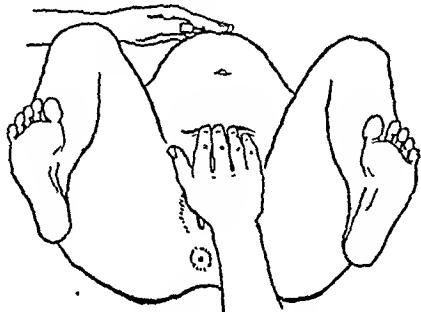

Fig. 1.

posterior or internal surface of the symphysis pubis (figure 2). To facilitate the recognition of the descent of the head, the assistant may be asked to press on the fundus, when the

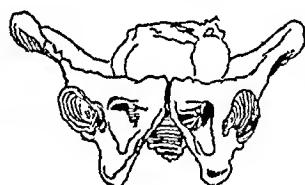

Fig. 2.

fingers will perceive it going down (figure 1). If it does not enter the brim, it would be riding the pubis. To judge how far it is overlapping the top of the pubis, the fingers are run up along the front surface of the head. By this means some conception may be formed about the amount of prominence of the head. Further, the fingers may be held stretched straight up on the head, the hand resting flat on the anterior surface of the symphysis pubis, as felt while the patient is lying on the back (figure 3). In this way the fingers can perceive whether the surface of the head is behind the plane of the anterior surface of the symphysis or forms a prominence projecting forward.

DYSTOIAS DUE TO ANOMALIES OF THE FÖTUS ASSOCIATED WITH DILATATION OF THE FÖTAL URINARY BLADDER

By GRACE EDWARDS BARAR, B.Sc., M.D., D.N.B.
Allahabad

DURING the past ten years three cases of marked dystocia, due to dilatation of the foetal urinary bladder, have come under my care.

(Continued from previous column)

vertical plane of the anterior surface of the pubis the overlapping is slight (figure 3). But when the prominence exceeds this limit and is felt to project beyond the anterior surface, the overlapping is great (figure 4). Determination of this condition is of practical importance because, so long as the overlapping is slight, there is every probability of the head engaging the cavity by undergoing safe moulding.

As the patient is placed with thighs flexed on the abdomen, the abdominal muscles are relaxed, and they allow of the head being readily felt. Furthermore, the pelvis, which, when a person stands, becomes tilted downwards and forwards, has its inclination reduced, when she lies on her back and her thighs are bent on the abdomen, its brim thereby coming to look upwards. With this the head is brought in a line with the middle of the pelvic brim, thus enabling it easily to occupy the inlet.

This mode of examination possesses certain advantages which are set forth below.

(1) The examination can be carried out readily at the outdoor or consultation rooms without much preparation of, or any inconvenience to, the patient.

(2) There is no need to introduce fingers into the vagina, thus creating no occasion to introduce sepsis.

(3) The examination can be done by this way every week in the last month of pregnancy, when the head is floating.

(4) Even in a multipara it helps to ascertain whether the head can be made to enter the brim.

(5) In slight disproportion, if induction of premature labour is contemplated, this method will indicate the time when it should be done.

(6) As the hand is held flat on the symphysis pubis with the fingers pointing towards the head, it can perceive more precisely the amount of overlapping, whether slight or excessive. This information obtained is of practical importance because, when it is slight, spontaneous delivery by the natural passages may be anticipated, but when excessive, Cæsarean section at term is at once indicated.

All have presented considerable risk to the mother. This is a large number of so rare an anomaly to come into the experience of one obstetrician. I desire to present my experiences with these cases that others may profit by them, particularly because, when the diagnosis is made early, the obstetrical problem is much simplified. The mother then can be saved from the danger of a long labour that can only result in her exhaustion and will avail her child nothing. I therefore feel justified in presenting these cases from memory, even though they may lack some scientific detail which I would have wished to give.

Case reports

(i) The first case was that of a woman of about 33 years, seen in the Harborview Hospital of the King County Hospitals of Seattle, Washington, U.S.A., during the spring of 1931. She was a gravida II, the first child, eight years of age, had been delivered normally. From the onset of the second pregnancy, the patient had been ill and had, at the time I first saw her, been in hospital for some time for a severe anaemia, questionably primary. The serological test for syphilis was negative. I recall certain prenatal findings which should have caused all of us connected with this case to suspect some such abnormality as was found at delivery. These were—(i) enlargement of the abdomen beyond the expected size for the period of gestation; (ii) the presence of the foetal head high up under the right maternal costal margin; (iii) the tension and globular enlargement of the lower half of the tumour of pregnancy.

At about the end of the seventh month of gestation, while she was being treated for a severe infection due to *Trichomonas vaginalis* by scrubbing the vagina, an unevenness of the cervical outline was palpated. This had not been present the preceding day at the time of treatment. A direct view of the cervix by speculum revealed the toes of one foot protruding through the long, rather hard cervix, dilated just enough to admit them to the external os.

The condition was reported immediately to the visiting staff obstetrician, who advised waiting till evening for pains to begin. Labour set in spontaneously late in the afternoon. From the first the pains were very distressing to the patient. The cervix softened and dilated almost completely, but the presenting parts failed to advance. At about midnight, the visiting staff obstetrician arrived and under his direction an attempt was made to effect delivery by bringing down the other foot. Traction was applied to both feet but the body failed to move. A contraction ring was considered to be the cause of obstruction. An episiotomy had been done to facilitate manipulation. Further traction, to the point of undue stress on the knee joints, was without effect. The patient was returned to bed with traction applied to the foetal limbs by way of a pulley over the foot of the bed and a strong sedative was given. By early morning no progress whatever in the descent of the foetus had been made. An x-ray was taken in the hope of demonstrating some abnormality of the foetus. The writer (the roentgenologist was not present at the time) thought that there was marked increase in the distance between the crest of the foetal ilium and the lower margin of the thoracic cage, which also seemed shortened and broadened. This was interpreted to mean that some abdominal tumour was pressing upwards flattening the thoracic cage in its longitudinal direction and broadening it in the anterior-posterior and transverse directions. The arms were raised to a level with the shoulder and the head was pressed far to the maternal right. This diagnosis was not then concurred in by either the senior visiting obstetrician

or the roentgenologist who later examined the film without knowledge of the clinical findings at delivery.

The patient's pre-delivery response to anti-anæmic treatment had not been satisfactory. Her condition became such that it was thought advisable to give her a transfusion before any further attempt at delivery should be made. Accordingly a transfusion, previously arranged for, was immediately given. The uterine contraction ring had now relaxed permitting the examination of the enlarged foetal abdomen to confirm the diagnosis. An incision was made above the foetal symphysis releasing a large amount of clear fluid and permitting a very easy delivery of a still-born premature child. The patient made an uneventful recovery except for a small localized stitch infection.

Pathological findings.—The foetal ribs flared outwards. The length of the thoracic cage was greatly shortened and the transverse diameter was relatively and probably actually greater than the longitudinal. Both legs had been dislocated at the knees. The abdominal wall was very wrinkled and the umbilicus showed evidence of great stretching. All abdominal organs were much compressed. The cloaca had not differentiated, the urogenital fold was incompletely formed. The urachus was enormously dilated forming a large cone stretching up towards the umbilicus. The gastro-intestinal tract was in a primitive stage of development, being almost a straight piece, long enough to reach from the diaphragm to the cloaca. The stomach was partly differentiated, and Meckel's diverticulum still attached the mid-gut to the umbilicus. The rectum, or rather cloaca, was imperforate. The external genitalia were very poorly developed. The ureters were patent and joined to the primitive cloaca. The penis was very small, the halves of the scrotum almost completely separated and the testicles undescended. I do not recall whether or not the urethra was patent. I have an imperfect remembrance that the kidneys were of the horse-shoe type.

(ii) The second case was that of a young primigravida who was admitted to the Frances Newton Hospital, Ferozepur, Punjab, in labour, in the spring of 1932. Physical examination showed a very anaemic young woman, about 18 years of age. The size of the uterus indicated a gestation of about thirty weeks. The lower half of the uterus seemed globular, distended and tense. The foetal limbs could be palpated easily in the fundus uteri. The vulva was in an indescribable state owing to a syphilitic lesion which occupied the fourchette extending 3.5 to 4 cm. up each side and about 3 cm. in the other direction. The edges were raised and hard, the base granulated and angry looking. The whole was bathed in a creamy pus flowing from the vagina. The probability of a foetal anomaly of this sort was immediately recognized. But the reluctance, both for the patient's sake and the doctor's, to undertake any surgical procedure can well be imagined. There obviously was no disproportion between the foetal head and the maternal pelvis, for the head came down and then receded with each pain. Soon it became evident that some surgical procedure could not be avoided, so the foetal thoracic cage was entered, and the diaphragm and then the distended bladder punctured. The remainder of the delivery was accomplished with ease. The lesion of the fourchette was very friable and inelastic. A laceration through this was inevitable. The whole lesion was excised and a repair done. This broke down in spite of vigorous anti-syphilitic treatment and a severe local and general sepsis ensued. Unfortunately our present-day chemotherapeutic armamentarium was not then available. At the end of a month, when we were despairing of her life, we gave her family permission to remove her to her village home. Two weeks later they returned for medicine, reporting great improvement.

This foetus was also a male. As I recall, the gastro-intestinal tract was much better formed in this case. The kidneys and the ureters appeared normal. The bladder and rectum were both completely formed though the bladder was enormously dilated. The external genitalia were poorly formed, the penis very

short, and the two halves of the scrotum separated by a deep cleft. The testicles were undescended.

(iii) The third case, a multipara, V or VI gravida, I do not accurately remember which, was admitted to the Mrs. Anson Hospital, Balrampur Estate, Gonda District, United Provinces, in the spring of 1938. She came to the hospital at about noon one day, having been in labour three days. One darkly discoloured foetal extremity, disjointed at the knee, and with part of the skin pulled off, hung from the swollen vagina. An untrained *dai* had delivered the extremity and exerted traction on it, but had failed to deliver the other foot. The characteristic shape of the uterus, globular and very tense in its lower half and comparatively relaxed in the fundal portion, along with the history of the labour, immediately suggested the diagnosis. Intra-uterine palpation of the foetal abdomen showed it to be very tense and distended. An incision into this released a considerable amount of clear fluid, allowing easy completion of the delivery. The patient and her mother, who accompanied her, maintained that the pregnancy was full term. It was well into the eighth month. Previous deliveries had all been normal.

The patient's condition at the time of delivery was generally satisfactory and the puerperium was entirely uneventful. Her Kahn test was negative.

An interesting incident occurred, illustrative of the poor development of the external genitalia. The patient's mother insisted on seeing the foetus. Her expression of amazement was most interesting as she exclaimed that this was truly neither male nor female! The penis was very short and the scrotum so deeply cleft that it was indeed difficult to determine the sex on a cursory examination. The urachus was widely dilated forming a coned-shaped top to the bladder. The ureters and kidneys appeared about normal. The gastro-intestinal tract, heart, lungs, liver, spleen and kidneys were apparently not abnormal. This, as with the other two, showed a characteristic shortening of the thoracic cage and flaring outwards of the ribs.

Discussion

Such cases have certain features in common which should make the alert obstetrician able to diagnose the condition; so that, after complete dilatation of the cervix, the technically very easy surgical procedure could be carried out before the mother is allowed to become exhausted. The only consideration in these cases is the well-being of the mother, for the prognosis for the child is fatal. Brothers (1896) states, 'The prognosis for the child is fatal, only one child having reached the age of five days'. The surgical procedure is of course somewhat simplified if the feet are presenting, as was the situation in two of my cases. In these three cases there is not much in common from the maternal point of view, except the obstruction to labour due to the foetal abnormality.

Only a limited amount of literature has been available to me. However I have combined the information accumulated from these three cases with that gleaned from the reports of seven other cases I have been able to find in the literature available to me. I have summarized these cases in regard to certain facts in the history and physical findings, both of the mother and the foetus, as follows :—

1. All patients were between the ages of 18 and 35.

2. Three were gravida I, one gravida II, one gravida III and the remaining five were gravida IV to VII.

3. Associated diseases : A history of syphilis with positive serological reaction is recorded in only one case. A maternal negative and a paternal positive serological reaction is reported in another case in which the mother had previously delivered six still-born children. One other report states that there was no sign of syphilis or tuberculosis. My other two cases were serologically negative for syphilis. Six other reports do not mention the disease.

One patient is known to have had albuminuria and another (mine) a severe anaemia, resistant to treatment before delivery. She also had a *Trichomonas vaginalis* infection.

4. Nine of the ten foetuses were males.

5. All were premature, varying from six to eight and a half months' gestation.

6. Seven were vertex presentations. One case was probably vertex though the position was not specifically mentioned. Two of my cases were foot presentations.

7. The shortest labour mentioned was ten and a half hours. Only one terminated without surgical interference, i.e., puncturing the bladder. That child lived sixteen days, the only case in this series to survive delivery. One other case, not in this series, is reported to have lived five days, but no mention is made of any surgical interference in the delivery.

8. Two of these cases had demonstrable obstruction of the urethra, one demonstrated by serial section. Some were definitely not obstructed. Obstruction cannot therefore be given as the cause of foetal bladder distension.

9. The method of delivery in nine out of ten of these cases was by puncturing of the foetal bladder. Deliveries were uniformly easy after this procedure.

10. Maternal post-partum progress was good in every case not seriously otherwise complicated. My second patient was the single exception. Her morbidity was marked owing to a secondarily infected syphilitic lesion of the fourchette, which had been present at the time of delivery.

11. Foetal prognosis is uniformly fatal. No survival seems to have been reported in this or any other list. I find mention of only two cases surviving delivery even a few days.

Jeffcoate (1931), summarizing the literature, says that the condition is comparatively rare, and quotes Goldberger as saying that, up to 1929, 217 cases had been reported but does not state whether dystocia was present in all. Jeffcoate further states that it has occurred usually in primigravida or in the early child-bearing period and that labour has often been premature. There was cephalic presentation in most of the cases. The children affected have

been mostly males. Foetal ascites has been a frequent association. Other abnormalities have usually been present, the most common being spina bifida, talipes, imperforate anus, and mal-development of the genitalia.

The outstanding differences in this group of ten is that the majority were not in primigravida and at least four of the ten occurred in the ages between 30 to 40, so that there is no majority even for the early child-bearing age. No case of spina bifida was present in the group.

In this group the malformations of the foetus are listed in the order of their frequency : dilatation of the bladder, with some degree of dilatation of the ureters and hydronephrosis in most cases, malformation of the external genitalia, talipes equinum varum, compression of the thoracic cage, imperforate anus sometimes associated with primitive cloaca, and, in one case, with an entire digestive tract in a primitive state of development.

There seems to have been a general tendency in the literature to regard the condition to be the result of an obstruction in the urethra. Jeffcoate (1931) points out that there have been reports of cases in which no obstruction of the urethra could be demonstrated, to account for the hypertrophy and dilatation of the bladder. He suggests that, in the group of cases in which there is no obstruction of the urethra, the underlying mechanism lies in the failure of proper development of the neuro-muscular system. To me this or some such explanation seems the most reasonable one in both of the groups in which urethral obstruction can be proved and those in which it is proved not to be present. I make this comment in the hope that someone coming on such a case may be able to study the neuro-muscular or even the central nervous system of one such case.

Conclusions

1. The condition of distended foetal bladder, sufficient to cause dystocia, can be diagnosed before delivery.

2. The surgical procedure on the foetus is comparatively simple.

3. Only the maternal welfare should be considered in dealing with these cases. The prognosis for the mother is good in otherwise uncomplicated cases.

4. The prognosis for the foetus is uniformly fatal.

5. Foetuses have some other anatomical abnormality of a serious nature.

DEVELOPMENTAL ANOMALIES OF KIDNEY AND URETER

By H. E. MURRAY, B.A., M.D., M.Ch. (Univ. Dub.), F.R.C.O.G. (Lond.)

Resident Surgeon, The Eden Hospital for Women, Calcutta

THE stages of development of the urinary system prove that the higher vertebrates are descendants of the ancestors of lower forms. The functioning kidney in higher vertebrates is evolved out of three renal systems. Evidence is found in the same individual of the formation of the simple kidney, retrogression of the same and the appearance of a complicated one in its place. The pro-nephros, the simplest renal organ (functioning kidney in tadpole), originates at the 3rd week of foetal life, in the lower cervical and in the upper dorsal region. Most of its elements retrogress and are replaced by the meso-nephros-thoracic kidney (the final functioning kidney in fish). The meta-nephros, the final functioning kidney in mammalia, is evolved in two parts, (a) the transporting tubular system develops from the ureteric bud of the meso-nephric duct and (b) the secretory system, from the intermediate mesodermic cell mass of the nephrogenic cord.

The meso-nephric duct (Wolffian duct) is utilized in the male as the transporting channel for sperms, while in the female it remains as a vestigial structure (Gartner's duct). At the third month the meta-nephros is fully formed and is found at the level of the 4th or 5th lumbar vertebrae. Permanent higher position is reached at the fifth month.

Anomalies of the kidney

1. *In position*. Congenital ectopic kidney in the pelvis or lumbar region, same side or crossed.
2. *In structure*. Rudimentary, atrophied or hypotrophic, cystic (single or multiple).
3. *In number*. Absence of one or both. Supernumerary kidney.
4. *In shape*. Horse-shoe, disc, 'S' shaped, or mass multi-lobular kidney.
5. *In blood supply*. Single aortic renal artery, bifurcating. Multiple aortic renal arteries. Renal artery originating from common iliac, inferior mesenteric, middle sacral, etc.

The mode of entrance of the artery into the kidney may be anomalous in relation to the renal vein or ureter. An aberrant branch may pass directly to the lower or the upper pole of the kidney.

Anomalies of the renal pelvis

1. *In number*. Duplication of the pelvis.
2. *In form*. Cystic pelvis.

Abnormal position or shape subject the kidney to (a) Trauma. (b) Tumour formation. (c) Infection, including tuberculous. (d) Calculus formation. (e) Hydronephrosis.

The following is an example of hydronephrosis in an ectopic kidney :—

Case 1.—Hindu female, single, aged 12 years, was admitted to hospital suffering from a painful suprapubic tumour of 6 months' duration on the right side. There was also a history of intermittent polyuria. Routine examination eliminated such conditions as ovarian cyst, or soft uterine fibroid. The diagnosis appeared to lie between a mesenteric cyst or lesion of the right kidney. Operation was advised and undertaken, when a huge right-sided hydronephrotic cyst filling up the right side of the pelvis and iliac fossa was discovered. Any effort to isolate and remove such a cyst would have taken a very long time if indeed it would have been possible. The patient began to show signs of distress under the anaesthetic, so the cyst was merely drained and marsupialized, and the patient returned to bed as soon as possible. She had a very stormy convalescence, and unfortunately the cyst became secondarily infected. When this subsided, a second series of skiagrams was taken, and as a result the patient was again operated upon, and this time we found the cyst and kidney at the level of 5th lumbar vertebrae and ala of sacrum with a narrow ureter issuing from its lower pole. The whole was removed with as much of the dependent ureter, as possible. Unfortunately the patient died during convalescence.

The following is a complete x-ray note which describes the radiological appearance very fully and our thanks are due to Dr. G. Galstaun for his interesting report:—

The opaque medium was seen to fill a series of large sacs lying at the level of the ilia and immediately anterior to the lumbo-sacro junction.

The outline of the sacs do not suggest that of the colon. They rather suggest the appearance of ectopic cystic kidney.

Note.—A plain skiagram of the renal area is advised in order to determine whether the normal renal outlines are present.

(The above is a description of the appearance after the abdominal sinus was injected with sodium iodide solution.)

Skiagram. Part examined—urinary tract. Position—posterior.

The shadow of the left kidney is clearly seen. It appears normal in shape, size and position.

In the renal area is seen an irregular shadow, which does not have the clear-cut outline associated with a kidney. On closer examination this shadow presents an appearance of hastration. Its limits too are somewhat higher than those of the left kidney.

The psoas shadow on the right side presents unusual appearances. At the level of the 3rd lumbar vertebrae it bulges markedly to the right side, the limits of the bulge being more than one inch lateral to that of the psoas shadow on the opposite side. The lower portion of this shadow is slightly more opaque than the opposite psoas. No calculus shadow is seen in the urinary tract.

Conclusions.—Appearances suggest the following:—

(1) The right kidney would appear to be absent from its normal position in the loin.

(2) The apparent bulge in the psoas shadow seen on the right side might be due to an ectopic kidney.

Pyclography is indicated, preferably retrograde pyelography, on the right side.

(3) *Date 14th February, 1941. Skiagram. Part examined—urinary tract. Intravenous pyelography. Position—posterior.*

The filling up of the left kidney at 5 minutes is normal. The outline of the renal pelvis is normal and the calyces show normal cupping. The right renal region shows no evidence of any contrast medium. The bulge in the outline of the right psoas muscle previously

noted is again seen. Irregular splodges of contrast material are seen here.

At 15 minutes after injection. The splodges previously noted have increased in area, a large saccular shadow being seen immediately lateral to the right sacro-iliac synchondrosis.

30 and 60 minutes after injection. Filling of the left kidney persists. The shadows on the right side are still seen. They do not present the same discrete outline as those noted in the last series where an injection of sodium iodide was made into the sinus.

Conclusions.—The appearances tend to confirm the diagnosis of ectopic kidney on the right side.

(4) *Date 7th March, 1941. Skiagram. Part examined—urinary tract. Retrograde pyclography. Position—posterior.*

The appearances are exactly similar to those seen at the examination on 7th February, 1941, i.e., those of an ectopic cystic kidney on the right side. The ureteric catheter passing into the substance of the mass.

Anomalies of the ureter

1. *In number.* Duplication throughout, or bifurcated above or below.

2. *In form.* Short or elongated or tortuous narrow or dilated (megaloureter).

3. Abnormal position of opening into bladder.

4. Opening into abnormal structures such as urethra, vagina, rectum, seminal vesicles or perineal region.

Abnormal opening such as into urethra, rectum, seminal vesicle or perineum needs no explanation. Opening of the ureter into vagina is difficult to explain. The vaginal cord evolves out of the Mullerian epithelial lining. Gradually it hollows out forming the vagina. The vagina is fully formed by the breaking down of the epithelial cord in the fifth month of foetal life (Keith). The urethral bud comes out of the meso-nephric duct at the sixth week, and the final kidney is fully formed by the third month. The termination of the ureter must have by this time been determined, so the uretero-vaginal fistula (congenital) is difficult to explain developmentally. No case has so far been described.

The following is an interesting case of congenital uretero-vaginal fistula (unilateral):—

Case 2.—Muslim female, single, aged 11 years. Admitted for continuous dribbling of urine from the vagina since birth. However, in addition to this dribbling the girl was able to pass urine in a normal manner per urethram at regular intervals.

On examination, the left kidney could easily be palpated and was obviously hypertrophied. The right kidney region seemed empty. Intravenous pyclography showed a large left kidney and ureter; the right kidney and ureter were not visualized. Cystoscopic examination was then done, and while the orifice of the left ureter was seen with ease, the right orifice was not seen. Not even a dimple in the wall of the bladder, where the orifice of the right ureter should have been, could be made out.

Per vaginam. The vaginal mucous membrane high up on the right side was arranged in the form of a fold close to the right side of the cervix uteri. The urine was dribbling from behind this fold, but no actual hole could be seen.

The diagnosis was not completely apparent. Either the condition was one of absence of right kidney with double or bifurcated left ureter, one branch of which was opening into the vagina, or of rudimentary right, ureter opening into the vagina. The patient was operated upon. On opening the abdomen, and incising the posterior peritoneum, the right ureter, a narrow

Bengal, Calcutta*

A COMPREHENSIVE idea of the arsenic content of common foodstuffs is of much importance in forensic toxicology. In cases of suspected arsenic poisoning the stomach contents, if analysed quantitatively for determination of arsenic, give the total amount of arsenic present in the stomach, but, unless the normal arsenic content of foods are known, it will not be possible for the analyst to express a definite opinion as to the amount of extraneous arsenic administered, either accidentally or with a criminal purpose. In fatal cases, when a large quantity of arsenic is found in the stomach or in the viscera, no difficulty arises in giving any such opinion, but in those cases, both fatal and non-fatal, in which a small quantity of arsenic is detected in the stomach, all sorts of complications arise, and in such cases it may be contended by the defence that the amount of arsenic found in the stomach might legitimately come from the food substances which were taken by the victim and was not of any criminal origin. To eliminate such difficulties in chemico-legal work, an investigation on arsenic in food was taken up in 1934 and a preliminary report was published in the *Indian Science Congress Proceedings* (Bagchi and Bose, 1935). Another short and premature report was also published in the *Indian Journal of Medical Research* by one of our co-workers (Bose, 1935). This piece

(Continued from previous page)

structure, was identified at the pelvic brim and was followed up to a rudimentary ectopic kidney ($1\frac{1}{2} \times 1 \times \frac{1}{2}$ inch) at the level of 5th lumbar vertebra. The ureter was seen issuing out of its lower pole, and a group of small blood vessels entered at its upper pole. The kidney with available part of the ureter was removed. The ureter was not traced downwards, the lower part being merely ligated. The dribbling of urine immediately ceased, and as soon as the patient recovered from the anaesthetic, there were no symptoms at all, and she left hospital perfectly fit. In addition the patient had a developmental error in the lumbosacral spine.

The case was therefore one of infantile kidney, a very rare anomaly (Da Costa) together with an abnormally placed ureter, the latter opening into the vaginal vault behind the fold of tissue referred to in the description.

The correlation of the clinical findings in this patient was not the least interesting feature of this interesting case. Anomalies of the kidney and of the ureter are rare, and therefore a case such as the above which displayed a developmental defect in both these organs is of special interest.

of work could not, however, be completed on account of some unforeseen circumstances and had to be discontinued in 1935.

The method adopted for determination of arsenic was that of Marsh-Berzelius modified by Chapman (1926). The quality of zinc required for this extremely delicate method could not always be obtained. Some of the specimens of zinc manufactured by Merck or Kahlbaum were not absolutely arsenic-free, as claimed by them, and some did not even give the typical mirror of arsenic. The standard mirrors prepared from a particular sample of zinc were sometimes found to vary widely from those prepared from another sample of the same manufacturer or of a different manufacturer. This phenomenon was obviously responsible for some erratic results detected later on in the arsenic figures of some of the foodstuffs, which were published in the preliminary notes referred to above. The sensitization of zinc by cadmium sulphate, as recommended by Chapman (*loc. cit.*), did not always succeed in getting rid of this discrepancy, and it was found necessary to prepare standard mirrors with every new packet of zinc. As this procedure involved much hard work and waste of time, it had to be given up as an unworkable proposition. The Marsh-Berzelius method was therefore abandoned in favour of the Gutzeit method. The difference in quality of the samples of zinc did not matter in the least in this method, as the standards were prepared every day for matching against the unknowns. Being less time-consuming, and easier and cheaper, the Gutzeit method, as recommended by the *British Pharmacopæia* (1932) and further improved upon by Davies and Maltby (1936) and the Association of Official Agricultural Chemists (1936), proved satisfactory for this purpose, as indicated by duplicate experiments and recovery of added quantities of arsenic from control tests. By this method, we carried out successfully our first investigation on the arsenic content of human tissues and excreta (Bagchi and Ganguly, 1937).

The next attempt to complete the investigation on arsenic in food was made under the auspices of the Indian Research Fund Association, and the work was taken up in 1939 employing the modified Gutzeit method for determination of arsenic. The preliminary oxidation of organic matter to liberate arsenic from its organic compounds was effected by means of concentrated nitric and sulphuric acids, as worked out by Ramberg (quoted by Cox, 1925). As this investigation was continued *pari passu* with that on lead in food, the technique of cleansing the samples of food-stuff from dust and other sources of contamination, as described in detail in a previous communication (Bagchi *et al.*, 1940), was as perfect as could be managed under the conditions of the experiments. Two samples of each kind of food, collected from two different sources,

were put to analysis. If the results were identical in both the tests or only slightly different, one figure giving the mean of the two was recorded. In cases giving widely divergent figures, both the results were shown and in such cases the results were confirmed by repeating the tests to eliminate the possibilities of experimental errors and contamination. All food substances were submitted to analysis in their fresh form, that is, in the condition in which they are usually taken or cooked. In the case of dried fruits and nuts, which are usually full of dust, care was taken in washing them in running water for several minutes and then drying them in the sun to their original weight before they were finally weighed for actual determination.

About 100 different articles of food and drink were analysed, the results of which have been classified and shown in the appendix. It has been observed that foods belonging to the vegetable kingdom are exceedingly poor in arsenic, while those belonging to the animal kingdom contain the maximum amounts of arsenic. In fact, no animal food in our list was found free from arsenic, while no arsenic was detected in as many as 21 out of 60 food-stuffs of vegetable origin. The denizens of the sea, e.g., the sea-fish, are fairly rich, whereas the terrestrial animals and those living in the rivers are comparatively poor in arsenic. It is interesting to note that hilsa fish, although they are netted in the rivers of Bengal, appear to belong, on account of their high arsenic content (3 to 4 mg. of As_2O_3 per kilo.), to the class of sea-fish. The zoologists or rather the piscatologists may make a note of this fact which is likely to lend additional weight to their observation that the hilsa is a denizen of the sea. The piscivorous people of Bengal, on the other hand, should take it as a warning against eating too much of this fish, although the amount of As_2O_3 (1/40 of a grain per pound of edible portion) is well within the dose (1/64-1/16 grain) prescribed by the *British Pharmacopædia*.

It is believed that some prawns are very rich in arsenic and in fact, in one specimen (a sea-water prawn from the London market), Chapman (*loc. cit.*) obtained 1.2 grains of As_2O_3 per pound of its edible portion (or 174 mg. per kilo.). This finding was, however, not confirmed by any other worker in this line. In our investigation, all the samples of lobsters were procured in Calcutta and all of them were of fresh-water origin, and the maximum amount of As_2O_3 that could be obtained was 1.70 mg. per kilo. This figure is undoubtedly much higher than that of any of the fresh-water fish we examined, but is insignificant in comparison with Chapman's figure. It is likely that marine prawns or lobsters may contain much larger quantities of arsenic, so as to produce a mild form of arsenic poisoning, as pointed out by Chapman. It is not unusual for a man to eat a pound of lobster and if the

specimen happens to contain about a grain of arsenic (As_2O_3) per pound, it will almost certainly produce gastro-enteritis due to arsenic, the minimum fatal dose of which is two grains.

As arsenic is a normal constituent of all human tissues, its source is obviously the food we take. The nature of the diet, that is, having a preponderance of animal or vegetable food substances, appears to determine the arsenic content of tissues and excreta of the individual. The diversity in basic diets and in habits of people of this country should, therefore, be taken into consideration in discussing toxicological and allied problems. This is also the reason why the figures for poisonous elements present in the human system, as worked out by the European workers on European subjects, are not quite suited for application to Indians in India.

APPENDIX

Arsenic content of common foods

(The figures indicate milligrammes of As as As_2O_3 per kilo. or litre as the case may be, or parts per million.)

A. Animal food

Meat (goat)	0.16
Beef	0.43
Mutton	0.33
Goat's liver	0.56
Beef liver	0.90
Mutton liver	0.35
Chicken	0.14
Egg (duck's)	0.035
(hen's)	0.028, 0.016
Koi fish (<i>Anabas testudineus</i>)	0.036
Magur fish (<i>Clarias batrachus</i>)	0.15
Rui fish (<i>Labio rohita</i>)	0.36, 0.66
Lobster (with shell)	1.98, 3.0
(edible portion)	1.42, 1.70
Hilsa fish (edible portion) (<i>Hilsha ilisha</i>)	3.0
(with scales and bones)	4.0
Vetki (<i>Lates calcarifer</i>)	0.18
Sea-fish (edible portion)—				
Pomfret (<i>Pompanus argenteus</i>)	3.13
Sole (<i>Cynoglossus lingua</i>)	2.6
Tie (plaice)	3.2
Halua	3.58

B. Vegetables

Potato	Nil
Brinjal or baigun (<i>Solanum melongana</i>)	Trace
Sweet potato (<i>Ipomoea batatas</i>)	Nil
Radish	0.008
Karola (<i>Memordica charantia</i>)	0.012
Shim or bean (<i>Dolichos lablab</i>)	0.008
Lao or louki (<i>Lagenaria vulgaris</i>)	0.007
Patol or parbal (<i>Trichosanthes dioica</i>)	Nil
Green plantain (<i>Musa sapientum</i>)	Nil
Jhinga (<i>Luffa acutangula</i>)	Nil
Lal kumra or pumpkin (<i>Cucurbita maxima</i>)	Nil
Cauliflower	0.036
Cabbage	0.13
Dumur or green fig (<i>Ficus glomerata</i>)	Nil
Spinach or palong sak (<i>Spinacia oleracea</i>)	0.030
Green papaya (<i>Carica papaya</i>)	Nil
Green peas or karai sunti (<i>Pisum sativum</i>)	Nil
Bhindi or lady's finger (<i>Hibiscus esculentus</i>)	0.008
Carrot	Nil
Beet	Nil
Pui sak (<i>Bassella rubra</i>)	Nil
Garlic	0.04
Onion	0.13
				Nil, 0.016

DETECTION OF ARSENIC IN BURNT HUMAN BONES AND ASHES

By S. N. CHAKRAVARTI

M. Z. FARUQI

and

K. R. GANGULY

(From the Chemical Examiner's Laboratory, Agra)

MAGISTRATES and judges often ask the question : 'Is it possible to detect arsenic in burnt bones and ashes?' In India, the practice of swift cremation is more prevalent than in any other country in the world, and this leaves a serious loophole for criminals. To avoid detection in cases of poisoning, criminals often resort to the practice of rapid cremation of the bodies of the poisoned persons. It is usually not possible to detect alkaloids and other organic or volatile poisons in burnt bones and ashes; and it is often contended on behalf of the accused that it is impossible to detect arsenic in burnt bones and ashes, as arsenic is a volatile poison and would be dissipated by fire and lost, beyond the possibility of detection, in anything reduced to ashes. That this contention is not quite correct is obvious from a careful study of the annual report of some chemical examiners (*Annual Report of the Chemical Examiner, Madras*, for the year 1902; *Annual Report of the Chemical Examiner, Punjab*, for the year 1931, page 11). Between 1924 and 1931, 92 samples of ashes and bones were examined in the Punjab and arsenic was detected in 10 of them. Between 1921 and 1940, 97 samples of ashes and bones were received for examination in the laboratory of the chemical examiner, United Provinces, Central Provinces and Agra, and arsenic was detected in 19 of them. The detection of arsenic, which would appear contrary to expectation to a lay mind, is really to be expected in genuine arsenical poisoning from a scientific point of view, for the following reasons :—

(1) Much of the arsenic in bones gets converted into arsenates, partially replacing the phosphates of the bones. Arsenates being non-volatile, arsenic can be detected in the bones even after strong heating for a long time.

(2) Even if all the arsenic were to be present in the bones in the form of arsenic trioxide or some other volatile form, all arsenic is not likely

(Continued from previous column)

to be lost, as the conditions under which cremation is usually carried out in India do not favour complete combustion, and condensation of the volatilized arsenic on the cooler parts of the funeral pyre is liable to take place and its loss thus be prevented.

When arsenic trioxide (white arsenic) is heated with salts of sodium or alkaline earth group, part of the arsenic gets converted into arsenate and becomes non-volatile. Arsenic (2 mg.) was strongly heated in a furnace with (i) calcium phosphate, (ii) calcium carbonate, (iii) sodium phosphate, (iv) sodium carbonate and (v) sand. After the heating, arsenic was still detectable by Reinsch's test in all the cases except in the sand mixture.

The amounts of arsenic present in bones, before and after strong burning, were studied in a systematic manner in 13 cases of arsenical poisoning. The results obtained are outlined below:—

death in these cases was probably due to chronic arsenical poisoning. Arsenic is detectable in bones, especially in the spongy tissues of the skull and vertebral bones, long after the disappearance of all traces of arsenic from liver, spleen, kidneys or brain, and the proportion of arsenic in the bones to arsenic in viscera should be greater in cases of chronic poisoning than in cases of acute poisoning. This point is being investigated and an account of these investigations is reserved for a future communication.

Magistrates and police officers often ask the chemical examiner to determine quantitatively the amounts of arsenic present in burnt bones and ashes. Quantitative estimation of arsenic in burnt bones and ashes only is not likely to serve any useful purpose, as arsenic is present only in traces in the bones and as only a small proportion of the bones and ashes are sent to the chemical examiner. Moreover arsenic can

Case number	Amount of arsenic in the whole of the viscera received	Amount of arsenic per 100.0 gm. of viscera	AMOUNT OF ARSENIC PER 100.0 GM. OF BONES RECEIVED	
			Before burning	After burning
1 (from Aligarh)	1,515.0 mg. (23.3 grains).	400.9 mg. (6.17 grains).	0.88 mg. 0.75 mg.
2 (from Bahraich)	670.0 mg. (10.32 grains).	246.3 mg. (3.79 grains).	Skull—0.83 mg. 0.50 mg. Radius and ulna— 1.79 mg.
3 (from Bulandshahr)	2,570.0 mg. (39.58 grains).	241.3 mg. (3.72 grains).	1.96 mg. 1.00 mg. 0.88 mg.
4 (from Kheri)	1.58 mg. (0.024 grain).	0.6 mg. (0.009 grain).	0.95 mg. 0.75 mg.
5 (from Bijnor)	155.0 mg. (2.38 grains).	17.6 mg. (0.27 grain).	0.80 mg. 0.70 mg.
6 (from Bara Banki)	4,883.2 mg. (75.19 grains).	506.0 mg. (7.79 grains).	1.75 mg. 0.75 mg.
7 (from Bijnor)	1,562.5 mg. (24.05 grains).	463.6 mg. (7.13 grains).	0.35 mg. 0.25 mg.
8 (from Bulandshahr)	125.0 mg. (1.92 grains).	13.7 mg. (0.21 grain).	1.38 mg. 0.88 mg.
9 (from Una)	0.064 mg. (0.00098 grain).	..	0.53 mg. ..
10 (from Bijnor)	220.0 mg. (3.39 grains).	21.6 mg. (0.33 grain).	0.13 mg. 0.12 mg.
11 (from Bulandshahr)	0.25 mg. (0.0038 grain).	..	0.15 mg. 0.13 mg.
12 (from Roorkee)	329.3 mg. (5.07 grains).	30.2 mg. (0.47 grain).	0.18 mg. 0.05 mg.
13 (from Bijnor)	574.0 mg. (8.84 grains).	44.0 mg. (0.68 grain).	0.15 mg. 0.08 mg.

Arsenic was estimated by the electrolytic Marsh-Berzelius method after the decomposition of the bones by the nitric acid method.

It is obvious from these results that arsenic can always be detected in cases of arsenical poisoning in burnt bones. Arsenic is in all probability present in the burnt bones in the form of arsenates.

In cases 4, 9 and 11, arsenic was detected in the bones although only minute quantities were found in the viscera, thus indicating that

enter the body in a great variety of ways in food, drink and medicines, and it has particularly to be remembered that arsenic may be detected in burnt bones of persons who die of a disease for which arsenic is, quite legitimately, being administered. How futile quantitative estimation of arsenic in burnt bones would be, will be evident from the following table, which gives the results of analysis of bones of 14 different persons (requisitioned for control blank experiments) who had died of accidents:—

Case number.	1	2	3	4	5	6	7	8	9	10	11	12	13	14
Nature of bone.	Skull	Cap of skull	Cap of skull	Cap of skull	Skull	Cap of skull	Cap of skull	Femur	Jaws and teeth	Humerus	Sternum	Cap of skull	Cap of skull	Cap of skull
Amount of arsenic in mg. per 100.0 gm.	11.89	0.42	0.56	2.88	1.06	1.19	1.31	1.25	9.76	2.05	71.88	0.98	1.06	1.14

It is also obvious from these results that when arsenic is detected in bones, criminal proceedings should be instituted only when other circumstantial evidence (e.g., other incriminating articles containing arsenic, symptoms of arsenical poisoning observed before death, etc.) are also found.

It is often asserted in the courts on behalf of the accused that arsenic is a normal constituent of the human body. This statement is not quite correct. We test the viscera of about 200 human bodies every year for the presence of arsenic, but arsenic is found only in a small proportion, and in the cases where arsenic is detected, symptoms of arsenical poisoning are generally present.

Arsenic is usually present in minute quantities in the soil in India. The following table gives the arsenic contents of some of the representative samples of earth obtained from the various districts of the United Provinces :—

Serial number	District from which the earth was received	Amount of arsenic in grains per pound of earth
1	Agra	0.055
2	Agra (from a different part of the district).	0.070
3	Allahabad	0.052
4	Bareilly	0.067
5	Benares	0.077
6	Bijnor	0.020
7	Bijnor (from a different part of the district).	0.070
8	Bulandshahr	0.098
9	Cawnpore	0.126
10	Cawnpore (from a different part of the district).	0.099
11	Etawah	0.140
12	Etawah (from a different part of the district).	0.120
13	Etah	0.070
14	Farrukhabad	0.087
15	Gorakhpur	0.042
16	Gorakhpur (from a different part of the district).	0.032
17	Kheri	0.025
18	Kheri (from a different part of the district).	0.056
19	Lucknow	0.098
20	Meerut	0.070
21	Meerut (from a different part of the district).	0.051
22	Moradabad	0.056
23	Muzaffarnagar	0.070

Serial number	District from which the earth was received	Amount of arsenic in grains per pound of earth
24	Muzaffarnagar (from a different part of the district).	0.044
25	Naini Tal	0.017
26	Pilibhit	0.061
27	Rae Bareli	0.067
28	Saharanpur	0.084
29	Saharanpur (from a different part of the district).	0.060
30	Shahjahanpur	0.070
31	Shahjahanpur (from a different part of the district).	0.018
32	Sitapur	0.075
33	Sultanpur	0.123
34	Una	0.052

It should be obvious from these results that a blank test should invariably be done (and the necessary deductions made) in all those cases where ashes, vomits or purgings are received mixed with earth.

COMBINED DIGITALIS AND RAUWOLFIA POISONING IN A HUMAN SUBJECT

By M. N. DE, M.B., M.R.C.P. (London)
Professor of Medicine, Medical College, Calcutta
and
TARAPADO CHATTERJEE, B.Sc., M.B.
Additional Surgeon, Howrah General Hospital

THE symptoms and signs of the toxic effects of digitalis are well known to the medical profession, on account of the cumulative action of the drug during its routine administration in cases of cardiac failure. Reference to poisoning with the drug by self-administration with a view to committing suicide has not been found in the literature; neither is there a record of such a large quantity as $1\frac{1}{2}$ ounces of Digifortis (Parke, Davis & Co.) being swallowed by a human subject in a single dose.

Rauwolfia is an Indian drug which enjoys the reputation of being useful in lowering the range of blood pressure and also as a sedative to an excitable nervous system. An overdose, or a large dose administered over a prolonged period, has been known to lower the blood pressure much more than one would desire, producing

unpleasant symptoms. Some susceptible individuals have been known to suffer from intense throbbing of the head and severe uncomfortable feeling in the whole body, but no one has hitherto had an opportunity of studying the effect of as large a quantity as 3 ounces of liquid extract of rauwolfia swallowed in a single dose, in order to commit suicide. The interest becomes undoubtedly much greater when we find that such a large quantity of the drug was taken simultaneously with 1½ ounces of digifortis.

Case report.—The circumstances under which the poisoning occurred were very tragic. An otherwise healthy adult male of 40 years was undergoing treatment for essential hypertension with retinopathy. His blood pressure was recorded as systolic 205 and diastolic 165 mm. of Hg, and his urine showed a trace of albumin but no casts. Along with other remedies, liquid extract of rauwolfia was prescribed and the patient had been taking it for nearly two months. As a result of treatment, his blood pressure was lowered to systolic 165 and diastolic 125 mm. of Hg. At this time, a serious calamity befell the patient, as his wife who was apparently healthy suddenly died. The shock of this bereavement was too sudden and severe for him and he lost all control over his mind. He decided to commit suicide, and his eyes suddenly falling on the phials of medicine on which there were poison labels, he took the phials of digifortis and extract rauwolfia liquid (Union Drug Co.), poured their contents into his mouth, and finished them at once.

This occurred on 28th April, 1941, at about 8 a.m. He vomited once after taking the drugs, but the exact time which elapsed between the swallowing of the poisons and the attack of vomiting could not be definitely ascertained. The fact that the patient had taken the poisons was detected at about 10-30 a.m. and since then till about 12 noon, he was made to vomit several times. His stomach was also washed out several times with potassium permanganate solution. At noon, he passed a stool of normal colour and consistency and a fair quantity of urine.

Everything seemed all right till 2 p.m. when the patient started to vomit every 20 minutes to half an hour. The desire to vomit was so great that every now and then he asked for a drink of water which he vomited immediately. The evacuations were fluid and frothy. He passed altogether 5 stools within the next 16 hours, commencing from 2 p.m. He was also extremely prostrated. Intramuscular injections of glucose were made to sustain him. No remarkable abnormality was detected in the pulse. Next day, at about midnight, however, when the patient was examined, his pulse rate was found to be very slow and was 46 per minute. No abnormality in the rhythm could be detected at this time. After a bout of vomiting, the pulse rate increased to 80 per minute, probably owing to exertion. As the condition of the patient was very weak, a subcutaneous injection of one pint of saline with glucose was given. On the 29th, at about 1 a.m. the pulse rate began to show alternate acceleration and slowing and there was also gross arrhythmia. An injection of 1/60 gr. of atropine sulphate was given, and within half an hour of the injection the irregularity of rate and rhythm disappeared and the pulse rate steadied at 70 per minute. Vomiting continued throughout the day and night of 29th April. He passed highly coloured urine twice, once at 8 a.m. and a second time at 6 p.m., the quantity being 4 oz. each time. He also passed 5 liquid yellow stools containing streaks of blood. He also complained of a burning sensation in the whole of his abdomen. Another subcutaneous saline with glucose was given. On the evening of the 29th, when the patient was examined, his pulse was found to be soft and his blood pressure was 140/90 mm. of Hg.

On the 30th April, vomiting and purging continued and the patient passed 3 ounces of urine in the morning.

He was very much prostrated, the surface of his body was cold and clammy but his rectal temperature was 100°F. At 4 o'clock in the afternoon, the pulse was regular and its rate was found to be 140 per minute but the blood pressure fell to 85/35 mm. of Hg. As the vomiting still continued and the patient became very restless, one injection of morphine gr. ¼ and atropine sulphate gr. 1/100 was given at 8-30 p.m. This induced sleep for nearly 6 hours and also stopped the vomiting. The next morning the vomiting started again though at longer intervals. The patient however remained restful and passed a fair quantity of urine and 4 liquid stools containing streaks of blood. The general condition of the patient was much improved but the systolic blood pressure still remained 110 mm. of Hg. From this time onwards for the next 2 days, the patient was kept under barbiturates by mouth and morphine by injection when necessary, and he was made to drink plenty of water. The vomiting and diarrhoea disappeared completely on the 4th May, i.e., 6 days after he took the poisons. His blood pressure on the 8th May was 130/90 mm. of Hg. It remained near this level till the 10th June, when it rose to 140/100 mm. of Hg. It was not till the 30th of August that the blood pressure rose to 180/140 mm. of Hg. The only remarkable thing during this period was that he suffered badly from hallucinations and suicidal impulses. The patient is now normal in every way except that his blood pressure is maintaining a high level.

From a study of the above case, we may note some interesting features which may throw some light on the clinical use of digitalis and rauwolfia. The first thing is the rapidity of absorption from the stomach and intestine. After swallowing the drugs, the patient vomited once, and, although the exact time of vomiting could not be ascertained, it must have taken place within 2½ hours of taking the drugs. It may be presumed that the portion of the poisons which remained unabsorbed in the stomach must have been thrown out during vomiting and the remaining trace was washed out. In spite of this fact, when we find that the toxic symptoms were so severe, we may infer that a large quantity of the drugs must have been absorbed quickly from the stomach. The effects of digitalis which became manifest earlier than those of rauwolfia appeared within 6 hours of swallowing the drugs and the first symptoms were the irritability of the stomach and intestines. Vomiting was more troublesome than diarrhoea. It took nearly 6 days for these symptoms to abate. The effects of digitalis on the heart showed themselves much later, nearly 16 hours after, and the bradycardia, 46 beats per minute, was the earliest and the most remarkable feature. The irregularity in the rate and rhythm was of a varied character, and as far as one could judge by feeling the pulse and listening to the heart, there were auricular fibrillation, flutter and severe degree of heart block. All these abnormalities, however, rapidly disappeared under the influence of atropine. The urinary flow was very scanty during the earlier stage, when vomiting and purging had been going on, but subsequently it was fairly free.

The effect of rauwolfia was detected about 36 hours after the drugs had been taken, but

POST-SULPHAPYRIDINE ANURIA

WITH A CASE REPORT

By S. K. SUNDARAM, B.A., M.D.

Assistant to the Professor of Medicine, Medical College, and Assistant to Physician, Government General Hospital, Madras

Hæmaturia with or without anuria has been reported after sulphapyridine therapy, but anuria without hæmaturia does not seem to have been reported. The following case report is therefore of interest:—

A Hindu male forty years of age was admitted into Lieut.-Colonel G. R. McRobert's wards in the General Hospital, Madras, on 26th September, 1940, with cough and fever of forty days' duration.

Patient had frank hæmoptysis just before and for some time after admission. On physical and radiological examination he showed evidence of definite consolidation of the right upper lobe. Sputum was repeatedly negative for tubercle bacilli. There was no sign of resolution at the end of a fortnight. Blood Wassermann reaction was negative but Kahn was positive.

The hospital tomograph had not been installed then. It was impossible to say that there was no deep-seated cavity in the lung which might be the source of hæmorrhage. The situation was rather puzzling till the patient began to bring out foul purulent sputum. His constitutional symptoms increased then.

Sulphapyridine therapy was started on 23rd October, 1940, and between then and the 5th November the patient had 58.5 g. of the drug. The white cell count was high throughout, the lowest figure being 9,400 per c.mm. on the 1st November, the count on the 5th November rising to 15,000 per c.mm.

On the 8th November, the patient had vomiting and considerable pain over the hypogastrium and had not passed urine from overnight. Usual technique for promoting micturition having failed, he was catheterized. Under an ounce of clear urine was drawn off. It was unfortunately not examined under the microscope. On the next day there was severe pain in the loins and down the back and complete anuria, and not a drop of urine in the bladder. He was given alkalis and got in the course of the day altogether two pints of 4½ per cent sodium sulphate solution and three lots of 10 per cent glucose in normal saline, given intravenously. Bladder was empty on catheterization at 2.45 a.m. on the 10th instant. On the forenoon of that day, the patient was sweating profusely, the tongue was nevertheless moist and the pulse volume and tension were fair. The blood urea was 110 mg. per cent, van den Bergh reaction was direct negative, indirect faint positive and there were no abnormal spectroscopic bands in the

(Continued from previous page)

it was not certain if these effects were present much earlier. The blood pressure fell progressively till it reached an alarmingly low level of 85/35 mm. of Hg. about 56 hours after taking the poisons. It also appeared that the rauwolfia effect lasted much longer, extending over a period of not less than 42 days.

After the acute symptoms had passed off, the patient had a severe attack of mental trouble, so much so that he had to be constantly guarded, lest he should commit suicide. Whether this mental factor was a continuation of his primary psychological trauma or whether rauwolfia played any part in its production is a matter which is difficult to decide. Personally, I would attribute it to the former.

blood. Twenty c.c.m. of 20 per cent NaCl at 12.30 p.m. and 20 c.c.m. of 25 per cent glucose were given intravenously. At 8 p.m. on the 10th instant the patient passed fifty-four ounces of clear yellow urine and thrice in the course of the night. The first specimen of urine was examined and was 1020 in specific gravity, alkaline to litmus, free from albumin and sugar, and contained in the centrifugalized deposit a few red and pus cells. The patient's condition rapidly improved and the blood urea came down to 26 mg. per cent on the 15th instant. There were no radio-opaque shadows in the urinary tract.

On the night of the 16th instant, the patient developed severe dyspnoea and respiratory distress. These were found on the next morning, on physical and radiological examination, to be due to an extension of the pneumonic process to the lower regions of the right lung. White cell count which was 8,750 per c.mm. on the 11th instant went up to 12,000 per c.mm. on the 17th instant.

There was an obvious indication for sulphapyridine but there was the danger of provoking anuria. It was ultimately thought worth while to take the risk. Sodium sulphapyridine was given intramuscularly, 1 g. in 3 c.c.m. four times in the day. Fluids were forced, by mouth and by rectum, and 25 c.c.m. of 25 per cent glucose solution were given intravenously every six hours.

On the 18th instant it looked as if the risk was well taken. There was considerable symptomatic improvement. The white cell count came down too to 8,000 per c.mm. Sulphapyridine treatment was accordingly persevered with. The improvement was deceptive. The patient developed anuria without hæmaturia again on that night and died on the next morning with, but presumably not of, anuria, for the blood urea immediately before death was only 21 mg. per cent. Autopsy was not allowed. A radiograph taken immediately after death showed no calculi in the urinary tract.

Discussion

Southworth and Cooke (1939) and Graham *et al.* (Tsao, 1939) were apparently the first to report three and seven cases, respectively, of hæmaturia after sulphapyridine therapy. Southworth and Cooke's patients were 40, 17 and 30 years old and developed hæmaturia after 25.5 g. in six days, 10.5 g. in three days and 52.5 g. in ten days, respectively. All recovered after discontinuance of the drug and administration of fluids in abundance. Graham's cases also recovered. Tsao *et al.* (1939) reported five cases of haematuria, one of which was fatal. Their patients were six to seventeen years old and developed the renal complications after 3.5 to 7.5 g. in twenty hours to six days. Their fatal case was that of an eight-year-old patient who died after 6.5 g. in forty-eight hours. The cause of death was given as broncho-pneumonia with uræmia due to anuria caused by bilateral ureteral obstruction.

Tsao *et al.* (1939) suggested cystoscopic treatment, believing that their patient would have survived if this procedure had been carried out. This was done successfully by Carroll *et al.* (1940). Their patient developed first, hæmaturia and anuria after less than 30 g. in under five days. They suggested that the symptoms of renal colic and/or hæmaturia should make one suspicious of crystalline concretions in the urinary tract and should not be mistaken for gastric upsets.

Sadusk, Jr. *et al.* (1940) have reported two cases of complete anuria during sulphapyridine therapy. There was gross haematuria in both, before and after anuria. The anuria was in both due to calculi of acetyl-sulphapyridine blocking the urinary tract at the uretero-vesical orifices. Treatment by cystoscopy and ureteral washing with warm saline, keeping the catheters *in situ* for twelve hours, and by subsequent forced fluids, was successful in both. One patient was thirty-five years old and anuria developed after 29 g. of sulphapyridine in five days; the other was thirty-nine years old and had 37 g. in seven days. One of the patients died of a neuro-surgical complication. The pathological changes in the upper urinary tract consisted essentially of great tubular and capsular dilatation, marked congestion and vacuolization within the glomerular tufts and acute haemorrhagic pyelo-ureteritis extending into the adjacent renal medullary tissue.

Fletcher (1941) has just reported yet another fatal case of anuria following sulphapyridine. Severe pain in the lumbar region and haematuria came on on the second day of administration, following 10 g. of the drug. Decapsulation was done on the fourth day of anuria (blood urea was then 155 mg. per cent). Kidneys were enlarged, lobulated and oedematous. No calculi were felt. Capsules stripped easily. The pelvis was bluish in colour from blood-stained grumous urine. In spite of pyelostomy and post-operative continuous intravenous drip transfusion, death occurred on the next day without any urine having been passed. In view of the failure of pyelostomy Fletcher presumes that the blockage was in the renal tubules and that ureteral lavage would have been useless. He makes no mention however of any post-mortem examination nor of the pathologist's report on biopsy specimens of kidney taken for section at operation.

That of all sulphonamide drugs sulphapyridine is most liable to cause renal complications, is well known. Factors promoting haematuria and concretion formation are discussed by Sadusk, Jr. *et al.* (1940) : It is not the reaction of the urine, for solubility of acetyl-sulphapyridine would appear to remain the same between pH 3.3 and 7.4 and does not seem to be sufficiently increased at pH 7.9; not the urinary output, nor the degree of acetylation, for neither is quantitatively related to the incidence of renal complications. Fletcher's (1941) suggestion of the prophylactic value of large fluid intake has thus no scientific basis. It will reduce too, the concentration of the drug in the blood and therefore its efficacy.

What then must be the methods of prophylaxis of renal complications after sulphapyridine? Children are apparently relatively susceptible. The total dosage of the drug has apparently no quantitative relation to the incidence of haematuria and/or anuria. It has recently been suggested that after initiation of treatment with

sulphapyridine, sulphathiazole may be used for maintenance effect. But Garvin (1941) has recently made a comparative study of the renal complications of sulphapyridine and of sulphathiazole. Of 54 patients on sulphathiazole he found crystals of acetyl-sulphathiazole in the urine of 33 patients and haematuria in 14.8 per cent; of 56 patients on sulphapyridine he found crystals of acetyl-sulphapyridine in 16 patients, but the incidence of haematuria was 10.7 per cent. Acetylation of sulphathiazole is less than conjugation of sulphapyridine, but a higher blood concentration is required for effective action with sulphathiazole than with sulphapyridine.

It is obvious that the only effective prophylactic measure consistent with effective antibacterial action is examination of the urine from time to time, and a careful lookout for renal symptoms. Flippin *et al.* (1941) have been concerned with reducing the toxicity of sulphapyridine without impairing its therapeutic value. They have failed to find a relationship between therapeutic effectiveness and blood concentration, for there is no appreciable change in the former between 2 and 15 mg. per cent of the free sulphapyridine in blood. Therapeutic effectiveness is not enhanced by more than 5 mg. per cent of free sulphapyridine and the toxic reactions increase with more than 5 mg. per cent. This finding is contrary to the belief hitherto held of need for greater blood concentration of free sulphapyridine for effective action. If confirmed, Flippin's findings will undoubtedly minimize toxic reactions.

Summary and conclusion

1. A case is described of anuria without obvious haematuria, twice following sulphapyridine therapy. Treatment by alkalis and forced fluids was successful on the first occasion, and the patient died of extension of the original disease soon after anuria on the second occasion.

2. The literature is reviewed on the incidence of haematuria and concretion anuria during sulphapyridine therapy. In every case previously reported there was either haematuria or anuria following on obvious haematuria.

3. Therapy, curative as well as prophylactic, is discussed. Forced fluids and alkalis may be enough in mild and moderately severe cases. Ureteral lavage, and perhaps pyelostomy, may be required in resistant cases. By way of prophylaxis, at the present moment, one can only be on the look out for renal symptoms and signs.

This case was presented at the Staff Clinical Meeting of the General Hospital, Madras, on the 30th November, 1940. We were not then aware of the value of ureteral lavage. My thanks are due to my chief Lieut.-Colonel G. R. McRobert, I.M.S., Professor of Medicine, Medical College, Madras, for his permission and encouragement to report this case.

THE PREVAILING TYPES OF PNEUMOCOCCI IN PNEUMONIA AND PNEUMOCOCCAL INFECTIONS

By R. B. JIWAN LAL, M.D., B.S.

*Professor of Pathology, K. E. Medical College, Lahore
and*

NAND LAL CHITKARA, M.B., B.S., D.T.M.

(Working under a grant from the Punjab Government)

A SURVEY of the prevalent types of pneumococci responsible for causing pneumonia, pneumococcal meningitis and empyema has been considered a useful line of investigation, because of the aid it may give in elucidating the epidemiology of pneumonias and in determining their specific therapy. Such a survey, however, is an extremely laborious and technical piece of work, involving as it does the investigation of all the members of a community, including the sick, the contacts, and non-contacts, and marking the carriers. How long potent pneumococci persist in carriers, and the liability to variation of types, are important problems that need an answer. This type of work is possible only in controlled communities.

A beginning was made in 1936-37 (Dick, 1939) in the form of an investigation of serological types of pneumococci in lobar pneumonia; they were classified as Types I, II and III of Avery by the macroscopic agglutination technique. The unclassified organisms were classed as group IV.

The present inquiry initiated by the Punjab Government in November 1938, was to elucidate the following three aspects of pneumonia:—

1. The incidence of serological types of pneumococci in cases of pneumonia and other pneumococcal infections.

2. The response to the therapeutic administration of Felton's concentrated specific anti-pneumococcal serum mixture against Types I and II in the corresponding infections, in combination with M.&B. 693.

3. The chemotherapeutic treatment of pneumonia with sulphapyridine (M.&B. 693, Dagenan) alone.

The detailed report of the laboratory part of the work is the subject of this communication. Report on problems 2 and 3 have been published

by Taylor and Chitkara (1940) and Taylor, et al. (1940).

The cases recorded are from the usual admissions to the Mayo Hospital, Lahore, mainly Indians, Punjabi Muslims, Hindus and Sikhs and a few Europeans and Anglo-Indians.

The Indian patients are mainly of the poor classes, admitted to the general wards of the hospital.

The work is based on 196 consecutive cases of pneumonia and pneumococcal infections, admitted to the Mayo Hospital from January 1939 to March 1940.

The pneumococci in the sputum and purulent discharges were typed according to Neufeld's method, confirmed in most cases by the macroscopic agglutination method, applied to pneumococci obtained from peritoneal washings of the dead white mice, which had been injected with the sputum or pus that contained pneumococci. The confirmatory typing of the causative pneumococcus obtained by the culture of lung puncture material and of blood could not be done on account of limitation of facilities.

Collection of material

Sputum that came from the deep respiratory passages, following upon a natural vigorous bout of coughing, was received in a clean sputum cup or petri dish.

In children and delirious adults, throat swabs were taken, inoculated in glucose broth, and incubated at 37°C. for 8 to 24 hours. The resulting culture was utilized for direct typing and for mouse inoculation.

The purulent discharges of pneumococcal infections of serous membranes were obtained through a sterile puncture needle.

A smear was stained by Gram's method. In the vast majority of pneumonias (lobar or broncho) the sputa were found to contain pneumococci in very great preponderance, and where these were scanty, examination for acid-fast bacilli was done, to exclude tuberculous infections.

A small amount of sputum was kept apart for direct typing, and from the remainder a firm portion about 0.5 e.cm. in diameter was sucked up into a sterile syringe without a needle, and washed three times in sterile salt solution. Then it was emulsified in about 1 to 2 e.cm. of sterile normal saline by sucking the sputum and the saline into the syringe, and spouting it out forcibly into a sterile petri dish. Repeating this process about a dozen times made a good emulsion, which was injected intraperitoneally into a white mouse. The animal was marked with a colour, and the coloured area recorded.

The exudates of the serous membranes showed pneumococci, generally in very large numbers.

Cultures from these were made in glucose broth and on blood agar. If the pneumococci were in small numbers, the fluid was centrifuged, supernatant clear fluid pipetted off and 1 to 2

c.cm. of fluid left at the bottom of the tube used for direct typing and mouse inoculation.

Precipitin methods of Krumwiede, Valentine and Oliver, have not been employed, because their results are not satisfactory in a fairly large proportion of cases, and as they entail an expenditure of large amounts of serum, they are uneconomical.

Direct typing (Neufeld's Quellung phenomenon)

Technique.—A small fleck of sputum or pus was placed with a platinum loop on a thin coverslip, mixed thoroughly with 2 loops of one of the polyvalent mixtures of known specific type sera (rabbit) and a loop of Loeffler's alkaline methylene blue. The coverslip was then inverted over a plane slide. The mixture spread out in a thin uniform layer, and was examined with an oil-immersion lens in artificial light made to pass through a blue filter. Such preparations were made with all the six polyvalent mixtures and examined for swelling of the capsule or 'quellung'. The swelling usually occurred in 2 to 5 minutes and occasionally in 15 to 30 minutes, therefore all negative preparations were re-examined after 1 hour. Having found out the positive quellung with a mixture, the test was repeated with the individual specific type antisera (rabbit) comprising the mixture.

These polyvalent mixtures are prepared so as to accord approximately with the relative incidence of various types, thus mixture A contains I, II and VII which are responsible for a very large percentage of cases. The mixtures used in this inquiry were the manufacture of Messrs. Parke Davis and Company and were made up as below :

Mixture A ..	Types I, II and VII.
Mixture B ..	Types III, IV, V, VI and VIII.
Mixture C ..	Types IX, XII, XIV, XV and XVII.
Mixture D ..	Types X, XI, XIII, XX, XXII and XXIV.
Mixture E ..	Types XVI, XVIII, XIX, XXI and XXVIII.
Mixture F ..	Types XXIII, XXV, XXVII, XXIX, XXXI and XXXII.

Special notes about direct typing

(1) Sputum not older than two hours should be used. Sputum placed in a refrigerator preserves the reacting power longer. During the course of this work, it was noticed that sputum expectorated 4 to 6 hours earlier showed the typical quellung phenomenon. In 3 specimens of pus, the reacting property was preserved even for 24 hours after it was removed from the body. The same observation is recorded by Beckler and MacLeod (1934). In older sputa pneumococci probably autolyse.

(2) Sputum or pus for typing should be taken before treatment with M.&B. 693 is given, because the drug is said to have a specific lytic

action on the capsule which may, therefore, not react properly with the antiserum. However, in one case of pneumococci in sputum, and in 4 cases of pneumococcal pus, quellung reaction occurred when 6 to 10 grammes of M.&B. 693 (Dagenan) had been already given. This is a chance observation, and no systematic work has been done on it.

(3) Hanging drop preparations take longer to prepare, and are difficult to focus, possibly because of the varying depth of the drop. The method described is carried out most readily, and gives a uniform clear view of the field (Beckler and MacLeod).

(4) It is useless to look for quellung in daylight. The contrast provided by the filtered blue light and the medium stained blue with Loeffler's methylene blue permits the glossy halo of the swollen capsule to be detected readily.

(5) The platinum loop must be flamed thoroughly, and cooled before it is dipped in the specific antiserum, so that the serum does not get contaminated. A contaminated serum loses its specific antibodies very soon.

To preserve the potency of the diagnostic sera it is essential that these be stored in a cool place, as they are liable to deteriorate if stored at room temperature.

The diagnostic sera supplied contained methylene blue as well. But in our observation, this is not sufficient and an extra loop of Loeffler's methylene blue is almost a necessity.

In these moist preparations, made with (rabbit) antiserum, quellung reaction could be noticed after 24 or even 48 hours.

Positive Neufeld reaction has been obtained with fresh cultures of pneumococci in glucose broth, and blood-agar. It is, of course, remarkably clear in serous purulent exudates of man, and the experimental animal.

Indirect typing with the macroscopic agglutination method

A mouse inoculated intraperitoneally usually died in 12 to 24 hours. If at the end of 24 hours it was listless, it was killed with coal gas.

The mouse was pinned on a wooden board with the abdomen facing upward. The skin was sterilized by rubbing with methylated spirit, and the hair was seared lightly. The skin was reflected and pinned down to the board. A longitudinal opening in the middle of the abdominal wall was made. Using a bulb pipette, the peritoneum was thoroughly washed with 3 to 4 c.cm. of normal saline, and the washings collected in a centrifuge tube. A smear is made, and stained by Gram's method and the presence of pneumococci in pure culture is determined. When the peritoneal washings show a mixed type of infection, the heart is exposed by opening the chest, it is seared with a red cautery, and a thin sterile capillary pipette is plunged into one of the heart chambers, the blood so sucked up is inoculated into glucose broth, and blood-agar. The culture thus obtained is

suspended in saline, and utilized for macroscopic agglutination tests.

The peritoneal washings are centrifugalized at low speed for a few minutes, the supernatant suspension of organisms poured into a second centrifuge tube and the sediment, which contains cellular debris, discarded. It is centrifugalized at high speed for 20 to 30 minutes or until it is perfectly clear. The sediment is re-suspended in normal saline solution for the agglutination test.

The titres of the type specific antisera (horse) are given on the bottles, corresponding dilutions are made and a mixture of equal volumes of emulsion and diluted serum made. This is repeated with all the specific antisera. The whole set is kept in a water-bath at 37°C. for 2 hours and the result read. The reading may be further confirmed after keeping it overnight in the incubator at 37°C.

Positive agglutination is seen in the form of numerous granules that settle at the sides and bottom of the small conical tubes leaving clear fluid above. The clearness of the fluid vehicle and the clumping of bacteria is the hall-mark of positive agglutination.

Special notes with regard to macroscopic agglutination

(1) If none of the specific type sera show agglutination the identity of the pneumococcus

(4) Rubber-capped serum bottles could be kept uncontaminated for a long time, as the serum was taken with a sterile syringe and needle.

(5) Do not forget to keep a control tube of the emulsion of pneumococci and saline, in each set.

(6) Dreyer's agglutination tubes or similar tubes improvised from quill tubing demonstrate the agglutination test.

Pneumococci obtained by culture have to be confirmed by the following tests :—

1. Bile-solubility test :—Add 1 c.cm. of clear sterile ox bile or 10 per cent sodium taurocholate to 3 c.cm. of serum broth culture. Prepare a control by adding 1 c.cm. of sterile saline to 3 c.cm. of culture. The pneumococcal emulsion becomes clear in about 10 minutes, the reaction may be watched for 1 to 2 hours. Pneumococci are soluble but streptococci are not. The tube containing pneumococci becomes transparent.

2. Fermentation of inulin.

Inoculate a tube of inulin-serum-water medium, which is usually fermented and coagulated by pneumococci, but not by streptococci.

Data and conclusions

Table I shows that 120 (65 per cent) of 186 cases tried could be typed immediately by the

TABLE I
The total cases typed and number of cases typed by each method

Number typed	DIRECT TYPING NEUFELD'S METHOD		INDIRECT TYPING			REMARKS
	Positive	Negative	Types I, II and III	Group IV or 29 types of Cooper	Indeter- minate	
41	39	2		Not done		Rabbit serum only available.
109	64	45	59	50	..	Horse serum for types I, II and III only available.
36	17	19	16	15	5	
10	10	..	
Total 196	120	66	75	75	5	

must be confirmed by tests such as the bile-solubility test and the fermentation test. As a matter of fact, a bile-solubility testing tube must be incorporated with every macroscopic agglutination set.

(2) The serum must never be contaminated, and always stored in a cool place.

(3) It is the most accurate test known for the typing of pneumococci. Hence, whenever direct Neufeld has been negative, the type has been found in the large majority of cases by agglutination test against pneumococci obtained from peritoneal washings of mice inoculated intraperitoneally with the discharge.

direct method. Various other workers have reported 70 to 80 per cent positive results by the same method.

Note.—1. In the above group cases have not been taken consecutively.

2. The column marked 'indeterminate', refers to cases in which pneumococci were present in the peritoneal washings of mice inoculated with the morbid discharges. These could not be typed by agglutination method against the specific type sera of 29 standard types of Avery and Cooper, the remaining three type sera (against types 10, 14 and 26) not being available. In view of the specificity of the agglutination reaction, one may say that these indeterminate strains might have been one of the missing types or new types altogether.

TABLE II
The detail of positive types by Neufeld's method

Types	1	2	3	5	6	7	8	10	12	15	20	21	Mixed 1 & 2
39	22	2	1	7	4	1	1	..	1
64	42	5	4	1	1	3	2	2	..	1	3
17	8	6	1	2

Discrepancy between the negative Neufeld's figures is explained under the heading 'Analysis of failures by direct typing' (*vide infra*).

TABLE III
Confirmation of direct typing by standard macroscopic agglutination method

Number	Direct method types I, II and III	CONFIRMATORY INDIRECT METHOD		Direct typing IV to XXXII	CONFIRMATORY INDIRECT METHOD		REMARKS
		Confirmed	Unconfirmed		Confirmed	Unconfirmed	
64	54	51	3	10	Confirmation not done		
17	15	15	..	2*	..	2	Specific type sera against types X, XIV and XXVI not available.

* These strains belonged to type 20 (by direct typing).

Thus 66 (93 per cent) of 71 strains were confirmed. It is however interesting to observe that these 5 strains could not be classified by agglutination. MacLeod and Beckler give 96 per cent of their direct typing confirmed by agglutination.

best illustrated by noting the reaction of the pneumococci of each case every day, till his discharge from the hospital. But this could not be done during the course of this work, because serum, or Dagenan treatment, was given soon after the case was admitted.

TABLE IV
The detailed comparison of direct and indirect typing

Types	1	2	3	4	5	6	7	8	10	11	12	13	15	20	21	25	Mixed 1 & 2	Mixed 7 & 9	Mixed 11 & 13	Group IV	Nenfeld's negative	Indeterminate
Macroscopic agglutination method.	62	12	7	2	1	..	2	1	2	1	1	5	1	2	50	..	5
Neufeld's method	60	11	5	..	1	1	3	2	..	2	2	1	..	3	64

TABLE V
The type analysis of 120 cases which were Neufeld-positive

Types	1	2	3	5	6	7	8	10	12	15	20	21	Mixed 1 & 2
	72	13	5	1	2	10	4	1	3	2	3	1	3

It will be seen from Table V that out of 120 direct positive cases 95 belonged to types 1, 2 and 7, while the other 25 belonged to all other types. It may be that the specific sera (rabbit) against types 1, 2 and 7 were more strongly antigenic than others.

Analysis of failures by direct typing

1. Out of 66 cases that failed, 9 could be typed directly from the pneumococci of the peritoneal washings of mice in which the same morbid discharges were injected intraperitoneally.

2. The termination of pneumonia is considered by many authorities to be the result of autolytic changes in the pneumococci, especially in their capsules. It was considered worth while to analyse the quellung response of the capsules of pneumococci according to the day of the disease. This fact would have been

best illustrated by noting the reaction of the pneumococci of each case every day, till his discharge from the hospital. But this could not be done during the course of this work, because serum, or Dagenan treatment, was given soon after the case was admitted.

Though the number of cases in Table VI is small the conclusion is striking. The remarkably high ratio of positive to negative Neufeld's on the first two days of disease amply bears out the hypothesis that the quellung reaction is best obtained early in the disease.

Table VII explains to a certain extent the discrepancy noted earlier.

It is seen that the highest incidence of pneumococcal infections is in the third decade and the lowest after the age of 50 years. This is practically the same as in many other acute infections, possibly because of increased stress and strain in the third decade of life.

Epidemiology

Type 1 is responsible for the largest number of cases. There is apparently diminished incidence of type 1 in the age groups 0 to 10 and 51 to 60. When these figures are taken in conjunction with the total number of cases in the age groups, and percentage incidence calculated, the real incidence will be found to be practically the same. The cases in other groups are very few, and correct deductions cannot be drawn. Incidence according to sex cannot be assessed from these figures, as Indian women do not come to the hospitals as frequently as men.

Pneumonia incidence in children is low because patients of this age group are generally

It is a popular belief amongst Indians that rainfall is followed by amelioration of respiratory disorders.

Apart from these factors which influence the activity of the pneumococcus, the constant relative preponderance of certain types over others suggests that the route of infection is by contact from case to case or from healthy carriers, as in many other infectious diseases. The present work has not been directed towards the elucidation of this problem. However, an interesting case illustrating the immense influence of contact infection is well worth mentioning. Two labourers were admitted into the wards the same day. They lived together in one small room and fell ill with pneumonia at an interval of one day. Their sputa contained

not brought to the hospital, so we cannot draw any definite conclusion from these figures. Similarly the number of cases in the age groups 41 to 60 are very small; any conclusion on a percentage basis would be fallacious.

Pneumonia cases occur throughout the year, being more numerous in winter than in summer. The number of cases begins to rise in November or December reaching the maximum generally in January or February, then recedes rapidly, rising again in May and June. This is in accord with the observations recorded by other workers.

Again type 1 is the commonest cause of infection in the larger part of the year. The incidence of the various types, however, varies considerably in the corresponding months of January, February and March 1939 and 1940. This is in accord with the opinion of Topley and Wilson that, 'Figures reported by various observers are sufficient to indicate that the incidence of the various types may vary widely from place to place and from time to time. Again the relative frequency of different types observed at one place at one time has not been maintained at other times and at other places'.

pneumococci type 1. Incidentally they responded equally well to the same serum, and Dagenan therapy.

The lobes most frequently involved are the lower lobes the incidence between the right and left sides being practically the same.

The progress of the disease, complications and mortality in this series of cases have been profoundly influenced by the serum and chemotherapeutic measures, and it is not fair to compare with those cases, which did not have specific treatment. This has been fully discussed in the clinical paper by Taylor and Chitkara (1940).

The phenomena of crisis and lysis in pneumonia have evaded satisfactory explanation. The administration of specific serum and the specifically-acting chemotherapeutic compounds is followed by crisis in a large number of cases, and is considered to be the result of their action on the pneumococcus capsule. Again, in Neufeld's quellung phenomenon, we have a method for finding out the intactness of the capsules. It would be interesting to repeat the Neufeld reaction from day to day right into convalescence, both in specifically-treated cases

BLACKWATER FEVER IN DARJEELING-TERAI

By JAGADISH C. BHATTACHARJEE, L.M.P.
Darjeeling Himalayan Railway Hospital, Tindharia,
Darjeeling

WITHIN a period of five years, 1935-39, twenty cases of blackwater fever have come under the writer's observation. The cases will be discussed from a clinical point of view with short notes on the treatment employed, as facilities for thorough laboratory investigations were not available in the locality.

Topography and climatology

The cases of this series have been encountered in Siliguri, a subdivisional town of Darjeeling district, Bengal, a place 300 feet above sea level and situated about 7 miles from the foot of the Himalayas. The locality is hyper-endemic for malaria, the spleen index amongst children under 12 years of age varying between 60 and 70 per cent. The climate is hot and moist in summer and cold and dry in the winter. Rainfall is heavy between June and October and the annual rainfall averages 160

(Continued from previous page)

and controls in order to find out, on a statistical basis, the truth of the above commonly accepted hypothesis.

Acknowledgments

Our thanks are due to the Department of Public Health, City of New York, U. S. A., for having kindly supplied the 29 standard diagnostic type specific (horse) antisera, free of charge.

Our thanks are also due to the members of the staff of the Pathology Department, K. E. Medical College, Lahore, for their technical assistance and suggestions.

Summary

1. Direct Neufeld typing of pneumococci is successful in two-thirds of the cases. This method gives higher positive results when employed in the first 2 days of the disease.

2. The technique of the Neufeld and the macroscopic agglutination method is given.

3. Failures with Neufeld's technique have been discussed.

4. 93 per cent of positive Neufeld cases could be confirmed by the macroscopic agglutination method.

5. Types I, II and III are the commonest types met with at all periods of the year.

inches. No regular anti-malaria measures are adopted by the municipality except occasional spraying of kerosene and crude oil mixtures in the principal breeding places of the town during the hot months, but the suburbs are always neglected. All the pernicious manifestations of malaria are encountered, especially during the monsoon months.

Incidence

From table I it will be noted that the maximum number of cases occurs in the winter months, when there is a natural decline in malaria incidence. This is borne out by other practitioners of the town as well.

TABLE I
Showing incidence of cases month by month

Month	Number of cases	Month	Number of cases
January ..	2	July ..	1
February ..	2	August ..	1
March	September ..	2
April	October ..	5
May	November ..	3
June	December ..	4
		TOTAL ..	20

Age and sex

The disease is more common in adolescence and males are more commonly attacked. Of the twenty cases treated, 15 were males and 5 females. The youngest patient was 4 years of age and the oldest one 56. Average age was 24 to 38 years. Of the twenty males of this series, one person has been included twice as he had two attacks in two consecutive years.

TABLE II
Showing age incidence

Age groups, years	Number of cases
1-10 ..	1
10-20 ..	6
20-30 ..	8
30-40 ..	4
40-50 ..	1
TOTAL ..	20

All the patients were middle-class Bengali Hindus in various employments, such as railway services, agriculture, household work, etc. Some of them are temporary residents of the place, while others have been domiciled here for more than one generation. Both these groups are equally susceptible. So far no case has been recorded amongst the Rajbansi community, the original inhabitants of the sub-Himalayan plains of Bengal.

Predisposing conditions

A lowered state of general health, over-exertion and exposure to chill were the exciting causes, but a history of frequent short attacks of fever was given in every case.

Onset

The onset of haemoglobinuria is always sudden, and it usually appears within the first few days of the occurrence of fever; in several cases it has been found to occur with the first bout of fever.

TABLE III
Showing the day of appearance of haemoglobinuria

Day of fever	Number of cases
1st day ..	3
2nd ..	3
3rd ..	7
4th ..	5
5th ..	2
TOTAL ..	20

Relation with quinine

Out of the twenty cases, intramuscular injection of quinine has been responsible for precipitating an attack of haemoglobinuria in 3 cases; whereas 7 cases had taken quinine either as tablets or in mixture, during the first few days of fever before the onset of haemoglobinuria. In one case, administration of one dose of 5 grains of quinine sulphate was responsible for precipitating an attack, but the urine cleared up quickly, soon after the quinine was withheld. The remaining 10 cases (50 per cent) had not taken quinine in any form during the particular attack of fever.

History of previous attacks

Of these 20 cases, 4 patients gave a history of a previous attack before they came under my observation; this number includes the second attack of the case that was counted twice in this series.

Clinical manifestations

The patient may have a previous attack of fever lasting for several days, and then a sudden superimposed abrupt rise of temperature, 104°F. to 105°F., accompanied by a shivering fit, pain in the loins and region of the spleen and liver and severe vomiting of bilious matter. There are however certain cases, though their number may be small, who had no history of previous fever; the patient has a sharp chill, followed by severe rigor, pain in the limbs and loins, and a high rise of temperature. He has a strong desire for micturition and then passes dark red urine. In a few cases, transient haemoglobinuria has followed a high

rise of temperature without other signs and symptoms of blackwater fever. The urine clears up as the temperature returns to normal. Though a high rise of temperature is the rule, yet haemoglobinuria has been observed in a patient whose temperature rose only to 100°F.

Urine.—There is always a tendency for diminution in the amount of urine, and in a severe case the quantity passed in 24 hours may be less than 15 ounces. In very bad cases, there may be total suppression. In typical cases, the urine is dark, coffee-coloured in the beginning and, passing through different shades, finally becomes tarry. In mild cases, the urine is passed freely, it is bright red in colour, gradually turning to brown, after which it clears up quickly. It always contains haemoglobin in solution. Albumin is present in severe cases and epithelium, hyaline, granular and haemoglobin tubular casts are found in the centrifugalized deposit. In our series of cases, the longest duration of haemoglobinuria was 7 days and the shortest, a few hours. The average was 2.85 days.

Gastro-intestinal tract

Nausea, bilious vomiting, and jaundice are found in all the typical cases. Vomiting is always a distressing complication and seriously interferes with the administration of nutrition and medicaments by the mouth. In one of the patients, the tendency to vomiting persisted even after he was apparently cured and rectal feeding and intravenous glucose had to be resorted to for days together. Hiccough and epigastric pain are also common accompaniments.

Jaundice sets in early and lasts several days after the urine is clear. The liver is often tender, perhaps on account of the extra strain to cope with the haemoglobin set free in the blood.

Blood

Blood was examined for malaria parasites in altogether 15 cases of which 6 showed presence of *P. falciparum* rings, 2 cases showing crescents as well. This gives a 40 per cent positive finding. In those cases, who had taken quinine before coming under observation, no parasite could be found in spite of repeated examinations.

TABLE IV
Showing result of blood examination

	Total cases treated	Total blood examined	M. P. found positive	Percent-age
Cases having previous quinine.	10	5	0	..
Cases without having previous quinine.	10	10	6	60
TOTAL ..	20	15	6	40

Differential count always revealed increase in mononuclear leucocytes, sometimes exceeding 20 per cent.

Toxæmia.—If the urine is free, the consciousness is undisturbed, but, in cases with suppression of urine, severe toxæmic symptoms are noticed. In the only fatal case in the series, the patient had continued suppression for 3 days. She was delirious at first, but later died of coma, perhaps due to uræmia.

Diagnosis

In practice, the only condition with which it can be confused in the early stage is bilious remittent malaria. In the latter condition, the onset is slow, an enormous quantity of bile is present in the urine, and jaundice is slow in appearance. A simple test is found in the textbooks: if a quantity of urine is shaken in a bottle, pink foam appears on the top in black-water urine; it is yellow in bilious remittent malaria.

Treatment

The main principle of treatment consists of:—

- (i) removal of specific cause; we must at present accept malaria parasites to be the cause,
- (ii) maintaining the flow of urine and combating toxæmia, and
- (iii) relieving distressing and urgent symptoms.

The patient should be put to bed and all quinine therapy, including quinine derivatives and combinations containing quinine, should be stopped at once. For controlling malarial infection, synthetic acridin derivatives, such as atebrin (Bayer) or quinocrine (May and Baker), should be administered. In this series of 20 cases, I have used atebrin with uniformly good result and no untoward effect, except that evidence of gastric irritation, has been noticed following atebrin administration. As a routine measure it was exhibited in full doses in all cases whether showing malaria parasites or not.

In severe cases, atebrin musonate, 0.2 to 0.3 gm., was injected intramuscularly during the first two consecutive days; this was supplemented by oral administration of atebrin tablets of 0.1 gm., twice or thrice daily for one or two days following. In mild cases atebrin was given by mouth. Atebrin is mainly excreted through the kidneys; hence in a case with a tendency to diminution in the amount of urine, the dose should be carefully adjusted. By this, the temperature usually returns to normal on the third or fourth day, when the urine becomes clear.

To promote the flow of urine and combat toxæmia, plenty of fluid in the form of barley, glucose, soda and green coconut water, etc., should be enforced from the beginning. The bowels should be kept open by saline purgatives. Alkalies should be given in plenty to maintain

alkalinity of blood and urine, which should be tested each time it is passed.

If vomiting is persistent and the patient cannot retain sufficient fluid by the mouth, rectal saline with 5 per cent glucose should be enjoined. Injection of 25 to 50 c.cm. of 25 per cent glucose solution, intravenously several times a day according to the severity of the case, is very efficacious in maintaining the heart and circulation and inducing diuresis. Five to 10 c.cm. of a 10 per cent solution of calcium gluconate may be combined with the first injection of glucose solution in the morning during the active phase of haemolysis. If suppression is imminent calcium may be replaced by 2 per cent sodium bicarbonate solution intravenously with glucose, and this may be repeated as often as necessary. Hypertonic saline and normal saline may also be injected according to indications. I have not tried large doses of sodium bicarbonate solution intravenously as recommended by Manson (Manson-Bahr, 1935). Amongst other measures, mention may be made of high rectal lavage, with warm water, dry cupping and hot fomentation over the loins. Liquid extract of *punarnava* and liquid extract of *Cassia beareana* in drachm doses may also help to maintain the flow of urine.

Of late, much importance has been attached to administration of infusion of leaves of *Vitex peduncularis* in the treatment of blackwater fever (Measham, 1940). The plant is popularly known as *ahoi* plant in the locality. In several cases of varying degrees of severity, we have used fresh decoction made from freshly collected leaves and found that, if it can be retained by the patient, it acts as a powerful diuretic, but unfortunately even in moderately severe cases its administration is complicated with extreme nausea and vomiting and the patients can hardly stand it; therefore, no therapeutic result is achieved in those cases. It appears to have no effect on temperature and malaria parasites, nor does it stop haemolysis.

For maintaining heart and circulation, pituitrin, adrenalin, coramine, cardiazol, caffeine and sodium benzoate, and injections of glucose solution, normal saline, and where possible blood transfusion may be resorted to according to indication. Some recommend injection of liver extract as a routine measure, as a disturbance of the function of the liver is also supposed to play a part in the genesis of blackwater fever (Nocht and Mayer, 1937). This being a powerful stimulant to the haemopoietic system also helps in the renewal of blood, which can be considerably promoted by iron and arsenic compounds, good nutrition, and adequate rest in bed.

Result of treatment

One patient died out of 20, giving a mortality rate of 5 per cent. Manson-Bahr (1935) recorded average mortality rate of 25 per cent

(Concluded on opposite page)

STAINS OTHER THAN BLOOD-STAINS AS MEDICO-LEGAL EVIDENCE

By S. D. S. GREVAL

LIEUTENANT-COLONEL, I.M.S.

Imperial Serologist and Chemical Examiner to the Government of India

and

S. N. CHANDRA

CAPTAIN (late I.M.S.)

First Assistant

(Imperial Serologist's Laboratory, School of Tropical Medicine, Calcutta)

THESE stains, in order of their importance, are caused by (i) semen, (ii) faeces, (iii) urine, (iv) saliva, (v) sweat, and (vi) miscellaneous substances. They are found on the same kind of objects which are associated with blood-stains.

(Continued from previous page)

and Rogers and Megaw (1930) from 10 to 40 per cent. The writer fully recognizes that the percentage of mortality in such a small series has but little significance. Moreover, in an attack of blackwater fever, often there is one haemoclastic crisis and the treatment is just to help the patient to tide over it; in most attacks, the haemoglobinuria ceases after a few hours of its own accord and all conclusions, therefore, regarding the value of any particular form of treatment have to be drawn with the greatest reserve. The only advantage we have over the older method of treatment is that since the introduction of synthetic anti-malarial drugs the control of malarial infection in cases of black-water fever has been easier.

Summary

1. Twenty cases of blackwater fever have been treated in the plains of Darjeeling-Terai, with one death.

2. The features common to the cases are : fever, haemoglobinuria, vomiting, jaundice and a tendency to diminution and suppression of urine.

3. The treatment employed mainly consists of administration of fluids, alkalis, non-irritating diuretics, intravenous glucose, plus atebrin parenterally and/or by mouth.

Acknowledgments

I record here my sincere thanks to Mr. G. P. Plackett, general manager, and Dr. S. K. Biswas, head of the Medical Department, Darjeeling Himalayan Railway, for the facilities obtained during the treatment of these cases. I am especially grateful to Dr. Biswas for his encouragement in sending this note to the press.

Seminal stains

On one point an important difference of opinion may exist between medico-legal workers: should a positive chemical test, in the absence of finding spermatozoa under the microscope, be accepted as evidence of semen? Some are in favour of doing so (Bagchi, 1937), others against (Owens, 1935; Thomas, 1937; Kamath, 1938; Glaister, 1938; McNally, 1939; Modi, 1940; Rhodes, 1940) and yet others appear to leave the question open (Smith, 1940). The majority, by far, are against accepting the chemical evidence alone. This laboratory follows the majority. All stains suspected or alleged to be seminal are examined microscopically for spermatozoa. The serological test is not applied if spermatozoa are not found.

The chemical tests referred to are the Florence test (formation of brown rhombic crystals of probably periodide of choline on the addition of iodine and potassium iodide) and Barberio's test (formation of slender yellow-tinted rhomboid needles on the addition of a saturated aqueous or alcoholic solution of picric acid).

The serological test, incidentally, is applied for detecting human blood-protein (biological test for blood), not human semen-protein (biological test for semen). It is easier to prepare a fully representative anti-human-blood-protein serum from pooled sera, for detecting blood of subjects of all blood groups and blood types, than an equally representative anti-human-semen-protein serum.

On the appearance of the spermatozoa there is again a difference of opinion : Should the cells be seen entire (head joined to a neck which is joined to a tail) or parts, heads (Chakravarti and Roy, 1938) specially stained (Ganguly, 1936) will do? The majority are for accepting entire cells only. This laboratory follows the majority.

It is recognized that meteorological conditions in India are often against the detection of spermatozoa microscopically; the cells either become too brittle and difficult to detach, or decompose. This, however, cannot be made an excuse for reducing the standard of evidence.

The use of ultra-violet light only aids in locating the areas which bear suspicious staining; a positive result with it does not supply an evidence of semen.

It is now well known that the group-specific substances of the blood, isohæmagglutinogens, can also be present in semen (Wiener, 1939). From a seminal stain, therefore, the group of the subject can be determined. The writers have no experience of this determination. From their experience of saliva, however (*vide infra*), they do not consider such evidence dependable or reliable.

Faecal stains

Two years ago these stains started figuring in criminal procedure in India. Scriptures and places of worship were stated to have been

defiled with faeces, during communal disturbances. Determination of the source of the faeces was required. This led to an investigation in this laboratory concerning (i) the identification of faeces as such and (ii) reaction of an extract from known human faeces with anti-human serum. Specimens free from blood were obtained from the helminthological department of the School of Tropical Medicine, Calcutta. Twelve specimens were tried. Both the attempts failed. It was not possible to be sure of the nature or source of dried faeces. Later, another worker's opinion to the same effect became available. 'Obstetrical stains, those made by urine or faeces, are not amenable to chemical examination' (Rhodes, 1940). Serological test to determine the source of a stain is not applied if the nature of the material under investigation cannot be first determined.

Salivary stains

There is nothing characteristic of salivary stains microscopically. The fresh undiluted fluid is inactive with benzidine, but reacts with anti-human-blood-protein serum. 'Secretors' may have 'isohæmagglutinogens' in their saliva : all subjects are not secretors. These substances when present are supposed to occur in a high concentration : groups of subjects have been determined from saliva present on gummed edges of envelopes (Schiff, quoted by Wiener, *loc. cit.*) or on cigarette stumps. The writers' experience of determination of group from saliva is limited to reactions obtained with the naturally occurring isohæmagglutinins. These reactions are unsatisfactory. Immune anti-A and anti-B sera are open to the objection that many haemagglutinogens occur in the red blood cells, and antibodies produced against them in the blood of the immunized animal may be responsible for many reactions still unknown (Greval and Chandra, 1941). Much more is known about the natural sera than about the immune sera.

It is stated that the isohæmagglutinogens are secreted in other fluids of the body by 'secretors' only, i.e., subjects who secrete them in their saliva. It follows, then, that the other secretions cannot be depended upon like blood.

The isohæmagglutinogen in the semen is supposed to be secreted in the liquid, not contained in the cells (Wiener, *loc. cit.*). If that be so, then, the seminal fluid is as undependable as the saliva.

To a stain only presumed to be caused by saliva serological test to determine its source will not be applied.

Urinary stains

As stated above these stains are not amenable to chemical examination. Determination of group from them has the same fault as the one from saliva.

Experimentally, discrepancy has been reported in work on gorillas (Candela, Wiener and Goss, 1940). A monkey reported AB from

urine, was found to be a questionable B from blood.

Serological test is not applied if the nature of the material under investigation cannot be first determined.

Sweat stains

Certain drugs are excreted in sweat. Drugging of horses can be established by chemical analysis of sweat.

In medico-legal work sweat interferes with the determination, by absorption, of blood group from stains. A blank control from the unstained portion of an article of clothing often absorbs one or both isohæmagglutinins totally or partially. 'Several authors have pointed out that in a surprisingly large number of cases this unstained material will contain one or more of the blood-group receptors, presumably from sweat, urine, animal matter, etc.' (Boyd and Boyd, 1937). Though an indication of the group can be obtained by comparison, the results are not definite and clear cut, and must for medico-legal purposes be rejected. Out of 247 controls tested in this laboratory the reaction of 143 was such that no opinion could be given on the exhibit corresponding to them.

Sweat (or presumably sweat or sweat plus animal matter from the surface of the body) on cloth, though it absorbs the isohæmagglutinins in a prolonged contact (overnight in a refrigerator), does not appear to react with the human-blood-protein anti-serum used in testing blood-stains; still, it indicates the need of controlling the precipitin test with an unstained portion of the cloth.

Identity of sweat cannot be established. Determination of blood groups from a stain only presumed to be caused by sweat is not possible as the serological test is not applied if the nature of the material under investigation is not first determined.

Miscellaneous stains

Dyes, paints, cosmetics, grease, juices from fruits and vegetables, and chemicals may produce stains looking like those of blood or semen. Attention has recently been drawn to a clay (bentonite) which simulates the benzidine reaction of blood (Greval and Roy Chowdhury, 1941). The clay is used in cosmetics. A brand of talcum powder has also been found to react with benzidine. Plant juices, such as potato juice and gum (often used in sticking labels on articles sent for examination), are known to react with benzidine.

Stains caused by these miscellaneous agents are of course found negative for blood spectroscopically and negative for semen microscopically.

Summary

1. *Seminal stains*.—Chemical evidence alone is not satisfactory: spermatozoa must be found. The spermatozoa must be seen entire, not heads

only. Ultra-violet light only locates suspicious areas: it is not evidence of semen. For determining a subject's blood group the semen is not as dependable as blood.

2. *Faecal stains*.—Nature and source of these stains cannot be ascertained.

3. *Salivary stains*.—Nature and source of these stains cannot be ascertained. Fresh saliva reacts with anti-human serum. Some subjects secrete the blood group specific substances, detected by specially prepared sera, in their saliva. Tests with the normal group specific sera are unsatisfactory. Normal sera are preferable to specially prepared sera for immunological reasons.

4. *Urinary stains*.—Nature and source of these stains cannot be determined. Blood group specific substances occur in urine. Discrepancy has been reported in determination of group from urine and blood in monkeys.

5. *Sweat stains*.—Drugs are excreted in sweat. Sweat (or sweat plus animal matter from the surface of the body) in clothes interferes with determination of blood groups from stains. Identity of sweat cannot be established and blood group of the subject from it cannot be determined.

6. *Miscellaneous stains*.—Dyes, paints, cosmetics, grease, juices from fruits and vegetables and chemicals produce suspicious looking stains. A clay used in cosmetics gives a chemical reaction of blood. Fruit and vegetable juices give the same reaction.

A METHOD OF OILING STREAMS AND DRAINS BY AN AUTOMATIC DRIP SYSTEM

By ANANGA KUMAR MISRA

In charge Antimalaria Work, Kakajan Division

DURING the monsoon in Assam heavy rainfall turns the streams and drains into fast-flowing rivulets, when natural flushing deals with the larval colonies in an efficient manner. As, however, natural flushing is not a dependable and constant factor, many drains and streams become abundantly 'positive' in the spells between heavy rainfalls. The oiling of the streams and drains periodically is, therefore, a necessity.

Type 1

- A. An ordinary bottle (beer or whisky) with cork.
- B. A cork.
- C. Glass tubing $\frac{1}{4}$ -inch calibre through the cork, $\frac{1}{2}$ inch outside the cork and $\frac{1}{4}$ inch beyond the inner limit of the cork.
- D. Stems of thatch grass 6 to 12 in number inside glass tubing.
- E. Bamboo rod.
- F. String tying bottle to bamboo rod.
- * If required make a very small hole here; this may be made by a steel driller. This is not necessary as bubbles of air find their way into the bottle via the spaces between the stems of thatch grass.

The drip system has many and various types. This note introduces a simple and efficient method by automatic drip which has been tried out in this district and has proved both efficient and economical.

Two methods are in use of which the first is perhaps the better.

Type 1.—An empty whisky or beer bottle is filled with oil and the cork inserted in the mouth. Through the cork is passed a 2-inch length of glass tubing $\frac{1}{4}$ -inch calibre so that

(Continued from previous column)

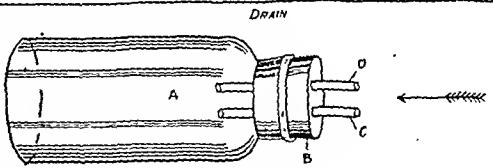

- THOMAS, D. R. (1937) .. *Rep. Chemical Examiner, Punjab*, 1936. Appendix, p. vii. Supdt., Govt. Printing, Punjab.
- WIENER, A. S. (1939) .. *Blood Groups and Blood Transfusion*. Baillière, Tindall and Cox, London.

about $\frac{1}{2}$ inch of the glass tubing projects on either side of the cork. Through the glass tubing are inserted 6 to 12 stems of dried thatch grass about 6 inches long, leaving about 1 to 2 inches projecting outside the tubing. The bottle is tied to a bamboo rod about 4 feet long and this is then inserted into the bed of the stream with the bottle in an inverted position. The accompanying diagram illustrates the method. Provided the oil is strained, blockage rarely occurs and air finds its way through the spaces between the stems of thatch grass to the space over the oil.

One pint of oil is sufficient for 4 to 6 hours and will efficiently oil a stream of about 2 feet wide and 600 yards long.

Type 2.—This needs a fairly wide-mouth bottle, through the cork of which two glass tubes of $\frac{1}{2}$ -inch calibre are inserted; the bottle is then filled with oil. The cork placed in position, the bottle is now put into the stream in a slant-wise position with the mouth facing the flow. The force of the current forces a little water into the bottle and an equivalent amount

of oil into the stream. The bottle should be anchored by a bamboo stake.

Type 2

- A. A wide-mouth bottle with cork.
 - B. A cork.
 - C. Glass tubing for entry of water.
 - D. Glass tubing for oil exit.
- The arrow indicates the direction of flow.

This method is as efficient as the first but perhaps needs a little more care.

The diagram illustrates the method.

I am greatly indebted to Dr. H. Giblin, the medical officer, without whose help this experiment would have been impossible, and also to Mr. C. Sheard, the divisional manager, Kakajan Division, for his kind advice and supply of necessary materials.

A Mirror of Hospital Practice

RUSSELL'S VIPER VENOM IN THREATENED MISCARRIAGE

By K. N. PRADHAN, L.M. & S. (Bom.), B.Sc. (Nag.)
The Private Hospital, Amrut Building, Main Road,
Sitabuldi

History.—13th February, 1941. Mrs. A., aged 25, has the following history. Last menstruation—September 1940.

Record of previous pregnancies:—

- 1st. Still-born.
- 2nd. Born at 8th month, lived 2 days.
- 3rd. Living now, 8 years (girl).
- 4th. Living now, 5 years (girl).
- 5th. Still-born.
- 6th. Still-born at 8th month.
- 7th. Bleeding for a week, nothing could stop it, and miscarriage at 5th month.

Present pregnancy.—8th. Bleeding commenced on 10th February and miscarriage appeared imminent.

Treatment.—14th February. Russell's viper venom intramuscular in the gluteal region. 1st dose 0.5 c.c.m. of 1 in 3,000 solution. Bleeding checked within 3 hours. No pain—no general reaction.

16th February.—2nd dose 1.0 c.c.m.

20th February.—3rd dose 1.0 c.c.m. Bleeding completely stopped.

26th May.—Pregnancy 8 months L.O.A. Foetal heart heard, head floating.

7th July, 1941.—I received the following report from the lady doctor in charge of the case:—

'I have just finished the delivery of Mrs. A. Unfortunately it turned out to be a most difficult case, with hydramnios, extended lower and upper extremities with no proper labour pains. I had given her two injections of pituitrin 0.5 c.c.m. with very slight effect. The foetal heart was quite good but the delay in the after-coming head (about half an hour) was probably the cause of death. It was a full-term male child.'

Summary

Russell's viper venom is of definite value in uterine haemorrhage.

AN ENCEPHALOCELE*

By M. N. PALADHI, L.M.F. (Bengal)
Medical Officer, Lohaghatal Dispensary, Almora,
Himalayas

I WAS recently sent for by a midwife in charge of the local child-welfare centre, Lohaghatal, on account of an abnormal child which had just been born.

It was a fully-developed female child with a fluctuating tumour the size of a green coconuts in the occipital region. It was completely covered by skin and there was thick black hair over about half of the tumour. The top of the head was flat and only about half an inch above the supra-orbital margins. The child was alive and the heart was beating normally but the respirations were somewhat slower than usual. The child died about 12 hours after birth. Incision into the tumour showed it to contain meninges, cerebro-spinal fluid and brain. I was not allowed by the parents to make any further examination such as opening the skull.

The mother gave a history of occasional very severe abdominal pain during pregnancy and it was stated that the pregnancy was of twelve months' duration.

The midwife informed me that the tumour presented first after the membranes were ruptured and labour ended in about half an hour, the placenta following the child almost immediately.

I wish to thank Dr. C. K. Misra, Civil Surgeon, Almora, for permission to report the case.

DECEMBER

THE EVOLUTION OF BLOOD TRANSFUSION AND THE PRESENT EMERGENCY

A CRITICISM frequently levelled at scientific medicine is that a treatment which is hailed as a great discovery one day is decried as being out of date the next. There is of course some truth in this criticism—but not much. We do, in fact, occasionally have our ‘fads and fashions’ which are acclaimed prematurely and on very inadequate grounds; these when put to the test of scientific proof are often found to be wanting, and are discarded. There are, however, few real advances, based on scientific investigation and well tested before they are given out to the world, that do not maintain their place in medical practice for many years, perhaps only to be discarded when some better drug, or method, comes along and replaces them; this, we claim, is progress.

Another charge, given very apt form by that great critic, Bernard Shaw, is that ‘every great medical discovery is made once every fifty years’. This criticism again has the semblance of truth, but does not reflect the whole truth, for it often happens that some method of treatment, let us say, which had a sound theoretical basis, was found in practice to be useless, or even dangerous, until fifty years later when some other advance is made which makes this same method now a useful and perfectly safe procedure.

Thus, although scientific medicine does sometimes appear to move in circles, at each turn of the wheel something more adheres to it and real progress is made. Perhaps the best example of all was the introduction of antiseptic methods which allowed the successful revival of many discarded surgical procedures, but blood transfusion provides yet another equally good example of a scientifically conceived procedure that took many years to become established.

Blood transfusion was first practised in the seventeenth century, at the very beginning of the present era of scientific medicine, and was again revived early in the nineteenth century; it must have achieved some dramatic successes or it would not have had the following that it enjoyed for a few years, but the disasters were equally dramatic and it was almost entirely abandoned for many years; it was in fact forbidden by law in more than one country. Then came Landsteiner’s great discovery of the isohæm-agglutinins and -agglutinogens, and Moss’s and Jansky’s determination of the blood

groups, and blood transfusion began to take its place in therapeutics.

The transfusion of compatible blood was found to be not only a perfectly safe procedure, but one that very frequently carries the patient over a critical period and saves his life. Its greatest uses are in severe haemorrhage and in shock *sine haemorrhage*; it is therefore a little surprising that blood transfusion did not come into greater prominence during the last war. However, blood transfusion services have been well established in most progressive countries for over twenty years, though it was the Spanish civil war with its very large numbers of civilian air-raid casualties that emphasized the very great value of blood transfusion in such conditions and gave a stimulus to blood transfusion organizations throughout the world.

Blood transfusion is usually an emergency measure and the inevitable delay in obtaining a suitable donor will frequently be serious; the possibilities of obviating this delay were therefore explored. It was found that, if blood is taken under strictly aseptic conditions and kept in a cool place, it will maintain all its therapeutic properties for at least ten days. Organizations were therefore set up for keeping a number of transfusion doses of blood of the various groups ready for immediate use. In large centres this worked very well in normal times, as the requirements could be estimated fairly accurately. But, at the beginning of this war, the blood transfusion services in England, anticipating a demand for blood, called up a number of volunteers and collected a large stock of blood against this possible demand; no air raids occurred in the early days of the war and much of this blood became time-expired and had to be discarded.

The idea of using serum or plasma in the place of whole blood was not a new one, and, as there seemed no means of prolonging the life of whole blood *in vitro* beyond the ten days, the possibilities of using the plasma removed from time-expired blood in the place of whole blood were further explored. Recent work has shown that, in many conditions, plasma is quite as useful as whole blood, and, as it can be preserved for a considerably longer time, for storage purposes plasma replaced blood.

Plasma however has its limitations; it has to be kept at a very low temperature or changes occur, and though it can be stored for a much longer time than whole blood, this time is limited, so that again wastage is likely to occur. It was next found that if the moisture is removed from the plasma, by some process that does not entail denaturation of the serum protein, it can be preserved at atmospheric temperatures for a very much longer time than fluid plasma could be preserved in the refrigerator; such dried plasma can be redissolved in sterile distilled water wherever it is required for use. This last advance has opened up great possibilities as it has facilitated very considerably

the transport of plasma, and will probably in actual practice remove the time-limit for storage almost entirely; it is now possible to collect plasma from anywhere in the world for use in any other part of the world. The practical result of this is that in neutral countries such as America, and in Canada, Australia and other parts of the British empire, numerous blood banks have been started for collecting blood from which the plasma is separated and dried, to be sent to the theatres of war and to towns in Great Britain for use for air-raid casualties. One thus has the humanitarian example of the American sympathizer in Kansas City giving his or her blood to save the life of an Indian soldier six months later at Keren, and of the Canadian residing in safety in London, Ontario, helping to build up the plasma reserves for his British cousins in the bombed areas in London on the Thames.

A scheme has recently been inaugurated under the auspices of the Government of India for drying plasma in India for use in the eastern theatres of war and amongst the civilian population in India in the event of air raids on our towns. An apparatus for drying plasma has been ordered from America and is expected in this country before the end of the year. The first machine is to be located in Calcutta. Before plasma can be dried, the blood from which it is to be separated must be obtained, and it is hoped that this blood will be obtainable on a voluntary basis.

The medical profession has a very important part to play in this scheme, by way of educating the public. Every medical man knows that a person in ordinary health can give a pint of blood without the slightest ill effects to himself; he knows that the physiological reserves of the body are quite capable of compensating this loss immediately without in any way affecting the body functions, that the stimulation to the healthy haemopoietic system caused by this blood loss is certainly innocuous and quite possibly beneficial, and that the loss will be made good within a week; but the average layman does not know all this, he thinks that, just because when he cuts his finger, he loses a few drops of blood, and feels faint, he will be seriously ill if he loses a pint of blood; he does not know that the faintness when he cuts his finger is entirely psychological in origin. He has also many entirely unfounded prejudices on the subject, fostered by fables and old wives' tales, and sometimes by distorted religious teaching, which it is the duty of the medical man to dispel.

We know the extreme value of blood transfusions in an emergency, and it is our duty to impress on our patients and on all those with whom we come in contact socially, not only the fact that blood can be given without harm to the donor, but that it is often the only substance that will save a wounded soldier's life, and that to give a relatively small quantity of blood, which they will not miss, is a very small thing to do for those who are fighting for them.

and

C. R. DAS GUPTA, M.B. (Cal.), D.T.M.

(From the School of Tropical Medicine, Calcutta)

B. TRANSFUSION

Transfusion of different elements of blood

1. *Whole blood.*—Whole blood which acts as a 'complete tissue graft' is ideal for transfusion where all the elements of blood are required, but transfusion of whole blood demands a special apparatus, or considerable dexterity and a team of trained workers when the ordinary syringe is used; also the transfusion has to be given very rapidly which may not be advisable. The whole operation of withdrawing and transfusing the requisite amount of blood must be completed within 3 minutes, as otherwise the blood will clot in the syringe. It is seldom practicable to use a syringe larger than 50 c.c.m. and of these three will be required; one to withdraw the blood and one to give it, the third one

being washed out with sterile citrate saline ready for use again.

2. *Citrated blood.*—As an anti-coagulant various strengths of sodium citrate from 2.5 per cent to 3.8 per cent, so that the final strength of the sodium citrate in the mixture is from 0.38 to 0.5 per cent, have been suggested. We prefer to use 3.8 per cent sodium citrate arriving at a final dilution of 0.38 per cent; with this strength the dilution of the blood is not great and it is easy to calculate the amount of sodium citrate solution required, viz, 10 c.c.m. for each 100 c.c.m. of the mixture.

Citrated blood can be used immediately, or, if collected with certain precautions, it may be preserved* in a refrigerator at 2 to 3°C. and used later; ten days is usually considered the maximum safe storage time.

* Following preservative is recommended for stored blood:

Sodium chloride	0.43 gm.
Sodium citrate (dihydrate)	1.05 "
Dextrin	8.5 "
Distilled water	100 c.c.m.
50 c.c.m. of solution with 100 c.c.m. of blood.		

A great advantage in using citrated blood is that the time factor is unimportant. The flow can be regulated, and if necessary it can be given by the drip method. Transfusion of citrated blood is, however, often followed by a mild reaction.

3. Plasma.—If the citrated blood is allowed to stand undisturbed in the refrigerator, the corpuscles completely settle to the bottom of the bottle in two or three days' time and leave the clear plasma at the top. The plasma can now be pipetted off without disturbing the corpuscles at the bottom.

Thus separated, the plasma, after being filtered, can be used at once, stored in a refrigerator for future use, or dried by various processes and later redissolved and used. The great advantages of dried plasma are reduction in bulk and ease of storage, as it is not necessary to keep dried plasma in the cold. Dried plasma can be used for more than a year from the date of its collection. Transfusion of plasma is not usually attended with any reaction, it does not transmit malaria, and grouping of the blood is made unnecessary if the blood of several persons of different groups is mixed before or even after the plasma is separated. It is an ideal therapeutic agent to combat shock and is being very extensively used in the war, as its small bulk facilitates transport.

4. Resuspended corpuscles.—The concentrated corpuscles remaining at the bottom of the bottle after the plasma is separated off can be used for transfusion in suitable cases of anaemia. According to Kolmer (1940), these red cells can be used with satisfactory results up to about eight days, after which their oxygen-carrying capacity and other properties begin to diminish gradually. The concentrated red corpuscles are diluted with glucose-saline—to each 400 c.cm. of sedimented red cells, 50 c.cm. of 1.1 per cent saline with 4.5 grammes of glucose is added; so that the final strength of the glucose in the mixture is 1.0 per cent. The chances of a reaction following the transfusion of the concentrated red cells will be reduced if the leucocytes and platelets, which form a white layer on the top of the red cells, are discarded, and if the mixture is filtered before administration (MacQuaide and Mollison, 1940).

5. Defibrinated blood.—The use of defibrinated blood is now almost obsolete, for the process of defibrination removes many vital properties of the blood and also renders it more toxic.

6. Placental blood.—It has been suggested that the blood left in the placenta at delivery should be utilized for transfusion. Not only is it very difficult to ensure the sterility of this blood, but any procedure that encourages the deprivation of the infant, of even a drachm of the blood that is its due, is in our opinion an immoral one.

7. Cadaver blood.—This has been used in Russia and in certain special circumstances

the utilization of the blood of a body that has no further use for it seems justifiable. In a hot climate the difficulties would be so great that the method need not be discussed here.

8. *The use of heparin as an anti-coagulant.*

(a) *In vitro*, heparin may be used in place of sodium citrate solution; 4 mg. for each 100 c.cm. of blood is recommended.

(b) *In vivo*, 1 mg. per kilogram body-weight is given intravenously to the donor. After the injection, the coagulation time is greatly lengthened; although this relative incoagulability of the blood persists for 30 to 60 minutes or more, it is recommended that the blood be collected from the donor 7 minutes after the injection, that the transfusion be given through a wide-bore needle, and that it be completed within 15 minutes. Injection of such a blood is not injurious to the patient in any way and does not alter the coagulation time of his blood.

Transfusion by this method can be given with a 50 or a 100 c.cm. syringe, and no special apparatus is required.

Indications for transfusion

1. After acute haemorrhage.—To make good loss sustained by an acute haemorrhage, the transfusion of whole or citrated blood, either preserved or fresh, is the most effective. The amount to be transfused will be dependent on the amount lost, but anything less than 500 c.cm. is unlikely to be effective.

2. In shock.—When this follows haemorrhage, it is probably most effectively treated by transfusion of whole or citrated blood, but shock without much, or any blood loss, following burns, for example, which is due to haemoconcentration and stagnation of the blood in the internal organs, is more effectively treated with plasma alone, fresh or reconstituted from dried plasma.

3. As a prophylactic measure against shock.—In weak or exsanguinated patients, even if their condition would not ordinarily demand transfusion, this is often a very valuable procedure to prepare them for a surgical or obstetric operation; blood or plasma is given according to the blood state of the patient.

4. In anaemia.—Blood transfusion is indicated to replace blood lost by haemorrhage or destroyed by other processes, to maintain life in the case of aplastic anaemia, and/or to stimulate blood formation. Whole blood, citrated blood, or resuspended corpuscles can be used. In anaemia, repeated small transfusions of 300 to 400 c.cm. are usually better than a single big transfusion of, say, 1,000 c.cm.; in either case slow administration is to be recommended.

5. For supplying other deficit elements, viz, platelets in thrombocytopenic purpura, leucocytes in agranulocytosis, or fibrin in some cases of clotting deficiency, transfusion of whole blood will sometimes be effective.

6. For ~~compounding~~ ~~toning~~ an increasing passive immunity that was at one time in favour, particularly in America; the bloods of convalescents or of others who had received injections in order to raise the antitoxic value of their blood, or to produce active immunity, were used as specific transfusions in certain cases. However, the new chemotherapeutic agents introduced in the last few years have put this procedure into the background.

Technique of collection and transfusion of blood

Apparatus and solutions required

- (i) Sphygmomanometer.
- (ii) Stethoscope.
- (iii) Bottle for collection of blood (figure 1).*
- (iv) Potain's aspirator, or a Higginson's syringe.
- (v) Glass container with an opening at the bottom to serve as a reservoir for the blood (figure 2).
- (vi) Drip apparatus (figure 3).

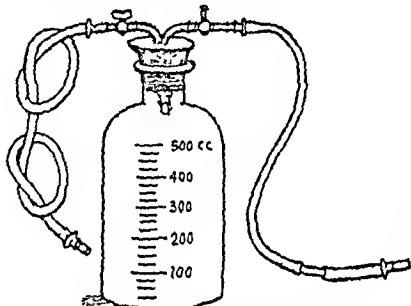

Fig. 1.—Ptain's aspirating bottle, used for receiving blood.

- (vii) Two moderate-size serum-syringe needles in a beaker containing liquid paraffin. It is better to have two sizes as a smaller bore is required for giving than for drawing blood.
- (viii) Rubber pressure tubing.
- (ix) Surgical silk thread.
- (x) Pair of scissors.
- (xi) Two enamel bowls.
- (xii) Lifter.
- (xiii) Drum of sterilized dressings and towels.
- (xiv) Thermometer.
- (xv) Rubber cloth.
- (xvi) Measuring cylinder.

* A Potain's aspirating bottle makes a very useful receptacle for taking blood from a donor. Pieces of pressure tubing are attached to the inlet and outlet taps; to the other end of the inlet tube a record adapter is inserted ready to receive the needle, and the other end of the outlet tube is attached to the Potain's syringe. As an extra precaution to prevent micro-organisms passing into the bottle during the back stroke of the Potain's aspirator, a piece of glass tubing containing a plug of sterile cotton-wool may be inserted in the length of the pressure tubing.

The bottle is graduated on its outer surface by marks at 25 c.cm. intervals up to 500 c.cm., so that the amount of blood collected can be seen at a glance.

The joints, taps, etc., must be absolutely air-tight.

There are many standardized bottles now in use in Britain and America which can be used for collecting, storing, and giving blood without transferring it; the chances of contamination are thus reduced to a minimum. The bottles are made so that for giving blood they can easily be hung in an inverted position, and an air inlet tube inserted. Such a bottle is described by Hamilton Bailey (1940) (figure 4). See also Hayes *et al.* in last issue of this journal.

- (xvii) Examination couch or easy chair for the donor.
- (xviii) 3.8 per cent sodium citrate solution and normal saline, both freshly prepared with pyrogen-free distilled water, and sterilized.
- (xix) Tincture of iodine.
- (xx) Tincture of benzoin.
- (xxi) Absolute alcohol.
- (xxii) Bowl of antiseptic lotion.
- (xxiii) Glass of water or some beverage to counteract any temporary psychological shock experienced by the donor.

Additional apparatus if the transfusion is given by the open method

- (i) A splint to immobilize the limb in which the transfusion is given.
- (ii) Dissecting instruments, *viz.*, scalpel, scissors, probe, forceps, and aneurism needle.
- (iii) Sterilized silk.
- (iv) Curved needle and silkworm gut.

Selection of donors

Strong healthy persons between the ages of 20 and 45 are the best donors, but healthy adults up to 60, at least, are quite satisfactory. The donor must be free from any infectious disease and his blood must always be examined for syphilis (Wassermann or Kahn reaction). He should be questioned about allergic manifestations, *e.g.*, asthma, urticaria, etc., as a temporary sensitivity to allergens may be

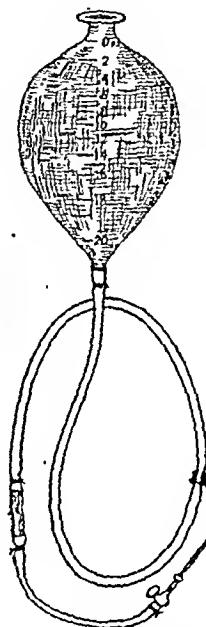

Fig. 2.—Transfusion apparatus for giving blood or saline, with the drip-feed apparatus incorporated in the tube (in this figure the length of the tubing between the drip-feed and the needle is shorter than it would be in practice).

Fig. 3.—Drip-feed apparatus.

† Water may be made pyrogen-free in the following way:

In a clean glass still, re-distil some freshly distilled water to which a little sulphuric acid and one or two crystals of potassium permanganate have been added to give it a faint pink colour. During the process of distillation, the pink colour disappears from the water in the still, a little more sulphuric acid and potassium permanganate must be added.

The distillate is collected in a closed glass flask which has been previously prepared by rinsing first with a solution of potassium bichromate and sulphuric acid, then washing out first with distilled water, and then with pyrogen-free water; and finally sterilized by autoclaving.

The pyrogen-free water is sterilized in an autoclave, and may be used for about 3 to 4 days.

transmitted through transfusion. Malaria in a donor is a special danger in this country, especially if the recipient has never had malaria.

Preferably, the donor should be of the same group as the recipient, but a 'safe universal donor', group O (*vide part XIII*), may be used for giving blood to people of all four groups and a 'universal recipient' (group AB) may receive blood from donors of all four groups. The following table shows the groups of suitable donors for different recipients :—

If recipient belongs to group	Donor should be of group
AB	AB, A, B, or O
A	A or O
B	B or O
O	O

In all cases, the cells and serum of the recipient must be cross-matched with the serum and cells of the selected donor, even when the recipient and the donor are of the same group.

After a transfusion this cross-matching of blood between the donor and the recipient must always be done again before another transfusion is given, because the previous transfusion may produce some change in the blood of the recipient which will render it incompatible with the blood of a donor whose blood was found to be suitable before a transfusion was given.

The same donor must never be used for the same recipient after an interval of more than 10 days after the last transfusion, on account of the dangers of an anaphylactic reaction.

A healthy donor of average size can give 500 c.cm. of blood once a

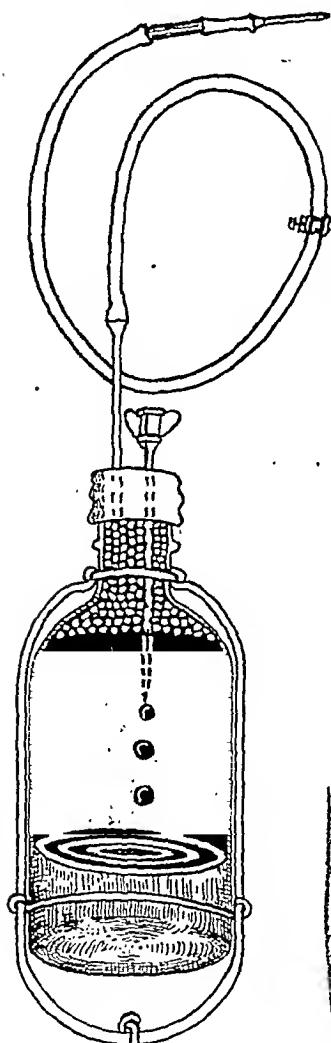

Fig. 4.—Transfusion apparatus in which blood is filtered through glass beads: air or oxygen is bubbled through the blood and helps to prevent the red cells settling.

month without any detrimental effect to his health. After such blood-letting it takes 7 days to make good the loss of blood, but the compensatory mechanisms of the body are so efficient that whilst this deficit is being made up the donor will not be conscious of the loss in any way and will be capable of performing his full day's work as usual.

Collection of blood

The donor should, if possible, fast for 2 to 3 hours before the blood is taken, because some articles of diet, though innocuous to the donor, may produce allergic symptoms in the recipient.

The donor should be made to lie comfortably on the couch and there should be sufficient light on the selected arm. A sheet of rubber cloth should be placed under the arm.

Put the requisite amount of 3.8 per cent sodium citrate solution (10 c.cm. for 90 c.cm. of blood to be taken or for every 100 c.cm. of the mixture) in the collection bottle, from which the air is now partially exhausted by pumping with a Potaïn's aspirator syringe, or with a reversed Higginson's syringe if the former is not available. Fit a needle of medium calibre on to the tube attached to the inlet tap and test the negative pressure in the bottle by immersing the needle in sterilized saline and partially opening the stop-cock in the inlet tap, when the saline will be sucked into the bottle. The bottle is now ready for use.

In the meantime an assistant has taken the systolic and diastolic pressure of the donor, and the pressure is kept midway between these two readings. The skin over the vein is sterilized with iodine and then swabbed with alcohol to remove the stain of the iodine. Puncture the vein with the needle* and, when it is in the vein, open the stop-cock in the inlet tap, when the blood will flow freely into the bottle. The bottle is shaken gently so that the blood mixes thoroughly with the citrate solution and does not clot. When the requisite amount of blood has been collected, let out the air from the sphygmomanometer, close the stop-cock, and then take out the needle from the vein. Apply digital pressure over the puncture for a minute or two, seal with tincture of benzoin, apply a sterile dressing, and put on a firm bandage.

Give the donor a drink of cold water or milk, or if he, or she, shows any signs of psychological shock, some stimulant, e.g., sal volatile, or some suitable form of alcohol.

Transfusion of blood

Make certain that all the apparatus for transfusion is ready and sterilized before starting the

* If the vein is not prominent or the operator is inexperienced, it is not advisable for him to attempt to puncture the vein with the needle alone, but to attach it to a syringe; a little blood is drawn into the syringe to make certain that the needle is in the vein; the syringe is then detached from the needle to which the adapter in the end of the collecting tube is quickly fitted. The 'vein seeker' which is sometimes recommended achieves much the same end.

operation. For the method of sterilizing the different parts see below.

Select a good vein and arrange the patient comfortably on the bed with his arm resting on a pillow covered with rubber cloth. Sterilize your hands and fit one end of a piece of sterilized rubber tubing to the bottom of the glass reservoir. A record adapter to which is fitted a needle of small bore is now firmly fitted to a narrow tube about 2 inches long; the other end of this tube is fitted by means of a glass connexion to the end of the long rubber tube attached to the glass reservoir. The glass and the rubber connections, the rubber tubing with the reservoir, glass tubing, and the adapter are now firmly tied with silk. If the transfusion is to be given very slowly, the drip apparatus (figure 3) is incorporated at about the middle of the long rubber tube attached to the glass reservoir. To the rubber tube, a little above the drip apparatus, is attached a pinch-cock to regulate the flow of the transfused fluid.

Wash out the apparatus by pouring sterilized normal saline into the reservoir, drive out the air bubbles in the tube by squeezing the rubber tubing, and see that the saline flows freely through the needle, leaving a little, about 10 c.c.m., of saline in the glass reservoir, but, when a drip apparatus is used, manipulate the pinch-cock above it so that the saline flows only in drops through the drip apparatus, and consequently also at the same rate through the needle at the extreme end.

The skin over the selected vein is sterilized with tincture of iodine and an assistant applies pressure with one hand just above the selected vein, in order to make it stand out prominently. The operator now punctures the vein; with a successful puncture the blood from the patient will flow back into the glass tubing, but, when the pressure above the vein is released, the flow is thereby reversed and the saline will pass into the vein. (As in the case of the donor, the puncture may first be made with the needle attached to a small syringe, a little blood withdrawn, the syringe detached from the needle, and the adapter at the end of the rubber tubing from the reservoir fitted to the needle.) When it is seen that the saline is passing into the vein, the citrated blood in the bottle is gently shaken and then poured into the glass reservoir through a few layers of sterilized gauze placed on the top of it.

The rate at which blood is transfused will depend entirely on the circumstances. In a case of acute and serious blood loss, a rapid transfusion is indicated, 500 c.c.m. being given in 10 to 15 minutes, but in chronic conditions, especially cases of severe anaemia, the drip-feed method by which 1 c.c.m. per pound weight of patient per hour is given, or an even slower rate in which it takes 24 hours to give 500 c.c.m., is preferable.

When most of the blood has been given, a little warm saline is added to wash out the residual blood in the reservoir and the tube, the

needle is taken out, and for a minute or so, pressure is applied to the puncture, which is then sealed with tincture of benzoin and a bandage applied over a sterile dressing.

The transfusion by the closed method is possible in all but extremely debilitated patients with very low blood pressure and collapsed veins; in those cases transfusion by the open method is resorted to.

The open method.—The vein used for open transfusion is subsequently ligatured and for that reason, and on account of the greater convenience of keeping the leg immobilized for a long time, the great saphenous vein is usually chosen. The leg is immobilized with a splint, the vein is opened, and a Rogers' cannula, which is used in place of the ordinary needle, is inserted into the vein. The cannula is kept in position with adhesive plaster. With this technique blood can be given by the drip method at a very slow rate over a long period, 24 hours or more, without tiring the patient or interfering seriously with his movements in bed.

Cleaning and sterilizing of the apparatus

Separate all the parts of the apparatus, wash first in tap water, and then syringe tap water through them.

Next wash with dilute solution of soap and rinse thoroughly in water to remove the soap.

Place all the parts in a large pan containing 0.1 per cent NaOH and boil for 5 minutes.

Transfer to another bowl and wash first with distilled water and finally with pyrogen-free water. Allow to dry and pack for sterilizing.

Wash the needle first with water and next with hydrogen peroxide, remove hydrogen peroxide with distilled water, dry in alcohol and ether, and keep it in a vessel containing liquid paraffin.

Sterilization

(i) Rubber and metal attachments by boiling in normal saline for 10 minutes.

(ii) Glasswares, e.g., bottle for collection of blood, and the glass reservoir for transfused blood—in an autoclave at 120°C. for half an hour or in a hot-air sterilizer at 180°C.

Drip apparatus sterilized in the same way.
boiling in liquid paraffin for about 10 minutes.

(iv) Cutting instruments—in strong lysol lotion and washing in sterilized distilled water before use.

Reactions after transfusions

Transfusion of citrated blood is very often accompanied by slight reactions, which are sometimes due to pyrogenic substances present in the apparatus and in the distilled water used for preparing solutions. Reactions after transfusion of stored citrated blood are often more severe than when fresh citrated blood is used. There is seldom any reaction after transfusion of plasma alone.

OCULAR MANIFESTATIONS DUE TO
LACK OF VITAMIN 'A' IN THE SYSTEM*
(WITH SPECIAL REFERENCE TO THE TREATMENT
IN GENERAL PRACTICE)

By R. B. BISWAS, M.B.

Clinical Worker, Indian Research Fund Association, Eye
Infirmary, Medical College Hospitals, Calcutta

It is a well-known fact that as a result of
vitamin-A deficiency people suffer from night

* Rearranged by the Editor.

(Continued from previous page)

Reactions after transfusion may be divided
into three groups :—

- (i) due to defects in the donor,
- (ii) due to technical causes, and
- (iii) due to autogenous causes in the recipient.

These reactions will therefore to some extent
be avoided by

(i) careful selection of donors, particularly
avoiding allergic subjects,

(ii) following carefully the instructions given
above and giving particular attention to the
following—washing all the apparatus with
normal or citrated saline so that no trace of
distilled water is left in any of them, and
avoiding excessive shaking, overheating and
rapid administration of the blood, and

(iii) taking action according to the circum-
stances, as follows :—

*Autogenous causes in
the recipient Remedies*

(a) Susceptibility of
the patient to
shock Lower the head end
of the bed, cover with
blanket and apply
heat to the extremi-
ties. If required 0.5
c.cm. of adrenalin
chloride may be given
hypodermically.

(b) Allergy Adrenalin chloride
0.5 c.cm. hypodermic-
ally; calcium by the
mouth and by injec-
tion; and calamine
lotion locally in the
case of urticaria.

(c) Lysis of recipi-
ent's blood
(generally seen
in cases of haemo-
lytic anaemia) An alkaline mixture
should be taken before
the transfusion, and
the transfusion should
be given very slowly.

blindness, and that when the deficiency becomes
extreme keratomalacia develops. This deficiency
in the system affects the general health and
is associated with several other diseases, e.g.,
boils, etc., with which general practitioners
deal every day. With a proper supply of
vitamin A along with the diet, or, if required,
as medicine, many eyes can be saved from
keratomalacia and its complications.

Keratomalacia is one of the commonest causes
of blindness in Bengal amongst children below
the age of 5 years. It does not develop
suddenly, but gradually passes from one stage
to the next, from mild to severe forms. It is
sad to see patients, especially children suffering
from keratomalacia, coming to the eye hospital in
such an advanced state that it is often impossible
to save the eyes. From the history, one usually
ascertains that they were under the treatment
of physicians for either gastro-intestinal or liver
complaints; or other systemic diseases. In the
course of the treatment, when the eyes were
affected, they were advised to attend an eye
hospital. If the conditions are not very
advanced the eyes are saved, but in many of the
cases the patients come when they are already
blind. During the investigation it has been
noted that out of 215 cases of keratomalacia 127
cases (i.e., 59 per cent) came in a late stage.

In this paper the following points will be dealt
with:—

- (a) The causes of deficiency of vitamin A
in the system.
- (b) Ocular manifestations of vitamin-A
deficiency.
- (c) Prophylaxis.
- (d) Treatment of these conditions.

Etiology

The causative factor is deficiency of vitamin
A in the system. The deficiency may be due to
several causes—(i) It may be due to want of a
proper supply of vitamin A in the food. Owing
to their poverty, a large percentage of people
cannot get sufficient food rich in vitamin A; e.g.,
milk, butter, green vegetables, etc. An insuffi-
cient supply of milk to children is one of the
commonest causes of this deficiency.

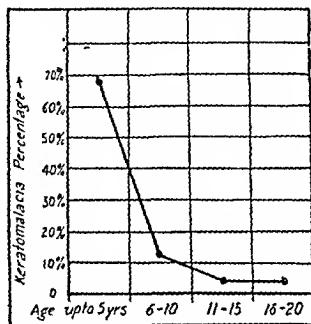

Owing to ignorance in many cases expectant
and nursing mothers are not properly supplied
with sufficient milk in their diet. In the case
of children this deficiency is commonly due to
insufficiency or absence of breast feeding. Where
breast feeding is inadequate, artificial feeding
very often is deficient in vitamin A. In many
cases of systemic diseases patients' diet does not
contain sufficient vitamin A, and in the course
of the disease the eyes are affected.

(ii). The supply may be sufficient but
absorption into the system may be deficient.
Intestinal disorders, e.g., diarrhoea, dysentery,
colitis, etc., and liver disease, e.g., obstructive
jaundice, cirrhosis, etc., interfere with absorption
of the fat-soluble vitamin A.

Excessive utilization of vitamin A in the system, as in acute infectious conditions, e.g., typhoid, may cause this deficiency when a proper supply is not maintained.

Age incidence.—The milder manifestations are found at all ages, the severe form mostly in children below 5 years; 74 per cent of our severe cases were children below 5 years of age.

Keratomalacia at different ages:
Distribution of cases

Note.—Only 13 per cent were above 21 years of age.

Gastro-intestinal disorders were present in 78 cases, out of which 68 cases (i.e., 87.16 per cent) were below the age of 5 years.

Climatic influence.—The ocular manifestations due to vitamin-A deficiency are more common in the rainy season, probably owing to frequent attacks of diarrhoea, dysentery, colitis, etc., being more common during this season.

Incidence in Bengal.—This is one of the commonest causes of blindness in the province. A large number of people suffer from this condition of deficiency with various ocular manifestations. In five different districts of Bengal (Pabna, Rangpur, Midnapur, Nadia, Khulna) it has been noted that 8.9 per cent show signs of vitamin-A deficiency.

Signs and symptoms.—The earliest manifestation of the ocular affection is night blindness (hemeralopia). In the case of children, the parents notice that the children cannot walk in the dark, and are unable to recognize or pick up anything from the ground in the evening, which they could do before. It should be always remembered that night blindness is not always

an indication of vitamin-A deficiency, because in cases of glaucoma, and also in many diseases of the retina, choroid, optic nerve, lens and the vitreous body night blindness occurs. These

conditions must be excluded before assuming that night blindness is due to vitamin-A deficiency. In cases of night blindness due to vitamin-A deficiency usually the vision is normal, or can be corrected by glasses to normal.

The second stage of this deficiency produces changes in the epithelium and in the colour of the conjunctiva, e.g., keratinization producing xerosis and Bitot's spots. The loss of lustre and dryness of the conjunctiva with Bitot's spots are usually noted in the bulbar conjunctiva in the palpebral fissure. The xerotic patches are noted usually on the inner and the outer sides of the cornea on the bulbar conjunctiva. Bitot's spots are white, foamy, triangular, raised areas situated in the palpebral fissure usually on the temporal side of the cornea. The base of the triangle is towards the limbus and the apex is towards the outer canthus. The pigmentation is most marked at the limbus and spreads to the fornices of the conjunctiva. These changes are not necessarily due to vitamin-A deficiency and are probably associated with other vitamin deficiencies. In many cases with these manifestations, the dark-adaptation tests reveal no vitamin-A deficiency in the system.

In the third stage there is a diminished sensibility of the cornea. Diminished sensibility of cornea can be tested by touching the cornea with a small point of cotton wool. When the cornea is touched the patient does not respond by closing the eyelids. In advanced cases of this stage there is a general haziness of the cornea. The appearance is not of opacity of the cornea but of diminished transparency.

In the fourth stage a number of areas of degeneration appear in the corneal structure—the deep layers of the cornea. They appear as grey areas, crescentic in the periphery and circular in the central region. Multiple areas may develop at the same time. The areas of

degeneration very quickly break down, leading to the next stage.

In the fifth stage the cornea breaks down. This is due to degeneration of the corneal tissue. The breaking down is not associated with an inflammatory reaction in the eye, in the absence of secondary infection. The cornea rapidly disintegrates, leading to perforation with prolapsed iris. This is the reason why it is called keratomalacia (softening of the cornea).

The sixth stage is one of blindness. The cornea has completely broken down leading to phthisis bulbi, anterior staphyloma, in the absence of infection or panophthalmitis in the presence of infection.

Prophylaxis

Babies.—A sufficiency of milk and butter in the diet of expectant and nursing mothers is essential; otherwise one teaspoonful of cod-liver oil or fish-liver oil twice daily should be taken. This will ensure there being sufficient vitamin A in mothers' milk, a large amount of which is required by the growing child. Mothers' milk is the best food for babies, if mothers' milk is not available humanized cow's milk with a little vitamin A in the form of two drops of adexolin or halibut-liver oil twice daily should be given.

Children and adults.—Sufficient milk, butter, eggs, green leafy vegetables, etc., should be taken in the diet. In many cases people cannot afford milk and eggs. They should be advised to take plenty of green leafy vegetables (e.g., palang shak, puni shak, cabbages, etc.), carrots, fresh fruits and fish.

Principle of treatment

1. To supply sufficient vitamin A and ensure its absorption into the system as soon as possible

- (a) with diet,
- (b) as medicine—
 - (i) oral administration,
 - (ii) parenteral administration,
 - (iii) by inunction.

2. To treat local conditions of the eyes.
3. To treat gastro-intestinal, bronchial and liver complications.

Oral administration.—In the absence of any liver or gastro-intestinal disorders vitamin A in the form of cod-liver oil, adexolin, halibut-liver oil or, medicinal fish-liver oil* should be used.

Inunction.—The skin of the chest back, axillæ and groins should be cleaned with

soap and tepid water and the areas should be thoroughly dried with a towel. One drachm of pure cod-liver oil or medicinal fish-liver oil (Shaliverol) should be rubbed into these areas gently for a few minutes and the child put in the morning sun daily.

This method of treatment is not so satisfactory as parenteral administration, but it is useful when vitamin-A concentrate suitable for intramuscular injection is not available.

Parenteral administration.—To get a prompt and satisfactory result, parenteral administration of vitamin-A concentrate should be used without delay. For this purpose 'Prepalin' (Glaxo Laboratories) parenteral vitamin A (1 c.c.m. contains 100,000 I. U.) can be used. It is used intramuscularly into the deltoid or the gluteal muscles. The dose for a child will depend on the development of the muscle into which the medicine is injected, e.g., 1 c.c.m. into a well-developed gluteal muscle. Prepalin is obtained in 1 c.c.m. ampoules, 0.5 c.c.m. can be injected into children. Injections should be at one week's interval. Two or three injections are sufficient for curing the condition. In the case of an adult 1 c.c.m. should be used at a time. The site of the injection should be gently massaged, and a warm compress advised over the area, specially where the muscles are weak and thin, as in emaciated children. In the presence of an inflammatory reaction in the area, a second injection should be given on the second day in another area, because in the presence of inflammation the absorption of vitamin A may be interfered with.

Treatment of eye complications

Along with the injections, the local conditions in the eyes require treatment. In the absence of secondary infection, local treatment in the first four stages is not necessary. In stages III and IV liquid paraffin drops twice daily should be advised. In stage V where corneal ulcer has developed, atropin ointment $\frac{1}{2}$ per cent is put in once each morning, and if there is secondary infection the eyes should be washed repeatedly with warm normal saline lotion and protargol 5 per cent dropped in once a day. If perforation is threatening (in the absence of secondary infection) the eyes should be bandaged.

The treatment mentioned above is very efficacious and gives very good results in all cases up to early cases in stage V, but, in advanced cases in stage V and in all cases of stage VI in which the eyes are already blind, practically nothing can be done to save the eyes. Treatment is then carried out only for the patients' general health.

Treatment of diarrhoea in children

- (1) Stop all feeds for 24 hours. Water may be given freely, if necessary sweetened with

* Medicinal fish-liver oil can be obtained from the Director of Industries and Commerce of Madras and Shaliverol from the Director of Marine Biology, Travancore.

a little saccharine or *tal misri* (sugar candy of palm juice).

(2) Mild laxative :—

R

Sodii sulphatis gr. x
Sodii citratis gr. v
Syrup m x
Aquam ad 5ii

Give this 2- or 3-hourly, 3 or 4 doses according to response. If there is much watery purgation kaolin gr. x may be added to each dose.

(3) Skimmed milk—with sugar of milk and sodium citrate if needed.

(i) Skimmed milk—4 ounces.

(ii) Water—4 ounces.

(iii) Sugar of milk (or *tal misri*) 2 teaspoonfuls. Feed the child 3-hourly.

When diarrhoea is cured, humanized cow's milk with a little vitamin A in the form of a quarter teaspoonful of cod-liver oil in each feed is advised.

Milk—4 ounces.

Water—4 ounces.

Sugar of milk (or *tal misri*)—2 teaspoonfuls.

Cod-liver oil— $\frac{1}{4}$ teaspoonful. The cod-liver oil is gradually increased according to tolerance.

Skimming of milk.—One pint or one quart of fresh milk is placed in a glass douche can in a cool place. The milk is allowed to stand for some time when the main cream content will settle in the upper layers. The lower three-quarters are syphoned off; this is skimmed milk (proportion—protein 3 per cent, sugar 4.8 per cent, fat 0.5 per cent, calorie value 10 per ounce).

My thanks are due to Lieut.-Colonel E. O'G. Kirwan, C.I.E., M.D., F.R.C.S.I., I.M.S., professor of ophthalmic surgery, Medical College, Calcutta, and to Captain K. Sen, M.B., F.R.C.S.E., D.O.M.S., honorary ophthalmic surgeon, Eye Infirmary, Medical College Hospitals, Calcutta, without whose help and guidance the production of this paper would not have been possible.

My thanks are also due to the staff of the Eye Infirmary, Medical College, and to Mr. H. C. Mukherjee, for their co-operation and help.

Medical News

MEDICAL ETHICS

ACCORDING to the resolution passed at the meeting of the general body of the Bombay Medical Union held on 7th April, 1941, two lectures on medical ethics are being circulated.

The question of observance of medical ethics by our colleagues all over India and especially in the Bombay Presidency, has been engaging the attention of the managing committee and different members of the Bombay Medical Union from time to time, for over 40 years.

From the very beginning as far as we know, there has been no teaching on this subject for students or post-graduates. It is very necessary that all our colleges should make provision to enlighten students and

subject before they are turned into medical men. They must be trained in their colleagues, their patients, and their profession. In no circumstances can we treat our profession as a mere trade. Not only is the teaching on the subject entirely omitted but what is worse the students and post-graduates see that some of their own teachers and leaders of the profession very often indulge in indirect practices of publicity and advertising in the lay press. Is it any wonder that they imitate the example of their teachers, in their professional life?

Fortunately, to our knowledge, there are a few honourable exceptions, who in spite of the provocations of their colleagues and in spite of great financial loss thereby, have stuck to the principles of professional honour and respect during the whole period of their careers. They deserve our greatest respect and admiration. As far back as 1910, our president Dr. Bacha had occasion to send a 'disclaimer' to the British Medical Journal because a few papers in Bombay had taken notice of his having obtained the Fellowship of the Royal College of Surgeons and at the time he sent a private warning to the papers not to publish anything of his professional career in future. As Dr. Bacha has been our president for the last two consecutive years the secretaries thought it worth while to request him to give a few lectures on the subject to the members of the Bombay Medical Union.

Instead of treating the subject in general only, he has very wisely stressed and emphasized the evil practices which are rampant in our profession. To our great surprise and satisfaction almost all the members who attended the lectures were unanimously of opinion that some practical ways and means should be found to discourage and stop these practices altogether.

The Bombay Medical Union has already appointed a sub-committee with this object. As Dr. Bacha says, we have a profession equal to any in the world as far as our skill and abilities are concerned; then, why should we be failing in the eyes of the medical fraternity of the world, in matters of medical ethics?

ADENWALLA MEDAL AND PRIZE IN OPHTHALMOLOGY

THE committee of the All-India Ophthalmological Society announces that the subject for the next award of the Adenwalla medal and prize in ophthalmology will be 'Changes in the cornea due to malnutrition'. The prize will be awarded to the best work on the above subject and is open to all ophthalmic specialists resident in India. The essays must be submitted to the secretary, All-India Ophthalmological Society, before the 15th November, 1942.

ORDER OF THE HOSPITAL OF ST. JOHN OF JERUSALEM

THE King has been graciously pleased to sanction the following promotions in, and appointments to, the Venerable Order of the Hospital of St. John of Jerusalem :—

As Commanders (Brothers)

Major-General Sir Gordon Gray Jolly, Kt., C.I.E., I.M.S., M.B., D.P.H.

As Officers (Brothers)

Lieut.-Colonel Frederic Allan Barker, C.I.E., O.B.E., I.M.S., (Retd.).

Public Health Section

REORGANIZATION OF THE MEDICAL AND ALLIED SERVICES IN GREAT BRITAIN

TOWARDS the close of the Great War of 1914-18, the inadequacy of the organization for the provision of medical and public health services came to be recognized by almost all the progressive national governments. The growth of knowledge that had taken place resulted in making more complex the measures necessary for combating disease and ensuring health. This resulted in increased cost of treatment, if the full range of medical service were to be utilized, and the bulk of the populace could not afford to pay for the specialist and other services required. Consequently, in order to bring the advantages of medical knowledge within reach of all citizens, it came to be recognized that the health of the populace should be a direct concern of the government.

In pursuance of this recognition, the Consultative Council of the Ministry of Health on Medical and Allied Services in Great Britain, 1920, drew up a scheme the aim of which was to make all the best means of maintaining health and curing disease available to all citizens. The main features of the scheme were: close co-ordination of preventive and curative medicine, regionalization of administration by means of primary and secondary units, and close co-ordination of a key-base hospital, wherever possible, with a teaching hospital.

However, as is usual, once the stress and strain of emergency was alleviated there was relapse to *laissez-faire*. It however continued to be recognized that the *status quo* was unsatisfactory and the passage of the Local Government Act of 1929 and the formulation of various schemes, particularly that of the British Medical Association in 1938, were the significant indications of this recognition. These, however, were of a fragmentary nature and could only ensure partial relief.

The stimulus of the present war is again focusing attention on the weaknesses of *ad hoc* medical organization. Significant steps are in process of initiation to remedy the situation. The Nuffield Provincial Hospital Trust gave effect early in 1940 to a scheme, in essence comparable to that adumbrated by the Consultative Council of the Ministry of Health in 1920. Three regional councils have been constituted for Berkshire, Buckinghamshire and Oxfordshire; Devon and Cornwall; and Northumberland, Durham and parts of the North Riding of Yorkshire. Regional medical advisory committees have been constituted in each of these three regions and in Scotland. It is also of particular interest to note how this stimulus has affected the medical profession itself as is

evidenced from the summary of the report of the special committee appointed by the West Somerset Medical Club to plan a scheme of post-war medical services—published in the Supplement to the *British Medical Journal*, 26th July, 1941—and which also conforms in general principle to the 1920 report. One naturally awaits with great interest the scheme that will be forthcoming from the Planning Commission of the British Medical Association set up in January 1941, the terms of reference of which are 'to study wartime developments and their effects on the country's medical services, both present and future'.

Sir Arthur Newsholme may prove to be one of those individuals who lives to see the fulfilment of his own prophecy in his own country. Sir Arthur defined the necessity for the socialization of medicine as the rendering available for every member of the community, irrespective of any necessary relations to ordinary conditions of individual payment, of all the potentialities of preventive and curative medicine. The trend in the past twelve months in England is increasingly towards the socialization of medicine. The development in New Zealand, noted elsewhere in this issue, is of significance in this respect.

PUBLIC HEALTH ADMINISTRATION

COURSE OF PUBLIC HEALTH EVENTS

I. NEW ZEALAND MEDICINE

(Extract from *Medical Care, Summer Issue, 1941*, p. 262)

NEW ZEALAND has a long tradition for advanced social legislation and one of the lowest death rates of any country in the world. In 1938 a comprehensive Social Security Act was passed, consolidating the already established unemployment insurance, old age, widows' invalidity, and other benefits, and adding a programme of medical care. The 'social security fund' out of which all these services are supported is built up partly by payments from employed persons, matched more-or-less equally by payments from general taxation.

Under the law, the 'health benefits' are administered by the Ministry of Health, and are 'available to all persons ordinarily resident in New Zealand without regard to economic status, race, or nationality'. They include (1) 'Medical benefits', i.e., care by a general physician; (2) Hospitalization; (3) Maternity care; (4) Ordinary drugs and medicines; and authority was given for adding, when practicable, specialist services, dentistry, home nursing, and domestic assistance.

Maternity care.—Opposition by the medical association which includes about 90 per cent of the 1,500 physicians of New Zealand, caused the Ministry of Health to defer the medical benefits and to start with maternity care, 15th May, 1939. Every woman is entitled to the services of a physician, home nursing, and two weeks' hospital care, if necessary. She has free choice of doctor, hospital, or nurse. 'Every doctor undertaking maternity work in the course of his practice will be entitled to receive payment from the social security fund . . . according to a scale of fees fixed by agreement between the Minister of Health and the Council of the . . . Medical Association.' Nearly all physicians who do any obstetric work have agreed to carry on under the scheme. Patients who employ officially recognized specialists in obstetrics may be

charged extra fees. Mothers may go to either governmental or private hospitals. The latter are paid fixed fees from the social security fund. 'The services of anaesthetists and consultants are also provided for' . . . (and) . . . 'medical services in relation to miscarriage, provided the patient has received approved ante-natal advice before the occurrence of the miscarriage'.

Hospitalization.—New Zealand has a developed system of public hospitals, governed by locally appointed boards and with salaried medical staffs, like the corresponding hospitals in England. There are also voluntary hospitals. 'Hospital benefits' under the new law went into effect 1st July, 1939. Public hospitals are paid from the social security fund a fixed *per diem* rate (6 shillings) for each patient who receives without charge medical and surgical attention as well as nursing and maintenance. Certain services are also available to out-patients. If the patient wishes to go to a voluntary hospital, he may do so. The hospital is paid the same rate from the fund and must apply that payment against its usual charges to the patient. Of the hospital and maternity benefits a New Zealand health official wrote last autumn that they were 'in smooth and efficient operation'.

Physicians' services.—Objections from the medical association caused the operation of this section of the Act to be postponed. In 1940, the law was amended, and in its new form was promulgated as in effect in May 1941. Services are for the present limited to those of general practitioners. There is free choice of doctor and freedom on the part of the doctor to accept or reject any patient.

Physicians are remunerated on a capitation basis, i.e., so much per year for each patient on his list (at present 15 shillings), plus mileage fees when required. Specialist services, being beyond the present scope of the scheme, must be paid for by private arrangement between specialist and patient. Professional advisory committees are provided for. Ordinary drugs and medicines are also paid for by the social security fund. This section of the Act was also put into effect in May, after the Ministry of Health had effectuated arrangements with the pharmacists.

An editorial in the *New Zealand Medical Journal* of February 1941, comments in part as follows:—

Under a cloak of innocent voluntaryism the amendments . . . are devised to bring the pressure of individual patients, and of organizations of patients, on individual doctors in order to undermine the profession, and to break down the resistance of the association to the socialization of medicine. They are calculated also to promote a spirit of defeatism by fostering distrust amongst neighbour doctors. 'What will B do?' A is supposed to ask himself. 'If he accepts, I shall have to accept too, or lose patients', A is supposed to conclude. There is no compulsion on the patient to present the contract, or on the doctor to accept it—none whatever. The patient has the easy alternative of paying twice, if he chooses; and the doctor may readily prefer to lose practice.

We fully understand that success in these tactics would result in complete bureaucratic control of medicine. Being paid from the social security fund, and governed by the regulations, the profession would be in effect civil servants; but civil servants without hours of duty, leave, promotion, or pension—civil servants without the status, amenities, protection or security of civil servants. Advantage would accrue to those who undertook the greatest number of patients, contenting themselves with physiognomic diagnosis and empirical treatment.

II. AMERICAN PUBLIC HEALTH ASSOCIATION YEAR Book, 1940-41

The single most significant measure of public health practice in the United States and Canada in the annual *Year Book* of the American Public Health Association is the reports of its committees. Generally, these reports lead to the eventual action by the Governing Council of the Association for adoption as standards of practice. The following abstracts from some of the

reports in the 1940-41 *Year Book* are of interest in reflecting the trend of public health administration and practice. The original should be consulted for further details. These year books are a *sine qua non* for workers in public health throughout the world.

Functions of public-health engineering personnel (Report of Committee on Co-ordination of Public-Health Engineering Activities)

A. Nature and scope of public-health engineering—

1. A number of different services are employed in the maintenance of public health, particularly those of two professions:—

(a) Medical health service which is concerned especially with the effects of environmental conditions upon the human organism and the adjustment of man to his environment.

(b) Engineering health service which utilizes the materials and forces of nature in the adjustment of the environment to man. When employed primarily for the protection and promotion of public health, this specialized branch of engineering is termed 'public-health engineering'.

2. Public-health engineering includes the public-health aspects of all types of environmental conditions whose control is based upon engineering principles, regardless of the magnitude or technical difficulty of the individual problems involved.

3. All procedures of federal, state, and local health departments that depend upon engineering, materials or methods should be considered as public-health engineering activities.

B. Personnel—

The preparation of public-health personnel should include opportunities for field experience under supervision. First-hand knowledge of procedures is important. Valuable field experience for public-health engineers can be provided by their employment for the supplementary activities mentioned above as a method of preparation for broader responsibilities.

C. Administration and supervision—

All public-health engineering activities should be under the supervision of a competent public-health engineer who should be directly responsible to the administrative health officer for all matters which affect their professional integrity.

Standards of water purity

(A progress report of the Committee on Waterways Pollution)

Aside from the U. S. Public Health Service standard of quality of drinking waters used by common carriers in interstate traffic, there are no other generally accepted and widely used standards. This standard for drinking waters provides that the *B. coli* index shall not exceed an average of 1 per 100 c.cm., and that no more than 5 per cent of the samples collected shall have an index of 6 or more per 100 c.cm. For waters to be purified for drinking purposes, Streeter has formulated the following standards:—

1. Impounded underground waters treated by chlorination only: *B. coli* index shall not exceed 50 per 100 c.cm.

2. Surface waters being treated by adequate filtration and chlorination processes: *B. coli* index shall not exceed 5,000 per 100 c.cm.

Dissolved oxygen.—In most instances, the dissolved oxygen determination is of most importance. It is well to note that the amount of dissolved oxygen that will barely support fish life varies with combinations of environmental factors at the time and with the size and species of fish. Temperature, pH, and carbon dioxide content are especially important in this connection.

III. RESEARCH AS A FUNCTION IN MUNICIPAL HEALTH ADMINISTRATION

The level of public-health-laboratory efficiency has long been determined by the quality of the research

produced as a bye-product of routines. It is, however, a marked step forward when public administration appreciates sufficiently the benefits of research to establish separately an institute without any routine responsibility purely for research for research purposes. The City and the Health Department of New York are to be congratulated on this departure whereby an appropriation of \$100,000 has been included in the 1941-42 budget for a new Public Health Research Institute to be used exclusively for scientific research essential for the protection and improvement of health, safety, and welfare, of the people of the city. The institute has been established as a scientific and non-profit-making organization, devoted entirely to obtaining for the city the best available biological products and advanced skill and procedures for combating disease and epidemics. The location of the institute enables it to secure on its Council such individuals, serving in an honorary capacity, as Rivers, Director of the Hospital of the Rockefeller Institute for Medical Research; Opie, Professor of Pathology, Cornell University Medical College; Baehr, Professor of Medicine, College of Physicians and Surgeons; and others from amongst locally eminent medical citizens.

IV. MEDICAL SUPERVISION IN FACTORIES

(Extract from *British Medical Journal*, 3rd August, 1940,
p. 175)

By the Factories (Medical and Welfare Services) Order, 1940, dated 16th July and published on 29th July, Mr. Ernest Bevin enacts that the occupier of any factory in which is carried on the manufacture or repair of any munitions of war or of any materials, parts, or tools required for such manufacture or repair, or any work on behalf of the Crown shall, if so directed on behalf of the Minister by the Chief Inspector of Factories, or by any other inspector of factories expressly authorized by the Minister to give directions under this Order, make arrangements to the satisfaction of the inspector by way of the whole or part-time employment of such numbers of medical practitioners, nurses, and supervisory officers as the inspector may specify for one or more of the following services: (a) medical supervision of persons employed in the factory in the aforesaid manufacture, repair, or work; (b) nursing and first-aid services for such persons; (c) supervision of the welfare of such persons. The Order came into force on 16th July.

Duties of the works medical officer

(Extract from *British Medical Journal*,
30th November, 1940, p. 755)

The factory department of the Ministry of Labour and National Service has issued a brief memorandum on medical supervision in factories. It sets out under nine headings the principal duties of a works medical officer. They cover much the same ground as the fifteen paragraphs in the resolution on this subject passed by the Annual Representative Meeting at Belfast in 1937, the year of the passing of the Factories Act. The duties of the officer as set out are briefly as follows:—to be responsible for the organization and supervision of first-aid services in the treatment of injury and sickness; to examine medically and advise persons referred to him by the management or individual employees who consult him; to assure himself of the fitness or otherwise of persons returning to work after illness; to advise the management on general hygiene in the factory; to co-operate on all matters affecting the health of the work people; to maintain an effective liaison with outside health services, including the medical practitioner services; to keep records of sickness and absenteeism; to promote the health education of the work people, and to assist in the A.R.P. services.

(Concluded at foot of next column).

INDUSTRIAL HYGIENE

A PRELIMINARY SURVEY OF THE INDUSTRIAL HYGIENE PROBLEM IN THE UNITED STATES. PUBLIC HEALTH BULLETIN NO. 259, UNITED STATES GOVERNMENT PRINTING OFFICE, WASHINGTON, 1940

INFORMATION provided by this bulletin shows that certain occupational groups experience excessively high mortality and morbidity rates, especially from respiratory diseases and from certain degenerative conditions. Some types of physical impairment are found to be more prevalent among occupations involving heavy manual labour. The data definitely indicate a need for a survey of the industrial hygiene problem in the United States.

In the development of industrial hygiene services in State and local health departments, the first step was a definition of the problem through an industrial hygiene survey. Surveys were made in certain States during the period 1936-39, which covered such items as existing health services in industrial establishments, exposure to materials and conditions which might influence health, and an inventory of control measures in use.

The present study is an analysis of such surveys conducted in 15 States, covering 16,803 plants, employing 1,487,224 workers. It is felt that the sample is sufficiently adequate and representative of industrial conditions in this country to warrant considering the data applicable to all industrial establishments of the type studied in the United States.

With reference to safety provisions, it appears that only 25.6 per cent of the workers had the services of a full-time safety director. Hospital facilities were found to be available to only 15 per cent of the workers, and first-aid rooms were provided for 51 per cent. Full-time services of a physician were available to 15.5 per cent, while full-time nursing services were provided for 33.3 per cent of the employees. The analysis revealed that although accident records were kept on nearly all workers, sickness statistics were available for only 45.4 per cent of the employees. For practically all of the health services now considered desirable, the larger plants were found to have these more frequently than the smaller plants.

(Continued from previous column)

V. THE CHEMICAL AND MECHANICAL PREVENTION OF SYPHILIS AND GONORRHEA

Preliminary statement by the special joint committee appointed by the American Social Hygiene Association and the United States Public Health Service

(*Journal of American Medical Association*,
5th October, 1940, pp. 1185, et seq.)

This committee, in reviewing the status of chemical and mechanical prevention of venereal disease, emphasizes that these means are entirely supplementary to prophylaxis through other channels. The review of the present status led the committee to make the following specific recommendations.

1. Safest method—
 - A. Use of condom of standard type.
 - B. Thoroughly wash the genitals and adjacent parts with soap and water as soon as possible (the sooner the better but within one hour at most) after removal of the condom.
2. In the absence of a condom—
 - A. Thoroughly wash with soap and hot water as already described.
 - B. After urination, inject 6 c.c.m. of 2 per cent strong protein silver solution, or other efficient, non-irritating, germicidal solution into the urethra and hold for five minutes.
 - C. Rub 33-per-cent ointment mild mercurous chloride (calomel ointment) into the genitals and adjacent parts.

The analysis of exposures of workers to various materials and conditions of health significance showed that slightly more than 1,000,000 persons are exposed in this country to the inhalation of silica dust and one and one-half million persons to silicate dusts. Of the various exposures to metal dusts and fumes, the analysis indicates that approximately 800,000 persons are handling lead and its compounds, 34,000 are exposed to arsenic and its compounds, and nearly 33,000 were found to be handling mercury and its compounds. The highest exposure of all was in connection with the agents known to produce dermatitis.

An analysis of the control measures now available for the protection of workers against the exposures found in the survey shows that much still remains to be done in this country for the protection of workers against industrial health hazards. Examination of control measures for 1,503,204 exposures shows that 14.3 per cent were provided with local exhaust ventilation, 3.2 per cent with enclosed operations, 3.2 per cent with respiratory protective devices, and, in the case of certain dusty trades, wet methods were employed in connection with 3.4 per cent of the exposures.

From the analysis of the survey in the 15 States, certain conclusions and recommendations were possible. These deal primarily with the establishment of industrial hygiene programmes in industry and in official agencies.

The most interesting parts of the bulletin relate to a programme for industry largely under private enterprise and a programme for an official state agency. These two sections of this interesting bulletin are quoted below *in toto*.

A programme for industry

Corrective measures in industry for the protection of the health of workers are accomplished by private effort and private funds. The important task for any industrial hygiene administration is to persuade industry to solve its own health problems. The official agency mainly serves in aiding industry to evaluate its problems, suggests ways and means for their control, develops standards of good practice, furnishes technical guidance and conducts educational programmes. In those industrial establishments capable of maintaining their own industrial health service, the functions of such services have been said to be as follows:—

1. Regular appraisal of plant sanitation.
2. Periodic inspection for occupational disease hazards.
3. Adoption and maintenance of adequate control measures.
4. Provision of first aid and emergency services.
5. Prompt and early treatment for all illnesses resulting from occupational exposure.
6. Reference to the family physician of individuals with conditions needing attention, co-operating with the patient and his physician in every practical way to remedy the condition.
7. Uniform recording of absenteeism due to all types of disability.
8. Impartial health appraisals of all workers.
9. Provision of rehabilitation services within industry.
10. The conduct of a beneficial health education programme.

A programme for an official State agency

In assisting the States in the development of their programmes, the Public Health Service has advocated the following functions:—

1. Consultation with plant management regarding needed corrections of environmental conditions.
2. Advice to the management and medical supervisor as to the relative toxicity of materials or processes, and advice concerning new materials prior to their introduction into the industry.
3. Assistance in developing, maintaining, and analysing absenteeism records.
4. Consultant service to medical supervisors, private physicians, compensation authorities, and other State agencies regarding illness affecting workers.

5. Provision of necessary laboratory service of both a clinical and a physical nature.
6. Integration of the activities of other public health bureaux in their programmes for workers, for example, the control of cancer, syphilis, and tuberculosis.

The determination of the scope and nature of the industrial health problem in a given locality has been determined in most of the States and is the subject of the present report. The fundamental information of the sort presented herein forms a basis for many of the activities just listed. To accomplish these activities successfully, it will be necessary to integrate the work of the industrial hygiene division not only with other health services in the health department but with the work of other State agencies concerned with health matters and with non-official

PUBLIC HEALTH REPORTS

REPORT ON THE WORKING OF THE HARcourt BUTLER INSTITUTE OF PUBLIC HEALTH, RANGOON, FOR THE YEAR 1940

DURING the year under report, Government was pleased to sanction the entertainment of a full-time sub-assistant surgeon of the Public Health Department, who has hygiene qualifications, to act as a special tutor for the public health inspectors training course. This arrangement proved to be highly satisfactory not only in respect of efficient teaching, but also in proper maintenance and upkeep of teaching materials. A noteworthy feature of this year's training of public health inspectors was that, coaching classes were held by the special tutor on all working days. The long-felt need for a whole-time demonstrator, who could devote his time solely to teaching work, was fulfilled during the year under report.

The demand for cholera vaccine was heavy during the year. The total number of doses of bulk vaccine manufactured was 834,095, as against 210,125 of the previous year. Approximately 700,000 doses were filled in ampoules and issued to the store-keeper for distribution, against 235,965 doses of the previous year. The technique employed for the preparation of this vaccine was the same as in previous years.

MALARIA BUREAU

Spleen census.—The reports received from 25 districts in 79 municipalities and 274 villages were recorded. During the year, 12,892 fish were produced in the central hatchery. Eight thousand six hundred and fifty-one fish were distributed to various parts of Burma, either for breeding purposes or for introduction into water collections, as an anti-mosquito measure.

Quinine distribution.—Approximately 63,252 treatments of cinchona febrifuge were distributed as against 177,942 in the previous year. The decrease was due to a restriction placed on free distribution of quinine.

Chemical laboratory.—A total of 1,035 samples, comprising 393 samples of water, 12 samples of effluents, and 630 samples of foods, drugs and other miscellaneous articles, were examined during the year.

Toddy-drinking—its influence on the incidence of cholera.—Toddy-drinking is very prevalent in Burma. A belief exists that in many cases, the onset of cholera takes place soon after toddy-drinking. An investigation was undertaken to verify this.

Toddy is taken either when it is sweet, and unfermented, or in the fermented state.

Histories of cholera cases recorded during the period, January to August 1940, were examined. Out of 407 cases recorded, only 10 gave the history of drinking toddy before the onset of the disease. Of these, in seven cases, the infection could definitely be traced to sources other than toddy. It is therefore difficult to incriminate toddy-drinking by itself, for the onset of cholera. Toddy, however, acts as a laxative and may thus hasten the onset of symptoms in previously infected persons.

REPORT ON THE PUBLIC HEALTH ADMINISTRATION OF THE CITY OF RANGOON, FOR THE YEAR 1940

THE total number of deaths registered during the year was 13,569 compared with 11,327 in the previous year, notifiable diseases being responsible for the increase of 350 and other principal diseases for 1,892.

The death rate calculated on the census population of 1931 was 33.89 per mille compared with 28.29 in the previous year. This is a considerable over-estimate as the census population of 1941 is 501,488 and the death rate based on this comes to 27.06. The Burmese, Hindu, Mohammedan and Chinese were the chief communities amongst which higher death rates were noticed when compared to the previous year.

The number of deaths from cholera was 46 compared with 11 during the year 1939, the average number of deaths for the last 10 years being 17.

There were 354 deaths from smallpox against 68 during the previous year and an average of 97 deaths for the last ten years. To cope with the epidemic of smallpox, besides the adoption of usual preventive measures, special stress was laid on the organization of a successful vaccination campaign. In the months of January, February and March, 180,673 persons or 46.33 per cent of the total population of this city were vaccinated. The effects of the vaccination campaign were striking. The number of smallpox cases which in February was twice that of January, decreased by nearly half in March. The months of April and May showed progressive decline.

There were 7 from plague compared with 6 in the previous year, a decennial average of 18. Ten deaths from measles were recorded during the year. There were 7 deaths from diphtheria against 17 in the year 1939. The number of deaths from cerebro-spinal fever was 17 compared with 16 during 1939, the average for the last ten years being 10. The number of deaths from beri-beri was 60 compared with 116 during the previous year. The average number of deaths for the last ten years was 105. Sixty-four deaths from enteric fever were recorded against 85 during the year 1939 and the average for the last ten years was 63 deaths. The number of deaths from pulmonary tuberculosis showed an increase of 111, there being 743 against 632 during the previous year. The average number of deaths for the last ten years was 829. Puerperal septicæmia accounted for 16 deaths as compared with 21 in the previous year.

The number of deaths from diarrhoea and dysentery was 1,141 against 728 during the previous year. During the rainy season there was an epidemic of bacillary dysentery.

Influenza caused 2 deaths only against 5 during the previous year. There has been an increase of 563 deaths from diseases of the respiratory system—there being 3,211 compared with 2,648 during the previous year. The number of deaths from malaria was 157 compared with 121 in the previous year.

The number of births reported was 12,519 compared with 11,511 in the year 1939, the birth rates calculated on the census population of 1931 for the years 1939 and 1940 being 28.75 and 31.27 respectively.

The infantile mortality rate was a little higher, being 275.05 compared with 270.52 during the previous year. The total number of deaths of infants under one year of age was 3,442 compared with 3,114 during the year 1939—an increase of 328.

The important causes of infantile mortality were, as usual, convulsions, bronchitis and pneumonia, premature birth, malnutrition, dysentery and diarrhoea.

Four thousand six hundred and seventeen infants were under the care of maternity and child-welfare scheme of this department and out of these 564 died giving a mortality rate of 122.16 per 1,000 against 133.05 in the year 1939.

The tuberculosis dispensary continued to function. The number of new patients and the total attendance being 6,485 and 42,213 respectively compared with 4,927 and 38,039 during the previous year.

The anti-mosquito work continued on the same lines as in previous years. Almost all the tanks in the city have been made mosquito-proof. In the suburban area, owing to the lack of co-operation of the public, the desired improvement could not be effected. The corporation, towards the end of the year, sanctioned on a permanent basis the staff employed to combat the mosquito problem.

BENGAL PUBLIC HEALTH REPORT FOR THE YEAR 1939. By LIEUT.-COLONEL A. C. CHATTERJI, M.B., D.P.H., I.M.S., DIRECTOR OF PUBLIC HEALTH

Vital statistics.—The number of births registered during the year was 1,597,651 compared with 1,521,254 in the preceding year. The deaths in 1939 numbered 1,090,530 against 1,315,886 in the previous year. The death rate being 21.9 per mille and 17.0 per cent lower than that in the previous year.

Against the quinquennial averages of 32.1 birth rate and 24.4 death rate, both the birth and death rates for 1939 showed a decrease of 0.3 and 10.6 per cent, respectively. Calcutta was the solitary district in which deaths exceeded births.

Infantile and maternal mortality.—The total number of infantile deaths in 1939 was 234,301 compared to 280,923 in 1938. The infant mortality rate per thousand births fell to 146.6 from 184.7 in 1938.

Maternity and child-welfare work is mainly a responsibility of the local bodies towards which Government made annual grants, inclusive of a grant for the training of *dais* and provided for training pupil nurses and *dais* in the state and private hospitals. Suitable recurring grants-in-aid were also given to certain maternal and child-welfare centres and towards educational propaganda through the Bengal Health Welfare Committee. With a view to encouraging the opening of maternity and child-welfare centres in rural areas and with the object of securing substantial development of the service, a moderate scheme for establishment of maternity and child-welfare centres providing a minimum standard of efficiency regarding staff, equipment, buildings, etc., was framed by the Public Health Department. Government approved the scheme during the year under review and offered to make suitable grants-in-aid to local bodies and recognized voluntary associations towards the establishment as well as maintenance of such centres. Government have appointed a lady superintendent for maternity and child-welfare work with the necessary staff, in order to promote and co-ordinate the activities of local bodies etc., in this direction.

Cholera.—The total number of deaths from cholera during the year under report was 33,221 with a death rate of 0.7 per mille against 71,133 deaths in 1938 with a death rate of 1.4 per mille, showing a decrease of 53.3 per cent over the figures of 1938 and of 41.7 per cent over the average of the previous quinquennium.

Cholera preventive measures.—All approved anti-cholera measures were adopted in combating this disease. Anti-cholera vaccine was freely used although the quantity of vaccine and the number of inoculations showed a decline, apparently owing to the fact that the incidence of cholera decreased in the year and to defective organization on the part of the local authorities in carrying out the work of preventive inoculation. As in the year 1938, the Director of Public Health deputed a number of mobile medical and sanitary units or floating dispensaries for anti-cholera and other epidemic work and also rendered assistance to local authorities by lending on requisition the services of medical and sanitary officers during epidemics.

Smallpox.—Smallpox took a toll of 7,029 lives in the year under review against 9,289 in the preceding year, the death rate being 0.1 and 0.2 per mille respectively. The mortality from this disease thus fell 50 and 75 per cent compared with the previous year and the previous quinquennium respectively. It represented 0.6 per cent of the total provincial mortality in 1939. The death

rate from the disease during the year was lower than in any other province except Madras and Central Provinces.

The number of persons vaccinated in 1939 was 7,925,382 against 7,843,545 in 1938. The slight increase might have been due to the greater attention paid by the local authorities than has hitherto been the case in the matter of vaccination.

The local bodies would do well to appoint female vaccinators in the rural areas as the *pardanashin* ladies resent being vaccinated by male vaccinators, with the result that a large percentage of population remain unvaccinated.

Malaria.—It is gratifying to observe that there was a reduction of 75,200 deaths in the total mortality from malaria in 1939, compared to the previous year in which 416,521 deaths were registered. The death rate correspondingly came down in 1939 by 18.1 per cent. Malaria was responsible for 49.6 per cent or nearly half of the total deaths from 'fevers' and 31.3 per cent of the total provincial mortality during the year under review as against 50.8 and 31.6 per cent respectively in the preceding year. 99.4 per cent of the total deaths from malaria occurred in the rural areas and 0.6 per cent in the urban areas compared to 99.3 and 0.7 respectively in 1938.

Kala-azar.—The disease accounted for 17,056 deaths with a death rate of 0.34 per mille against 21,642 and 0.43 respectively in 1938. The number of deaths in the rural areas decreased by 4,540 from that of the previous year. The decrease was most noticeable in the districts of Jessore, Rangpur and Tippera. The special anti-kala-azar campaign undertaken in the district of Darjeeling was continued during the year under review. Twenty kala-azar treatment-centres and 2 undictated shelters were maintained and 11 medical licentiates and 2 sanitary inspectors were employed for carrying out effective treatment and intensive propaganda work throughout the kala-azar affected areas of the district.

Special anti-malaria measures.—The comprehensive malaria survey of representative areas in different parts of the province, which was started in 1937 was concluded in November 1939. The survey and control measures in connection with the anti-*ludlowii* campaign in the vicinity of Calcutta were continued satisfactorily in the Salt Lake area, Budge Budge and the suburban areas with the co-operation of the Corporation of Calcutta and other local authorities and interests concerned.

The special anti-malaria scheme on a five-year plan for the town of Jessore and its adjoining rural areas financed jointly by the Indian Research Fund Association and the Provincial Government was undertaken with effect from July 1939. Various anti-malaria measures were taken up such as filling up of *dobas*, borrow-pits and low-lying lands, kerosinization of tanks and water-pools, rearing of larvical fishes, removal of aquatic vegetation from rivers, *khaals*, etc., opening of culverts for free flow of water and improvement of drainage.

The system of doling out grants to local bodies for local minor anti-malarial measures which was in practice so long, was found to be largely ineffective and wasteful. Government therefore decided to make larger grants available for expenditure on comprehensive anti-malaria projects of a more or less permanent nature.

Pneumonia took a toll of 47,888 lives against 52,258 in 1938, showing a decrease by 8.3 per cent.

Pulmonary tuberculosis accounted for 12,422 deaths compared to 14,668 in the preceding year or 0.25 per mille against 0.29 per mille in the previous year. There was thus a decrease in mortality from this disease in 1939. Of the total deaths in the urban areas from this cause in 1939, Calcutta alone was responsible for 69.9 per cent, the death rate being the highest (2.61 per mille) of all districts. No deaths from pulmonary tuberculosis were reported from 20 towns.

As a first step towards the effective control of tuberculosis in the province, a tuberculosis survey of certain selected typical areas—industrial and rural—was sanctioned by Government and two centres, one at Scampore and the other at Barisal, were started during

the year under review. A comprehensive scheme for the control of the disease was also drawn up by the Public Health Department. It comprised three main stages, each stage being expected to be worked out in a period of five years. The Bengal Tuberculosis Association continued to carry on valuable publicity and propaganda work in the province with the usual grant from Government. The Association also trained a number of tuberculosis workers and home visitors during the year.

Enteric fever.—There were 8,290 deaths from enteric fever compared to 9,808 in the preceding year. Mortality from this disease however increased in Calcutta by 8.6 per cent.

Influenza.—The number of deaths registered as due to influenza went up during the year under report to 2,467 from 2,143 in 1938, the rural areas being responsible for the unexpected rise.

Cerebro-spinal fever accounted for 1,721 deaths against 1,337 in 1938, indicating that the disease made a rapid headway during the triennium ending with 1939. The death rate from this disease increased by 155.6 per cent in Calcutta.

Typhus fever which is predominantly a disease of the rural areas, has been on the increase since the year 1936. Four thousand four hundred and forty-three deaths occurred due to this disease in 1939 against 4,034 in 1938, showing an upward move by 25 per cent.

Dysentery and diarrhoea were responsible for 27,301 and 27,152 deaths respectively, compared to 37,966 and 31,266 in 1938. Of the total provincial mortality in the year under review, 5 per cent was attributed to these two diseases together against 5.3 per cent in the preceding year.

Leprosy.—One thousand five hundred and fifty-seven deaths from leprosy occurred in 1939 of which a vast majority, *viz.* 1,446 were reported from the rural areas. Leprosy is a growing menace in the province for the control of which a provincial anti-leprosy scheme, to be brought into operation by stages in five years, has been formulated. The first item of this scheme, *viz.* a special course of training of medical and health officers in leprosy and anti-leprosy work was arranged with the British Empire Leprosy Relief Association, since the close of the year under review.

Fairs and festivals.—The Public Health Department and the local authorities concerned co-operated with great success in undertaking medical and sanitary arrangements for the welfare of the pilgrims and the prevention of outbreaks of infectious diseases in the chief *melas* in the province. The St. John Ambulance corps rendered valuable assistance at the Ganga Sagar *mela* where of the five cholera cases only one proved fatal. No deaths occurred from cholera either at the Nangalbund or at the Sitakund *mela*. Unfortunately, cholera broke out in an epidemic form at the Tarakeswar *mela* and spread to the neighbouring areas. The epidemic was quickly brought under control as a result of the combined efforts of the Public Health Department and the public health staff of the district board. Of the 14 cases of cholera at the *mela* ground only 3 proved fatal.

Health propaganda.—The publicity branch of the Public Health Department was transferred to the newly created Publicity Department of Government with effect from August 1939. The ten touring cinema parties and the Government exhibition van carried on publicity work as usual.

ANNUAL REPORT OF THE PUBLIC HEALTH COMMISSIONER WITH THE GOVERNMENT OF INDIA FOR THE YEAR 1940

ALTHOUGH the year has been a period of wide unsettlement as a result of the war, in India the peace that we have enjoyed has protected us to a large extent from that deterioration in health which is inseparable from the privations and physical disabilities attendant on war. Apart from the usual local variations in the prevalence of the common epidemic diseases, the year under review was not marked by any abnormal outbreaks of disease.

As was emphasized by the Hon'ble Sir Girja Shankar Bajpai, in his opening address at the third meeting of the Central Advisory Board of Health in July 1940, war, however grim its reality and however imperative its claims, is a passing phase in the course of history, and the maintenance of health activities on the home front must not be neglected. In spite of the demands of war, the activities of voluntary organizations, such as the Indian Red Cross Society and the Indian Council of the British Empire Leprosy Relief Association, continued uninterrupted and their peace time activities were maintained and even extended in some directions.

Yellow fever.—Owing to the large expansion of aerial communications and the extension of the war to Africa, the danger of the introduction of yellow fever into India has increased. Measures have, therefore, been taken to avert the possibility of such a calamity. Persons arriving from yellow fever areas have to produce evidence of satisfactory inoculation or spend the incubation period in some non-infectious area before entering India. Persons arriving in India in contravention of this rule are kept in quarantine at Karachi, until a period of nine days elapses after their leaving the yellow fever area. Aircraft arriving from infected areas are compelled to produce a certificate that they have been effectively cleared of insects at either Khartoum or Cairo. Apart from these measures, steps have also been taken to deal with any possible outbreak of the disease in India. The health authorities of the provincial and state governments have been requested to report promptly even suspected cases of the disease. The Central Government will place an expert unit at the disposal of provincial and state governments for the diagnosis of such patients. One of the most important measures in combating an outbreak is the intensive and efficient control of mosquito breeding in the infected area and, in order to ensure this, an expert unit from the Malaria Institute of India will be placed at the disposal of the government concerned. Through the generosity of the Rockefeller Foundation, ample stocks of the vaccine for preventive inoculation are now available.

Cholera.—The third meeting of the Central Advisory Board of Health, which was held at Poona in July 1940, discussed the reports of two committees, one on compulsory inoculation of pilgrims against cholera and the other on the control of food adulteration. Both reports were approved by the board and the recommendations of the two committees were commended for adoption by the provincial and state governments. The report of the committee on the inoculation of pilgrims expressed the desirability of governments selecting suitable festival centres in their areas for trying out a system of indirect compulsion for inoculating pilgrims (successfully adopted by the Government of Bombay at Pandharpur), and of taking certain measures for providing funds and the trained personnel necessary for carrying out mass inoculation.

Food standards.—The Food Adulteration Committee divided the problem of controlling adulteration into three aspects: technical, legislative and administrative. In the report submitted to the Board, the committee discussed only the technical aspect of the problem. The others are to be considered shortly. The committee prescribed, and the board recommended the adoption of, standards of purity for individual articles of food and set out the general principles on which the technique adopted for food analysis by the different laboratories in India should be made to conform to uniform standards.

They recommended that a standing committee should be set up, named, 'The Central Committee for Food Standards' to act in an advisory capacity on the lines of the Society of Public Analysts in England and the British Standards Institution. This committee, which will consist of public analysts, health administrators, and representatives of dairying, agricultural and trade interests, will guide provincial and state governments in the formulation of such measures as are necessary for the control of the purity of food supplies.

Public health laboratories.—Another subject discussed by the Central Advisory Board of Health was the

proposal that governments should provide laboratories at suitable centres for the free examination of clinical material from cases of infectious disease, sent either by a medical practitioner or by a government medical officer. The board commended for adoption by the governments a plan for providing laboratory facilities, which was set out in a memorandum on the subject submitted to the board by the office of the Central Advisory Board of Health. This plan provides for a central laboratory for each province or state, capable of dealing with the highest type of diagnostic work and research, for regional laboratories for groups of districts, and for laboratories in individual districts. The memorandum also deals with the questions of personnel and of distribution of the cost between the government and local authorities.

The desirability of raising the standard of diagnosis by medical men of suspected cases of infectious disease which they meet with in their practice is unquestioned and it is to be hoped that the governments will now initiate steps to introduce the scheme in some suitable areas in the provinces and states and gradually expand it over the whole territory as and when funds permit.

Tuberculosis and overcrowding.—The effect of unhygienic and overcrowded housing conditions on the incidence of tuberculosis has long been recognized by health authorities all over the world, and town planning, slum clearance and the construction of well-ventilated and airy dwellings on such cleared areas have been an important part of the campaign against the disease in all progressive countries. In India, while town-planning and slum clearance have been carried out in some of the larger cities by improvement trusts, the beneficial effects of these measures have, in many cases, been largely offset by the indiscriminate construction of insanitary buildings on the cleared areas, through the failure of local bodies to exercise their powers, under the building bye-laws, to regulate house construction. The board therefore urged strongly on all provincial and state governments the necessity, in the interests of public health, for the strict enforcement of building bye-laws.

Health administration in railways and jails.—A welcome feature of recent years has been the increasing collaboration between the railway, civil and military health authorities through the establishment of local committees in the investigation of common problems with a view to taking appropriate action for their solution. Another direction in which good results have followed from the co-operation of the railway and civil health authorities is in respect of the measures necessary for safeguarding the health of the pilgrims attending large fairs and festivals.

The Indian railway administrations together constitute the largest employers of labour in India—over 700,000 persons were employed by them in 1938-39. In spite of the wide prevalence of the common infectious diseases such as cholera, smallpox and plague among the general population, their incidence among railway employees and their dependents who live in railway premises is very low.

As regards malaria, the reports of the chief medical officers of the railways show that the gravity of the malaria problem has been recognized and that preventive measures are being carried out.

For instance, the total number of malaria cases treated during 1939-40 in eleven stations on the Madras and Southern Mahratta Railway, where anti-malaria measures were in progress, was 720 as against 6,662 before these measures were started.

The number of days lost by the railway staff on account of malaria during 1939-40 was 23,666 as against 8,111 before the adoption of preventive measures. In regard to the splenic index remarkable reductions have been recorded in these places. In one station the splenic index was reduced during the period from 33.3 per cent to nil.

Referring to the health administration in Indian jails the report shows that the death rate among prisoners has been reduced, within the last 20 years, from 21 per 1,000 in 1921 to 8.9 per 1,000 in 1940. In recent years

the provincial governments have also encouraged general and physical education among the prisoners

and adopted other measures which include lectures in first-aid and health propaganda.

Management of Varicose Veins in Private Practice

By I. A. BRUNSTEIN, M.D.

(From *New York State Journal of Medicine*, Vol. XL, 15th June, 1940, p. 918)

SINCE the general practitioner is the first to see the patient, it is important that he be proficient in the correction of varicose veins, for upon his skill and experience the patient's health depends. Treatment of varicose veins is simple and effective and hence may unhesitatingly be advised in the early stages, so as to avoid disabling complications such as varicose eczema, ulcer, phlebitis, and embolism. Instead of waiting until the patient presents himself for treatment of his varicosities only, prophylactic treatment should be encouraged if these are observed during a routine examination. Though the treatment is quite popular, many patients still believe their condition permanent and are surprised to learn that their varicose veins can be corrected.

Every patient undergoing treatment for an associated disease should be examined for the presence of varicosities, and if these are found, no matter how slight, their correction should be suggested. It is gratifying both to patient and physician to observe varicosities resembling a small bunch of grapes or plums slowly disappear after the use of the proper amount of sclerosing solution and compression and to note the disappearance of a long-standing varicose eczema with its distressing pruritus or the healing of an old varicose ulcer after obliteration of the offending veins. A patient of mine with dermatitis haemostatica and chronic psoriasis of the lower extremities, confirmed by biopsy at a large skin clinic, was treated locally for this skin lesion without any improvement until the underlying varicosities were obliterated.

Every practitioner capable of giving an intravenous injection is able to inject varicose veins. However, one rule of safety must be observed: first, ascertain that there are no contra-indications to obliteration of the varices, and, second, start slowly and with caution.

Preventive treatment

Until recently, treatment was suggested only when the patient complained of pruritus, burning, aching, fatigue, heaviness, and oedema of the extremities and when the varicosities were of sufficient size and number to warrant the use of sclerosing solutions. To-day, my opinion is that the correction of varicosities is justified even when there are no subjective symptoms. After treatment, these patients state that their legs feel lighter, that they can walk farther without undue fatigue, and are rather surprised not to have noticed their previous discomforts. Treatment of the varicosities should, therefore, not be postponed until there is manifest disturbance or actual disability but should be undertaken as a prophylactic measure.

Recurrences following injection treatment

When suggesting injection therapy, the patient should be advised of the possibility of recurrences and the importance of periodic re-examinations. The need of correction of new varicosities as soon as they appear should be stressed so that the previous abnormal state is not reached.

If ligation is not indicated, the patient should be advised that the combined treatment of ligation of the great saphenous vein and the injection of the varicosities will minimize the possibility of recurrences. It is well known that, even with this combined procedure, recurrences from collateral channels of the superficial

systems of veins may develop. With this treatment the incidence of recurrences has been reduced from about 60 to about 15 per cent, and when recurrences do take place, they are usually delayed and the varicosities less numerous. It is apparent from the reports of various authorities that the advantages of the combined ligation and injection of the saphenous vein have now been generally accepted.

Assurance should be given to the patient that the operation is a simple procedure and that the number of subsequent injections necessary for complete obliteration is often less than one-half the number of injections required in similar cases without ligation. Quite frequently the patient will refuse the ligation but will submit to injections only. In such instances treatment should not be withheld. The patient, having been convinced of the advantage of treatment, may later accept ligation to ensure more permanent results. Thus one avoids discrediting the merit of this treatment and retains the confidence of the patient.

Indications and contra-indications to active treatment

After a detailed history, minutely investigating the complaint of the patient with special reference to post-operative or post-partum phlebitis, such as phlegmasia alba dolens, a general physical examination and urinalysis should be made. In advanced age, senility, or in the presence of debilitating conditions with short life expectancy, a constructive treatment should be employed. Associated conditions, such as uncontrolled diabetes, cardiac failure, severe anaemia, exophthalmic goitre, should be corrected before treatment is begun. Other conditions such as the menopausal syndrome, prostatitis, or skin conditions, can be treated simultaneously. Pregnancy does not contra-indicate active treatment, but delay is preferable, as treatment may not prevent recurrences even before parturition. Moreover, in the majority of pregnant women, varicosities diminish to such a degree that little, if any, active treatment is required. When injection treatment of varicose veins during pregnancy is undertaken, it should be limited to the larger abnormal veins which cause pain, discomfort or appear to be on the point of rupturing.

In deciding upon the advisability of treatment the physician should rule out local circulatory disturbances and the presence of other conditions that would contra-indicate treatment. Obstruction to venous flow, such as the presence of a pelvic tumour, should be looked for. Advanced arterial deficiency, either arteriosclerosis or thromboangiitis obliterans, would contra-indicate the use of sclerosing solutions.

A history of intermittent claudication should make one suspect the presence of peripheral arterial disease. To confirm it, the presence of plantar blanching on elevation, rubor on dependency, diminished temperature, and the patency of the dorsalis pedis and posterior tibial arteries should be looked for. Oscillometric recordings help to indicate the state of patency of the entire vascular bed. In doubtful cases of patients past middle age, a consultation is advisable before sclerosing the veins.

The presence of phlebitis in the deep veins is an absolute contra-indication to injection treatment, as the resulting obstruction of the deep venous flow generally produces a compensatory dilatation of the superficial venous system. The obstruction will usually disappear in six to eighteen months, after which period careful treatment of the varicosities may be instituted. It is, therefore, of greatest importance to determine the patency of the deep venous system.

As a matter of short review it may be stated that the greater volume of the blood from the lower extremity

DEC., 1941]

returns by way of the deep veins. It is from the superficial veins of the leg that varicosities develop, especially from the internal or long, external or short saphenous veins and their tributaries and from the superficial veins of the anterior, posterior, and mesial surfaces of the leg and thigh. Numerous tributaries, normally not noticeable, may develop into medium or large-sized varicosities. There are frequent varicose anastomoses between the external and internal saphenous system. The communicating veins are short vessels, connecting the deep and superficial venous systems. Normally, the flow of blood is directed from the superficial veins to the deep system of veins.

Tests to evaluate the circulation in the venous system of the lower extremity affected by varicosities

There are various tests to determine the state of venous circulation in the lower extremities. Of these, Perthes', Brodie-Trendelenburg's and the recent comparative tourniquet test of Mahorner and Ochsner are the most widely employed.

Perthes' test

The Perthes' test to establish the patency of the deep venous system consists of applying a tourniquet to the patient's thigh tightly enough to compress the internal saphenous vein. The patient then walks rapidly, and if the varicosities diminish, the communicating and deep veins are known to be open. However, if the deep venous system is obstructed, the superficial veins will become more prominent, and the patient will complain of distress in the extremity. Another test is to bandage the leg from ankle to knee joint with an Esmarch rubber bandage and then make the patient walk for two hours. If no discomfort is felt, the deep veins are open. However, should obstruction be present in the deep system, discomfort and pain proportionate to the degree of obstruction will appear. If the occlusion is complete, the patient will be able to wear the bandage for a short period of time only.

Trendelenburg's test

The Brodie-Trendelenburg test determines the competency of the valves of the saphenous and communicating veins. With the patient in the recumbent position, the leg is elevated until the veins are emptied, and a tourniquet is applied near the fossa ovalis. The patient then assumes a standing position and the tourniquet is rapidly released. If the veins distend immediately from above, it indicates retrograde flow of blood in the great saphenous vein and incompetency of its valves. This is the positive Trendelenburg test, and there is little danger of emboli from injecting such a vein.

The same test may be used to determine the competency of the communicating veins. If the tourniquet is applied as before and the patient then assumes a standing position, it requires thirty-five or more seconds for the varicosities to distend. The blood has passed through the normal channels of the capillaries, and the valves of the communicating veins are competent. Should the varices fill in less than thirty-five seconds, it indicates that blood, unable to return to the great saphenous vein because of the tourniquet, has returned, totally or in part, by way of the communicating veins with incompetent valves. Accurate information as to the competency of the valves in the communicating veins is necessary to insure good results.

Mahorner-Ochsner comparative tourniquet test

The comparative tourniquet test devised by Mahorner and Ochsner is more reliable for the determination of the circulation in varicose veins. For this test, the patient walks to and fro in front of the observer with the lower extremities fully exposed and illuminated by light coming from behind the observer. Even without a tourniquet, the varicosities become less prominent when the patient is walking, as the muscles exert a pumping action on the deep veins, thereby aiding the emptying of the superficial veins. A tourniquet is then applied around the upper third of the thigh, tightly

enough to obstruct the return venous flow in the superficial system of veins including the great saphenous vein. The patient again walks at the same speed. The physician compares the prominence of the varicosities before and after the application of the tourniquet. The same procedure is employed, applying the tourniquet around the middle third, and then around the lower third of the thigh.

The interpretation is as follows: if a maximum diminution in size of the varicosities occurs when the tourniquet is around the upper end of the internal saphenous vein and if there is no further improvement when the tourniquet is around the middle or lower third of the thigh, the valves of the communicating veins are competent, and the only source for retrograde flow is through the main opening of the internal saphenous vein into the femoral vein. In this case, high ligation alone is sufficient. If there is additional improvement, manifested by less prominence, with the tourniquet around the middle third of the thigh and still greater improvement with the tourniquet around the lower third it indicates that the tourniquet is below the lower communicating veins with incompetent valves. In this instance, high ligation alone will be insufficient, and ligation, to be effective, should be below the communicating veins with incompetent valves. Therefore high and low ligation is indicated to reduce the incidence of recurrence. There never is less prominence of the lower varicosities with the tourniquet around the upper end of the internal saphenous than when the tourniquet is around the middle or lower third of the thigh. The interpretation of the Mahorner-Ochsner tests depends upon the degree of prominence of only those veins that are below the level of the tourniquet.

Sclerosing solution and amount of solution to be used

The question most frequently asked is: 'What is the best sclerosing agent?' This is to be expected, in view of the great number of solutions. Moreover, every manufacturer extols the superiority of his product. Any solution that has no general toxic reaction and produces effective thrombosis by destroying the intima on contact is a good solution. Phenol, bichloride of mercury, Preg's iodine solution, and mercuric iodide have long ago been eliminated as injection agents because of their dangerous reactions.

A question less frequently heard but of greater importance is: 'How much of the sclerosing solution should be used?' Especially for the first few injections, safety lies in the proper dosage. Experience has taught us to start with a very small initial dose of 0.5 to 1 c.c.m. of invertose 60 to 75 per cent or 0.1 to 0.25 c.c.m. of sodium morrhuate 5 per cent, gradually increasing the amount in proportion to the reaction to the previous injection and later regulating the dosage to the size of the varicosity to be injected. It is neither necessary nor desirable to obtain occlusion with the first two or three injections. Slow procedure is advisable to avoid unnecessary pain and alarm, and the physician is not annoyed by night telephone consultations. Too often patients are heard to complain of having been bed-ridden for days and even weeks after the initial injection. These patients will dissuade their friends from such a 'dangerous experience' and bring a fairly safe method of treatment into disrepute. One such experience was that of a young physician who, following the package literature suggestions, used 2 c.c.m. of quinine and urethane as an initial dose. As a result, the patient suffered massive occlusion of all the superficial varicosities and a swollen leg, and the physician made numerous visits to the bedside of the patient, with nothing more to offer for relief than a prayer for speedy recovery.

Quinine is a strong irritant and therefore is unsuitable for initial injections. It may be employed only when the use of weaker irritants, such as sodium chloride 20 per cent or sodium morrhuate 5 per cent, has failed to produce the desired results. Starting with a small dose of a weak irritant solution is important, because as noted by Biegeleisen, have infected veins. The

infection may be latent, chronic, or sub-acute, and the use of a large initial amount of sclerosing solution may result in massive occlusion of the varicosities with a severe degree of local and general discomfort.

Injection treatment in the presence of phlebitis

Phlebitis or thrombophlebitis in varicose veins is evidenced by pain, tenderness, swelling, and slight induration. Thrombosis may precede or follow phlebitis. At times there is increased surface temperature, and in severe cases fever and redness are present. It has been observed by many that upon subsidence of an acute process of thrombophlebitis there is improvement in the condition of the varicosities, probably due to a state of immunity acquired by the patient. This immunity can be produced by injection of small repeated doses of weaker irritants, thus causing a mild acute thrombophlebitis in patients with latent thrombophlebitis. The inflammatory reaction to the irritant in the phlebitic vein is often delayed for five or more days and may occur in distant, non-injected varicosities or along the course of the injected vein. Therefore the presence of latent or subacute phlebitis is no longer a contra-indication to injections if such treatment is carried out slowly and carefully. The initial injection will produce a mild phlebitic reaction, but as one proceeds with increasing doses, the reaction will be similar to that in the non-phlebitic varicosities. Thereafter one may employ gradually increasing amounts of stronger irritants.

In case of extensive acute phlebitis it is advisable to delay treatment until the process becomes quiescent. When there is a history of post-operative or post-partum phlebitis (*phlegmasia alba dolens*) of one extremity, I begin by injecting the varicosities of the non-affected leg, using mild irritants for the initial injection, and only after some lapse of time is the affected leg treated. It has been my experience that varicosities in a previously involved extremity will react favourably to much smaller amounts of the sclerosing agent than the varicosities of similar size in the non-affected leg. It may be a safer procedure first to inject varicosities of the leg before sclerosing those situated on the thighs. In case there is a thrombophlebitic reaction spread of emboli into upper structures is less likely to occur. After obliteration has safely begun, the amount of sclerosing solution to be used depends upon the size of the varicosity.

Allergic reactions

The possibility of an allergic reaction should be borne in mind, and a change to a different solution should be made at the first sign of sensitivity. Small initial doses help to avoid severe allergic reactions. A variety of such reactions following the use of sclerosing solutions has been described by various authors. The reaction, as shown by Smith, may produce an erythema of the extremity or of the entire body and may persist over a period of time. Severe allergic reactions are probably caused by a marked idiosyncrasy to the sclerosing solution, and collapse may be due to the sudden entrance of the solution into the general circulation. Some shock generally accompanies the injection in allergic patients varying in degree from a mild fainting spell to a deep surgical shock. Recovery usually follows rapidly. When surgical shock occurs, the systolic blood pressure drops, and the pulse is barely perceptible and at times even imperceptible. Recovery usually follows rapidly.

When injection treatment has been interrupted for a period of several weeks or is undertaken for the correction of recurrences, a new sclerosing agent should be employed, as sensitivity to the former drug may have developed during the interval. If the use of the previously employed agent seems preferable, the same small initial doses must be used.

Pulmonary infarction, mentioned in the literature as another complication, may occur from the fifth to the twentieth day after the injection. The symptoms depend upon the size and location of the infarct.

Technique of injections.

For the injection of smaller varicosities, I prefer the patient to stand so that the varices become more prominent. In medium-sized varicosities, the sitting posture is preferable, unless the site of the varicosity does not permit this, for in the sitting posture the prominence of the varicosity will be diminished and a less protruding thrombus will result. Large-sized varices are best injected with the patient lying down. A tourniquet is applied above the varicosity, the needle is inserted, the tourniquet is removed, and the injection is made into a collapsed vein. Quite often the use of the tourniquet may not be necessary. After the varix has been injected, a gauze pad is applied with sufficient pressure to bring the varicosity to the level of the surrounding tissues. A flat pad is preferable to a cotton ball or gauze sponge, as it will insure smoother compression.

At times it may be advisable to use light pressure with the finger tips upon the varicosity during the injection to avoid the formation of a large protruding thrombus. A number 25 or 26 gauge needle about three-quarters of an inch long with short bevel is best suited for the average-sized varicosity. Longer needles may be necessary for the injection of the great saphenous vein. It will be found advantageous to use separate needles for the aspiration of the solution and for the injection itself. This will avoid possible contact dermatitis in individuals who may be sensitive to the solution employed, and at the same time the sharpness of the needle point is not impaired.

When there is no obstructing factor such as induration or eczema, I prefer to make the puncture about one-third of an inch from the varicosity. The entry into the lumen of the vessel will be felt when the resistance of the vessel wall is overcome. This technical procedure minimizes the possibility of any extravasated sclerosing solution reaching the skin surface. I have employed this technique during the past four years, and I have encountered no case of slough at the site of injection, although others who inject directly over the varicosity have stated that slough formation is also a very rare occurrence. However, I consider the former technique invaluable when injecting extremely superficial, partially intracutaneous varicose veins. These are of a deep blue colour, covered only by a thin layer of skin. It is advisable to introduce the needle parallel to the longer axis of the varicosity, as this makes transfixion of the vein less probable. Dislodging of the needle can be avoided by firm but gentle pressure of the fingers supporting the syringe on the extremity.

Extravasation, periphlebitis, and slough can be prevented by starting the injection in healthy tissue, avoiding puncture of a pigmented, indurated, or eczematous area. The injection of smaller isolated varices, loosely attached to the perivenous tissues, is facilitated by fixing the vessel with pressure or traction on the overlying tissues.

Retrograde flow of blood is to be considered when injecting varicose veins. At times, the reaction will occur at a lower level of the injection, and a protruding thrombus may result. It is therefore better to begin with the injection of the lower varicosities or the lower segment of a varicosity. After having established the tolerance of the patient to the sclerosing solution, I do not hesitate to make multiple injections at one sitting if the nervous temperament of the patient does not contra-indicate it. A diagrammatical drawing of the injected veins with remarks as to the date of injection, dosage, reaction, discolouration, etc., will be of great help and will save considerable time.

One should watch for skin sensitivity to adhesive tape. The patient should be instructed to remove the strapping as soon as he feels intense burning or if a skin eruption develops. Should a mild sensitivity to adhesive plaster be present, I generally insert gauze strips between the adhesive and the skin, leaving only about one inch at both ends of the adhesive fastened to the skin. In cases of absolute intolerance, one must resort to the use of bandages to secure the compressing pad. Following the injection of larger varicosities it

DEC., 1941]

is advisable for the patient to wear a supporting bandage during treatment.

Returning to the question of the choice of sclerosing agents, I have found that sodium morrhuate 5 per cent is most widely used in the majority of the clinics. Sodium chloride 20 per cent is used in one of the oldest clinics in the country, with quinine urethane as the second choice for smaller varicosities. Where sodium morrhuate is used as the solution of choice, treatment is immediately stopped at the first sign of sensitization and another solution substituted. Sodium morrhuate can be given in amounts of 5 c.c.m. or more when there is no sign of sensitivity on the part of the patient. In some cases this amount may fail to produce obliteration in a larger varicosity, while a second attempt with the same dosage or an additional 1 c.c.m. may be successful perhaps as a result of the previous irritant action upon the intima of the varicosity. Slow injection of the sclerosing solution is helpful in the obliteration of larger varicosities. Rest for 10 minutes in the office, following injection of a larger varicosity, may help to localize the sclerosing solution.

Quinine urethane, a stronger irritant, can also be used in larger amounts after one has carefully determined the tolerance of the patient to this drug. For smaller intracutaneous varicosities, it is best first to try 2 c.c.m. invertose 60 to 70 per cent. This is often the safest method for obliterating so-called 'spiderweb' formations. The viscosity of the solution can be diminished by heating the ampoule or vial before use. A characteristic blanching that spreads along a wide net of these veins can be observed when 1 or 2 c.c.m. of this solution is injected.

In their latest book, Mahorner and Ochsner mention the use of sodium gynocardate 5 per cent as an efficient sclerosing agent, especially for the larger varicosities or large blood lakes. Sodium morrhuate is their second choice, with quinine urethane or quinine and urea hydrochloride occasionally used especially when treating small intracutaneous or superficial veins.

Monethanolamine oleate, which has a fairly wide safety margin, may also be used in larger quantities. Although other workers have reported allergic reactions, I have not as yet encountered any.

The quantity of sclerosing solution for each injection depends entirely upon the response of the patient to the same or to a different solution employed at the last injection. However, even a carefully measured dose may sometimes produce a severe reaction with extensive occlusion and pain. It may, therefore, prove to be of some value, in certain instances, to caution the patient about the possibility of such an occurrence. For intense pain, cold applications should be applied. The patient need not interrupt his work even if a marked reaction from the injection occurs. Adequate support will minimize swelling and pain.

Discoloration following thrombosis

Discoloration often occurs after thrombosis of the varicosities. I have observed that this may be lessened in the same patient by changing the solution. Unavoidable discolouration frequently occurs after the injection of a varicosity and, for cosmetic reasons, is objectionable to most women. Having observed that discolouration is only slightly visible after treating patients with sun-tanned extremities, I have succeeded in eliminating this deterrent to treatment by exposing the extremities to artificial sun-ray irradiation.

Technique of ligation

Ligation of the saphenous vein is best done in a hospital because of the availability of the operating room facilities and the necessary assistance. The operation is painless and is done under local anaesthesia. Administration of a sedative to patients of nervous temperament is advisable. Palpation of the femoral artery in determining the location of the fossa ovalis is helpful. McPhee's percussion test also is used for locating the femoral saphenous junction. The incision need not be longer than three inches. Most workers prefer an incision parallel to Poupart's ligament. Ochsner, however, thinks that the longitudinal incision

gives a better exposition of the tributary veins at the upper end of the saphenous vein. The vein is doubly ligated, and about 2 cm. of the intervening vein is resected. Transfixion of the vein stumps is done by many workers and omitted by others. Most workers consider ligation and transection of the tributaries of greatest importance to minimize the possibility of recurrences. The most constant tributaries are the external pudendal, the external superficial iliac, and the superficial inferior epigastric. From 3 to 5 c.c.m. of the sclerosing solution is injected into the distal segment of the transected vein. The patient is permitted to go home an hour after the operation and is advised to be ambulatory. An elastic bandage is applied to give support.

Care of varicose ulcers

In the presence of varicose ulcers before the injection of veins is begun, any existing infection should be cleared up by rest in bed, elevation of the extremity, and the application of hot hypertonic solution packs. Mahorner and Ochsner advocate small doses of sulphanilamide to control infection in long-standing ulcers. Krieg uses vitamin B₁ for the control of pain. Ten mg. doses are given three times daily to obtain early saturation, and thereafter half this amount is prescribed. As an efficacious dressing, Mahorner uses gauze that is impregnated in white vaseline containing xeroform 5 per cent. A rubber sponge or the Unna paste boot for compression will control stasis and pain. In office practice, medicopaste or cruricast bandages, an elastoplast, or numerous other similar products will answer the purpose of compression. Where there are ulcers of long standing with considerable scarring, Owens excises the scar tissue and then applies skin grafts.

General ability to recognize dermatologic lesions will aid materially in treating varicose veins and their accompanying skin complications. Quite frequently it is the deficient circulation of the extremity that prolongs the duration of a co-existing skin lesion. Tar products will be found beneficial in the treatment of varicose eczemas. The use of x-ray therapy in small amounts (about 2 skin units total) will also help to obtain satisfactory results.

The frequent association of fallen arches and neglected varicose vein conditions is not a mere coincidence. The care and correction of associated foot deformities is important in the treatment of varicose veins.

Conclusion

Varicose veins are seen frequently, and the general practitioner should attempt to discover the early cases and treat them prophylactically long before they cause disability and complications. Authors vary as to the incidence of varicose veins, but a survey of crowded beaches will convince anyone of the prevalence of this condition.

In order to detect early varicosities, it is best to examine the patient while he stands on a chair or table, since in this elevated position the small varicosities are more easily visible.

Patients rarely request treatment of early varicosities, for many of them are unaware of having them, but they appreciate the suggested obliteration while under treatment for other conditions. Careful treatment will result in physiologic and cosmetic improvement, thereby gaining for the physician the patient's confidence.

A Plea for Enlightened Nihilism in Drug Therapy

By L. I. ROBERTS, M.R.C.S., L.R.C.P.

(Abstract of an address from the *Journal of the Christian Medical Association of India, Burma and Ceylon*, Vol. XVI, July 1941)

THE term 'therapeutic nihilism' has been used to indicate the belief and practice of those who do not accept the usual orthodox theories of therapeutics. It is one of the glories of our profession that freedom

of honest thought and action is considered to be not only an incontestable right but also a compelling duty. A recent contributor has stressed the importance of independent thought and investigation and has reminded us of the fact that we owe much to healthy nihilism in our profession. We all know how much unnecessary labour and time to ourselves and how much suffering to our patients has been spared by the bold nihilism of Winnet Orr and Trueta in the treatment of septic wounds.

It has now come to be my firm belief that we can to a large extent dispense with the use of drugs, particularly in out-patients' clinics and dispensaries. This does not include, needless to say, the specifics like quinine and organic arsenic. Nor does it apply to the truly ameliorative drugs, the analgesics, anti-spasmodics, hypnotics and some others. The above two classes of drugs which may be considered indispensable, form about twenty-five per cent of the drugs in our pharmacopœia. The remaining seventy-five per cent go mostly to make up the placebos, the bottles of medicine which are so dear to the heart and the stomach of the patient and which go to swell our drug bills. These can be cut down by at least half, if not more.

This belief of mine, I think, is held by many in the profession. It is not a 'hobby'. It is a burden which I wish you to share with me.

I cannot do better than quote somewhat at length from an address which Osler gave to the Canadian Medical Association in 1902. This is what he said:

'In the fight which we have to wage incessantly against ignorance and quackery among the masses, and follies of all sorts among the classes, diagnosis, not drugging, is our chief weapon of offence. . . . The peril is that should the physician cease to think for himself he becomes a mere automaton, doing a penny-in-the-slot business which places him on a level with the chemist's clerk who can hand out specifics for every ill, from the "pip" to the "pox". The salt of life for the physician is a judicious scepticism, not the coarse, crude form, but the sober sense of honest doubt expressed in the maxim, "Be sober and distrustful; these are the sinews of the understanding". It may keep him from self-deception and out of the clutches of the arch enemy of his professional independence—the pernicious literature of our camp followers, a literature increasing in bulk in meretricious attractiveness and in impudent audacity. To modern pharmacy we owe much, and to pharmaceutical methods we shall owe much more in the future, but the profession has no more insidious foe than the large, borderland pharmaceutical houses. No longer an honoured messmate, pharmacy in this form threatens to become a huge parasite eating the vitals of the body medical. We all know too well the bastard literature which floods the mail, every page of which illustrates the truth of the axiom, "The greater the ignorance the greater the dogmatism". Much of it is advertisements of nostrums foisted on the profession by men who trade on the innocent credulity of the regular physician quite as much as any quack preys on the gullible public.'

Osler was a philosopher physician. He seems to have been a prophet also. The address I have quoted from was delivered nearly forty years ago. How true it is of to-day! There is no doubt but that our therapeutic armamentarium has been since strengthened greatly by salvarsan and its progeny, by insulin and by the sulphonilamides, to mention but a few. But the health of mankind, physical, mental and spiritual, does not depend for its improvement and perfection so much on the discovery of newer and better remedies for diseases as it does on their prevention and this depends, at the last resort, on the regeneration of man.

Osler was concerned with the good of the soul of our profession. What is truly good for one must be truly good for another, the good of the physician being for the good of the patient and vice versa.

So, I believe that it will be for the good of our patients' souls and for our own souls if we would withhold, as far as possible, the bottle of medicine—

I use this but as the symbol of recently the needle has become a to the bottle—which patients in their ignorance desire most of all and which we, in our weakness and from misplaced kindness, give to them.

In the process of evolution, which, sad to say, has taken some queer turns, man has discovered the magic of medicine, and an in the efficacy of medicine-drinking for all and sundry ailments.

Nowhere is this more true than of our country with its almost limitless variety of plants and herbs which provide a happy hunting ground for the numberless medicine men, from the most primitive to the most pretentious and plausible, that infest the country. These foster the belief from self-interest that for every ailment there is a corresponding medicine to take.

The quack probably does not know the great truth that the body, and the mind also, can to a large extent heal itself and he may honestly believe that his medicines effect the cure. But we who know better must also share the blame. 'To whom much is given of him much is expected'. The 'much' that is expected of us is, I believe, not to increase the number of drugs we want but to decrease them. Medicine is an art, and true art consists in achieving one's object with as little an outlay as possible. We should avoid the risk of perpetuating this false belief in medicines as belief in an untruth to both science and religion is one of the mortal sins and this one is all the more dangerous because it brings popularity and profit.

Two factors, as much as any other, have contributed to this false belief in and utter dependence on medicine-drinking by our patients. These are, firstly, the unwieldy number of patients at most of our out-patients' clinics and dispensaries, and, secondly, the ease with which they can be sent away happy with the bottle of medicine. This is the broad gate and the wide way that leads to the loss of not only the doctor's soul but the soul of the patient also. If a doctor is expected to treat from one hundred to three hundred patients in a few hours, the treatment is bound to consist mostly in prescription writing and in a kind of service which cannot but be very second rate. The impressive figures that adorn the pages of a hospital report may not be, from the standpoint of scientific medicine, a matter for congratulation at all but rather, on the contrary, may be a matter for real concern and commiseration.

In spite of the ready medicine-giving and ready medicine-drinking, patients improve and get well. Then why refuse the bottle, this 'faith in solution' as it has been flippantly called?

How are we to cure our patients of the false belief that treatment consists chiefly in medicine-drinking? To do this, first of all, the physician must heal himself. The profession in the West, if one may judge from the medical journals, has passed through a healthy phase of 'therapeutic nihilism'. There has been an outcry against the enormous quantities of mixtures handed out at hospitals and in general practice. There seems to have been a certain reaction even among the public.

But in India we are slow to move. The illiterate villager and the educated townsman have inherited the age-long false belief that for every ailment there is medicinal treatment, external or internal. Let us set ourselves the difficult task of removing this false belief whenever possible. The places for preaching and practice are in our out-patients' departments and our dispensaries. The younger generation is easier to teach and to cure than the older one.

If one doctor has to deal with a very large number of patients, numbering hundreds, a careful interrogation and examination of even 25 per cent of the patients will be impossible. The troubles of at least 50 per cent of our patients are said to be as much psychological as physical in origin. These will need careful interrogation and they can be convinced that a bottle of medicine is not their primary need.

It has been recognized that out-patients are even in greater need of the services of the experienced senior physician or surgeon than are the in-patients. These latter will be in need of careful nursing more than of diagnosis because the diagnosis would usually have been well established before admission except in obscure conditions.

It is only with the help and moral support of the senior member of the staff that the junior member who has been entrusted with the out-patients can speak with authority and say that the bottle of medicine is not needed, or is of very secondary importance.

Another way of protecting the junior from the temptation of prescribing the unnecessary bottle is to cut down rigorously the expenditure on stock mixtures

which adorn the dispensing table. One is thus forced to do something more than mere prescribing.

I have said enough, though in a laboured and disjointed manner, to show that the present practice at the large public dispensaries and out-patients' departments of hospitals is not what it might be. Let us resolve to make our service worthy of the knowledge we possess and the faith we profess.

[We sincerely hope that our readers will understand the message conveyed in this address better than did at least one distinguished member of the audience, and further that some of them will have the courage to act upon what so many of us know to be the truth regarding the abuse of the placebo, and will cease to prescribe or inject just because it 'comforts the patient.'—Editor, *I. M. G.*]

Reviews

TECHNIQUE OF GASTRIC OPERATIONS.—By Rodney Maingot, F.R.C.S. (Eng.). 1941. Oxford University Press, London, Humphrey Milford. Pp. xii plus 240. Illustrated. Price, 15s. Obtainable from the Oxford University Press, Bombay and Calcutta

MR. RODNEY MAINGOT has added another bright light to his already extensive array of books, and this volume may be classed as one of his most informative works.

The Technique of Gastric Operations was written primarily with the object of combining in one treatise all those operations which are usually or unusually practised on the stomach. Mr. Maingot has himself performed all these operations, and consequently his opinion of those which he considers the best must command attention.

The illustrations are for the most part original, and are excellent, especially for their clarity. The closing chapters of the book are devoted to a brief account of the preparations of the patient for his operation and also the details of post-operative treatment, both of the complicated and uncomplicated cases.

A splendid book, and one which will prove of great help to any surgeon.

A HANDBOOK ON DIFFICULT LABOUR.—By M. L. Treston, F.R.C.S., F.R.C.O.G., Colonel, I.M.S. 1941. A. B. M. Press, Rangoon, Burma. Pp. 124. Illustrated. Price, Rs. 5

COLONEL TRESTON has written this small book for the express purpose of bringing together many of the factors which give rise to difficult labour. For as he truly states, when a lecturer or student wishes to look up in a textbook certain points in connection with dystocia, he has to search textbooks from end to end in order to obtain anything like a comprehensive list. The author has achieved this design albeit in a small volume. He has furthermore not confined himself to the subject which the title of the book would suggest, but has touched also on conditions such as post-partum haemorrhage, and the treatment of chronic inversion and of uterine displacements. He closes his volume with a description of the operation of dilatation and curettage, which description is illustrated with two excellent diagrams. He is to be congratulated on the inclusion of this all-important operation, which as he truly states is so frequently described as such a simple performance that anyone can do it.

The volume can be recommended to students, and when read in conjunction with textbooks will prove of useful help.

SUPPLEMENT TO PHARMACOLOGY AND THERAPEUTICS (WITH SPECIAL REFERENCE TO TROPICAL DISEASES).—By M. A. Kamath, M.B. & C.M. 1941. Published by the Author from Sharada Press, Mangalore. Pp. 98 plus ix. Price, Re. 1-8

This little book of about 100 pages is intended to supplement the text of the older book of the same

title published in 1933 by the author, in collaboration with Dr. R. Narayan Nair. Much water has flowed under the bridges since 1933 and in keeping with the progress of medicine and chemistry, the science of pharmacology and therapeutics has advanced considerably. By issuing the supplement to the original text, the author has evidently made a pious attempt to bring the subject-matter up to date and in line with the modern state of knowledge on the subject. While he has achieved a certain amount of success in this respect, the reviewer feels that it would have been much more profitable to the reader if the author decided to have a new edition of the book wherein he could avail himself of the opportunity of revising the old text thoroughly. On critical reading, it seems clear that the old text of 1933 requires a considerable amount of revision, re-writing and incorporation of new material, as our ideas with regard to the action and uses of many old remedies have undergone a good deal of re-orientation along with progress in knowledge about new therapeutic agents.

In line with the main treatise on pharmacology and therapeutics to which this book is a supplement, the text is arranged in alphabetical order, emphasis being given to the non-official remedies and other recently-introduced medicinal specialities, such as sulfanilamide compounds, mandelic acid and its salts, protamine-zinc insulin, histidine, nicotinic acid, prostigmine, etc. Commendable effort has been made in the compilation, but the description of individual remedies is often so condensed and reduced that clarity is sometimes sacrificed. Subject grouping has been rather peculiar in some places. As an example may be cited the mention of 'physostigmine salicylas' under the head 'organotherapy'. The book may be of value as a ready and handy reference manual for busy junior practitioners but it is hardly likely to earn a place in the library of those who wish to possess an authoritative reference manual.

B. M.!

ANNUAL REVIEW OF BIOCHEMICAL AND ALLIED RESEARCH IN INDIA. Volume XI for 1940. Published by the Society of Biological Chemist, Hebbal P. O., Bangalore (India). Pp. 173. Price, Rs. 3 or 6s.

THIS is a well-bound and well-printed book of 162 pages with complete indexes of authors and subjects.

It is divided into 16 sections written by different authors and each section gives an adequate account of all the papers appearing on the particular subject during the year.

This book is essential for all biochemical workers in India to prevent their duplicating or repeating work already done, and it will also be of value to workers in other countries to indicate to them the great scope in India of this increasingly important branch of science.

A HANDBOOK FOR INDUSTRIAL NURSES.—By Marlon M. West, S.R.N., S.C.M. 1941. Edward Arnold and Company, London. Pp. xi plus 134. Price, 3s. 6d.

THIS excellent manual should be a reference book for every worker in industrial health, for two reasons. Firstly, it outlines in detail the duties of the industrial nurse in a manner that not only serves as a guide in nursing but, what is equally important, provides the medical officer with an outline of those industrial medical activities, essential for any standard of industrial health which can only be carried out by the qualified nurse. Secondly, Miss West has provided an admirable summary of the industrial medical service in England, including not only legislation affecting factory workers and the general duties of the medical officer, but also coordination of industrial health with other welfare services. The chapter on records and record-keeping is of particular usefulness. The book should prove of real value in India where industrial medical services are now extending but as yet chiefly under private initiative and consequently without standards for which this manual can serve as guide.

J. B. G.

HEALTH BULLETIN, NO. 16 (MALARIA BUREAU, NO. 7). 'SYNOPTIC TABLES FOR THE IDENTIFICATION OF THE FULL-GROWN LARVAE OF THE INDIAN ANOPHELINE MOSQUITOES'.—By I. M. Puri, M.Sc. (Punjab), Ph.D. (Cantab.), F.R.E.S. Fourth Edition. 1941. Published by the Manager of Publications, Delhi. Pp. v plus 109. Illustrated. Price, As. 14 or 1s. 3d.

As this bulletin is primarily intended for the use of field-workers, the advanced synoptic table given in previous editions is considered unnecessary and only one main table is given in this edition (3rd). This main table includes all those species, so far recorded from India, Burma and Baluchistan, of which the larva are known.

The whole of the anopheline fauna of the Indian area appears to be composed of a number of different elements—the Mediterranean element, the Indian element, and the oriental element (including the oriental alpine element). Though there is a great deal of intermingling of the different elements yet there are certain species whose distribution appears to be restricted to particular areas. The identification of the larvæ of all the species constituting the different elements is undoubtedly considered much more difficult than that of the adults. Unfortunately, no diagnostic characters simpler than those already used in the synoptic table have so far been found practicable, and the main synoptic table, dealing with all the species belonging to the three elements which have so far been recorded from India, is at times considered very complicated. This is especially the case in regard to those workers who are dealing with only the limited number of species occurring in their own particular area. In order to facilitate identification of larvæ by such anti-malaria workers, five separate tables have been given in this bulletin in addition to the main synoptic table. Each of these tables deals with only a limited number of species and is intended for the use of persons working in particular areas.

Until recently no reliable characters were known for differentiating the larvæ of *A. sundaeicus* from those of *A. subpictus*. Ghosh (Bengal) and Venhuis (Dutch East Indies) have now drawn attention to certain characters which, though not diagnostic in 100 per cent of cases, may, when taken together, serve to differentiate a large majority of specimens of these two species. These characters have now been incorporated in this new edition (4th) and it is hoped that those working in the *sundaeicus* areas will find them helpful. It will, however, be advisable not to rely on any one character by itself but to base the identification only on a combination of these.

This bulletin is a publication of vital interest to entomologists and malarialogists in India.

Abstracts from Reports

ANNUAL REPORT ON THE WORKING OF THE ASSAM MENTAL HOSPITAL, TEZPUR, FOR THE YEAR 1940. BY LIEUT-COLONEL A. M. V. HESTERLOW, M.B., Ch.B. (EDIN.), B.Sc., P.H. (EDIN.), D.T.M. & H. (EDIN.), I.M.S., INSPECTOR-GENERAL OF CIVIL HOSPITALS, ASSAM

THE whole hospital population was regularly treated for hookworm and other intestinal parasites. Skin diseases and cases of pyorrhœa alveolaris were regularly attended to. New admissions were vaccinated against smallpox and inoculated with cholera vaccine as a prophylactic measure. Blood specimens (serum) of all admissions were sent to the Pasteur Institute, Shillong, for Wassermann test—positive cases were given anti-syphilitic treatment. Mental patients are given as much freedom as is compatible with safety. The staff of keepers and guards have been taught the ideal of treating the inmates as sick persons and that their attitude towards them should be that of a nurse.

The former superintendent recommended in his report of 1939 under General Remarks—'Gradation of Patients'—the construction of a convalescent home for those patients who are on way to recovery. The present superintendent endorses and repeats the recommendations. The suggestion deserves sympathetic consideration, as such patients during the process of recovery are adversely affected by association with chronic cases requiring asylum, and their chances of complete recovery may be permanently prejudiced by such contact.

Though the sinking of a 2½-inch diameter tube-well during 1939 eased the water situation to some extent the supply is still very inadequate for a population of over 1,000 including staff. The total available water

per day is about 6,500 gallons. It is clear from the previous reports and representations of the superintendent that even with the new tube-well to supplement the water-supply from the Municipal mains, the dearth of water is still very great.

About 5,600 articles of clothing have to be dealt with such as blankets, blanket-kurtas, cotton-kurtas and cotton-jungiahs weekly, and infected and soiled clothing daily in an old crude blanket boiler. Such a large quantity of clothing cannot be effectively and regularly dealt with in such boilers. The necessity of a proper disinfecter of the high pressure steam variety has been placed before the Government. This is under consideration of Government and is an urgent need which should be met as early as possible.

SEVENTY-EIGHTH ANNUAL REPORT OF THE GOVERNMENT CINCHONA PLANTATIONS AND FACTORY IN BENGAL FOR THE YEARS 1939-40

THE most notable feature in the quinine trade during the past decade has been its steady price subject only to minor fluctuations following mainly on exchange movements. The outbreak of hostilities in Europe in the year under review has, however, profoundly affected the trade.

There has been a steady increase in the price of quinine and related products until quinine sulphate now stands at Rs. 37 as against an average of Rs. 24 immediately before the war. The rise in the basic price has, however, been small amounting to only 7 per cent of the total rise. An export duty imposed by Java accounts for another 5 per cent while the increase in freight and insurance charges amounts to

DEC., 1941]

8 per cent. The balance of the difference between pre-war and present rupee prices is accounted for by the exchange depreciation.

Apart from high prices the consumer of quinine in India is also suffering from a shortage of supplies. The usual European sources have naturally dried up. Java has ample stocks, but transport difficulties and withdrawal by Java of the usual credit facilities have restricted the import trade. Government supplies, whether of local manufacture or of foreign origin, meet, as before, only a portion of the total demand. The situation points to the importance of regarding quinine as a key industry in tropical countries. It is to be hoped that India will make a serious effort towards the attainment of self-sufficiency in this essential commodity.

Of the total quinine sulphate only 5,056 lb. were left in the crude state, the rest being purified to the Government standard. A further 23,889 lb. of the Government standard quinine had to be prepared from old stocks of crude to meet the total demands in the reserve and unreserved fields of distribution. Quinine sulphate of B.P. standard was manufactured to the extent of 16,025 lb. from previous crude stocks for supply to agents.

Other quinine salts manufactured during the year came to 1,736 lb., of which 1,636 lb. is accounted for by quinine hydrochloride and quinine bishydrochloride and the remaining 100 lb. by quinine bisulphate and bishydrobromide. The installation of a new plant for quinine hydrochloride and bishydrochloride was completed during the year. The bishydrochloride is now made only to the B.P. specification while the hydrochloride is made of a cheaper grade as well.

The provincial stock of quinine, the great mass of which lies in the crude state, was 49,022 lb. at the end of the year, being 17,536 lb. down on the opening balance. Quinine tablets by weight are up from 2,632 lb. to 2,761 lb. and by treatments are up from 7,465 boxes to 18,420 boxes. Febrifuge powder is up from 11,653 lb. to 13,697 lb. and febrifuge tablets down from 1,665 lb. to 1,658 lb. The stock of dry plantation bark opened at 1,124,834 lb. and closed at 1,395,159 lb.

ANNUAL REPORT OF THE CHEMICAL EXAMINER TO GOVERNMENT, UNITED PROVINCES AND CENTRAL PROVINCES, FOR THE YEAR 1940

THE following cases illustrate the danger of the practice of administration of drugs by incompetent persons:-

Two persons were suffering from asthma; they were under the treatment of a *vaid*, who gave them some yellowish powder as medicine. Soon after taking the medicine, they began to vomit and purge and both of them died within 12 hours. Potassium dichromate was detected in quantity in both the viscera.

(ii) In a case from Etawah, portions of viscera of a man, who died within 20 minutes after taking some medicine for gonorrhoea, were received. Potassium cyanide and arsenic were detected in the portions of viscera and in the liquids seized from the accused.

(iii) A *vaid* brought a letter of recommendation (alleged to have been written by a Raja) to one Raja Sahib. The latter was advised to utilize the services of the *vaid* for treatment of the Rani Sahiba, who had no child. The *vaid* assured them that the Rani Sahiba would have a child after taking the medicine given by him. The *vaid* took 2½ tolas of gold, 3½ tolas of silver and 5 tolas of copper from the Raja Sahib and mixed them with medicine and amulets in a *handi*. In the evening, he transferred the contents of the *handi* to a cup and sent it to the Rani Sahiba, who was asked to drink the liquid and return the gold, etc. to him. He then pretended to transfer the gold, etc. to the *handi* and left. The Raja Sahib had some suspicion and he had the *handi* opened. The *handi* contained only pebbles. The *vaid* was sent for and, on search, gold and all other articles were recovered from him. The liquid medicine seized from him, on analysis, was found to be dilute nitric acid.

TRIENNIAL REPORT OF THE CIVIL HOSPITALS AND DISPENSARIES OF MODERN MEDICINE, GOVERNMENT OF MADRAS, FOR THE YEARS 1938 TO 1940

Medical relief.—The number of civil hospitals and dispensaries in the province rose from 1,283 to 1,336 during the three years ending the 31st December, 1940. The number of beds in hospitals increased from 10,670 to 13,510 during the period. The beds reserved for women increased from 5,590 in 1938 to 6,123 at the end of 1940. The number of in-patients treated increased from 310,030 in 1938 to 352,951 in 1940. The proportion of women patients has steadily increased since 1912; in 1912 only about 3 women were admitted for every 5 men; in 1940 about 14 women were admitted for every 17 men. The number of out-patients increased from 18,692,411 in 1938 to 19,655,711 in 1940. Operations and labour cases numbered 687,894 and 129,045 respectively, the corresponding figures of 1938 having been 735,101 and 123,381.

Among the diseases which accounted for the largest number of patients treated, there was a marked fall in the number treated for diseases of the eye. There was also a decrease in the number treated for diseases relating to the ear and the circulatory system. On the other hand there was an increase in the number of patients treated for diseases relating to the digestive system (excluding diarrhoea, dysentery and tumours), and diseases of the respiratory system, malaria and rickets.

The Madras Provincial Tuberculosis Association was organized in 1939 and district associations have been formed. The immediate object of the district association is to provide a tuberculosis clinic at each district headquarters hospital. To provide qualified medical officers for these clinics, the Government have sanctioned the Tuberculosis Diseases Diploma Course. The course lasts nine months and the first course began in July 1940.

Rural medical relief.—The number of subsidized rural dispensaries rose from 404 at the end of 1937 to 435 at the end of 1940. Several reforms were introduced during the triennium to improve the scope of the Rural Medical Scheme—particularly in respect of (a) appointment of midwives to rural medical dispensaries, (b) disciplinary control over rural medical practitioners, (c) deputation of rural medical practitioners to neighbouring villages. The scheme was originally intended to induce medical practitioners to settle in villages, where they would earn a living by private practice among the richer classes and give free treatment to the poor in return for a Government subsidy and a free supply of drugs. Government are now examining the extent to which these purposes have been achieved.

Leprosy.—From the 1st April, 1939, intensive and concentrated work on leprosy was entrusted to the Provincial Branch of the British Empire Leprosy Relief Association. In addition 464 leprosy clinics were functioning throughout the province for treatment of leprosy cases under the supervision of the district medical officers and superintendents of hospitals.

X-Ray departments.—X-ray departments in Government hospitals continued to be of great help both from the diagnostic and from the therapeutic standpoint. In 1939 x-ray equipment was installed at the Headquarters Hospital, Palamcottah, the Government Tuberculosis Sanatorium, Tambaram, and the Government X-ray Institute, Egmore, Madras. Two courses of training in radiology have been organized, the D.M.R. (Diploma in Medical Radiology) course for medical practitioners and the C.R.A. (Certified Radiological Assistants) course for subordinates in radiological departments.

Medical education.—The outstanding change has been the abolition of the L.M.P. course. This involved the abolition of the Lady Willingdon Medical School for Women, Madras, and the conversion of the Stanley Medical School into a College. A Central Institute of Anatomy and Physiology, including organic chemistry

and biochemistry, has been provided to serve both the medical colleges in Madras.

Medical services.—Two women civil surgeonies were created in 1938. In 1940 the post of Superintendent of the Victoria Caste and Gosha Hospital, Madras, which had for a long time been held by a member of the Women's Medical Service, India, was also converted into a civil surgeony, so that it might be held by a member of the Madras Medical Service (Women's Branch).

In teaching, four posts of lecturers were converted into posts of Professors. Government issued orders which would lead to the steady replacement of paid medical officers by honorary workers. Experience has revealed certain difficulties in the practical application of the scheme and Government are now considering necessary changes.

Nursing staff.—Early in 1940, a committee was appointed to report on various questions relating to nursing services in hospitals. Orders have been issued on some of the recommendations and others are under the consideration of Government.

General.—The Government note with satisfaction the testimony borne by the Surgeon-General to the work done by the advisory committees and the visiting committees of the various hospitals. They welcome the tendency of charitable persons to make donations for the treatment of sick persons. Private philanthropy has been responsible for the provision of—

- (i) a cancer ward in the Government Women and Children Hospital, Madras;
- (ii) a dining platform for patients in the Ophthalmic Hospital, Madras;
- (iii) a block of buildings for conducting instructional classes for defective children in the Mental Hospital, Madras; and
- (iv) a maternity block in the Government Hospital, Kollegal, and patients wards in a few other mofussil hospitals.

ANNUAL REPORT OF THE DIRECTOR OF MEDICAL SERVICES, HONG KONG, FOR THE YEAR 1940

The health and sanitary conditions in Hong Kong during 1940 continued to be influenced by the presence of several hundred thousand refugees from war areas in China, with resulting overcrowding, high rentals, increased cost of food and fuel and noticeable under-nutrition amongst a large proportion of the population.

Shortage of food of satisfactory quantity and quality was reflected in the appearance in epidemic form for the first time in the history of the colony of a fatal form of pellagra (953 cases, 442 deaths). Deaths from beri-beri, including the infantile type, rose from 3,189 in 1939 to 7,229 in 1940. Tuberculosis also took a higher toll with 5,751 deaths during the year under review as compared with 4,443 in 1939. These figures are all the more significant in view of the fact that the population at risk was lower at the end of 1940 than at the beginning of the year.

The cholera outbreak started late, but was attended by a high case mortality (66.2 per cent) and left behind an under-nourished community with a high 'carrier' rate amounting to over 20 per cent in certain congested districts. This combination, associated with a sadly defective system of nightsoil collection from 65,000 tenement floors, is likely to be followed by very serious consequences in 1941.

Smallpox was controlled to some extent by mass vaccination, over 2½ million vaccinations being performed during the year. In relation to this, it should be remembered that British river steamers alone brought to the colony over one million passengers during 1940, all of whom were vaccinated before landing if they had not been so protected during the preceding three years.

Typhoid and dysentery continued to exact a heavy toll on human life and may be expected to do so in future until the primitive methods of town conservancy are finally eliminated, and the cost of food and fuel for the masses is more in keeping with their earnings.

Correspondence

LEUCODERMA

SIR.—In your September issue, the importance of treatment of bowel condition has rightly been stressed. In some of the few cases that came under my treatment, I have not had good results with oil of bouchi application, though intestinal antiseptics have been administered for a long time. In these cases the application of oil of bouchi gave good results when some polyglandular substance was also given. Often in females, I have found leucoderma patches appearing with the onset of puberty, and in some they increased considerably during the time of the menopause.

S. B. DAS GUPTA, M.B. (Cal.).

SHILLONG,
17th November, 1941.

Service Notes

APPOINTMENTS AND TRANSFERS

To be D.D.M.S. of a Command

P. Kailasam.	P. Chand.
P. I. Jacob.	M. Said.

Notes

AVITOL

THIS is a medicinal fish-liver oil, which is suitable as a substitute for cod-liver oil.

It is being manufactured in different places in India. It is known as medicinal fish-liver oil in Madras, and shaliverol in Travancore State.

Its vitamin-A content is much higher than that of cod-liver oil and, chemically, it is practically the same as cod-liver oil.

Its efficacy of treatment in vitamin-A deficiency cases is quite satisfactory; it has now been used in Calcutta

for the past year; it has been found an excellent substitute for cod-liver oil; clinically no untoward symptoms (e.g., nausea, vomiting, diarrhoea, etc.) have been encountered. Its smell and taste are the same as cod-liver oil and the cost is less than the pre-war prices of cod-liver oil.

It is available in bulk (1) in Madras (as medicinal fish-liver oil) from the Director of Industries and Commerce, Madras, (2) in Travancore State (as shaliverol) from the Director of Marine Biology, Travancore State, Travancore, and (3) in Calcutta (as avitol).

CADMINOL

THE UNION DRUG CO. announce the introduction of their latest product Cadminol, containing cadmium thiogluconate 1½ per cent in oily suspension for the treatment of tuberculosis.

Reports on pre-introduction trials indicate that the preparation is dependable in every respect. Trials are also being conducted in some of the tuberculosis sanatoria and hospitals in this country.

Cadminol is issued in 10 and 30 c.c.m. phials. For further details members of the medical profession are requested to refer to the manufacturers at 25, Bowbazar Street, Calcutta.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints gratis; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more, after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributors should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.
